The leishmaniases are a group of diseases caused by several species of the genus *Leishmania*. Each species tends to occupy a particular zoogeographical zone and the disease is endemic in 88 countries. It has been estimated that 1.5 million new cases of cutaneous leishmaniasis occur annually and more than 80% of the total of cases affect individuals in developing countries. Brazil, Iran, Afghanistan and Sudan suffer the highest prevalence and the disease is a priority for public health in all hyperendemic regions of the world. The species are morphologically identical, and are distinguished by isoenzyme pattern and DNA analysis. Monoclonal antibodies have also proved useful for rapid identification of isolates, especially in the field [1]. Clinical patterns are poor indicators of species, although certain disease characteristics may be commonly associated with a particular species [2]. *Leishmania* spp. undergo a cycle of development in the gut of female sandflies, of the genera *Phlebotomus* in the Old World, and *Lutzomyia* and *Psychodopygus* in the New World.

In its vertebrate host, the amastigote form of the parasite is found in cells of the reticuloendothelial system or in the dermis following severe parasite load and mononuclear cell necrosis. It is round or oval, 2–3 μm in diameter, with no protruding flagellum. The nucleus and kinetoplast stain deeply with the Romanovsky stains, giving the organism its characteristic appearance. In the sandfly and in artificial culture media, *Leishmania* spp. are the elongated promastigote stage, motile with an anterior flagellum.

Sandflies find their precise requirements for temperature and humidity in a wide variety of niches, commonly in rodent burrows, and crevices and holes in banks, trees and houses in the Old World, and in tree canopies and forest litter in the New World [3]. Infection is transmitted by the bite of the fly, usually at night and outdoors; however, infected vectors can take a blood meal during the day if disturbed and also are responsible for inoculating parasites indoors within the household environment. Commonly, the infection is zoonotic; one species of *Leishmania* may be associated with one, or many, natural vertebrate hosts, which provide the reservoir of infection. Humans are commonly accidental hosts, although there are situations in which they may be the reservoir in an anthroponotic cycle. For these reasons, human leishmaniasis has a very wide geographical distribution and range of climate and altitude (Fig. 32.35), and different epidemiological patterns (Table 32.2) [4].

Human leishmaniasis is usually classified as cutaneous or visceral, but the species that cause visceral disease may also cause skin lesions. In South and Central America, skin disease due to parasites of the *L. brasiliensis* complex may be complicated by the development of metastatic mucosal or mucocutaneous lesions. Mucosal disease is relatively rare with the other species [5].

Old World cutaneous leishmaniasis

SYN. ORIENTAL SORE; BOUTON D'ORIENT; DELHI BOIL; ALEPPO BOIL

Aetiology and epidemiology. Cutaneous leishmaniasis of the Old World is due to *L. major*, *L. tropica*, *L. aethiopica* and to *L. donovani infantum*, which is responsible for all the cutaneous disease on the northern Mediterranean littoral west of Greece and for some of the disease in North Africa [6,7] (Table 32.2). In endemic areas where transmission is stable, children are especially affected, and the cumulative rate of infection as determined by the presence of scars and positive leishmanin tests may approach 100%. In less stable situations, for example around oases, epidemics occur affecting all ages and sexes [8]. The disease is commonly imported into non-endemic countries by immigrants and returning travellers.

Pathogenesis. Sandflies inoculate the infective metacyclic promastigotes when taking a blood meal from the superficial vascular network in the human dermis. Inoculated promastigotes are taken up by histiocytes and newly immigrated monocytes, in which they multiply. Most inoculations do not seem to result in clinical disease as phagocytosis, and complement-mediated killing of leishmania parasites results in clearing of the infection. A minority of successful parasite inoculations result in localized or disseminated clinical cutaneous leishmaniasis. After a period of time, which depends on parasite species, size of inoculum, and the host's cellular immune response, a clinical lesion appears. This lesion comprises parasitized macrophages, lymphocytes and plasma cells, with little structure (Fig. 32.36) [9]. With time, piecemeal and focal necrosis of parasitized cells is found, probably the result of antibody-dependent cell-mediated immunity. The overlying epidermis becomes hyperkeratotic and breaks down, causing an ulcer whose surface is covered in a crust composed of hyperkeratotic debris, dried exudate, dead cells, and live and dead parasites. This activity continues for several months, while the lesion appears clinically static. In other, especially chronic, cases the more classical epithelioid cell, and sometimes

giant cell granuloma, develops with relatively little necrosis, but similar epidermal changes (Fig. 32.37). In these cases, parasites are difficult to find [10]. Rarely, when cell-mediated immunity fails to develop, as in diffuse cutaneous leishmaniasis, histology shows masses of parasitized, often vacuolated, macrophages, with little or no lymphocytic infiltrate, and a normal or attenuated epidermis [11].

Clinical features [12]. All previously uninfected individuals are susceptible. The incubation period is usually measured in months, but ranges from a few days to over a year. One or more lesions occur on unclothed parts of the body, particularly on acral skin over bony prominences easily bitten by *Phlebotomus*, usually in a child. The face, neck and arms are the commonest targets. Lesions do not necessarily occur all at exactly the same time, but in endemic areas a family of children may all present with lesions and a history strongly suggesting infected sandfly bites all acquired in the same room on the same night.

The natural history of the lesions due to the four species tends to differ but there is much overlap, reflecting the variety in host response [2], so that lesions and their

DCL, diffuse cutaneous leishmaniasis; Sb, antimony as pentavalent antimonial.

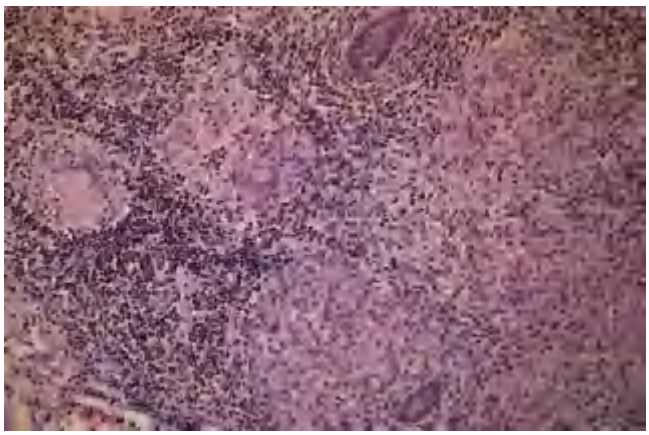

Fig. 32.37 Chronic cutaneous leishmaniasis. Granulomatous dermatitis without necrosis. There are no amastigotes to be found in this case, and the differential diagnosis may be difficult between the other granulomatous dermatitides. (Courtesy of Professor S.B. Lucas, King's College, London, UK.)

outcome are not always characteristic of the species (Table 32.3) [4]. The sequence of nodule, crusting, ulceration and healing with scar formation is common to all the self-healing sores.

Cutaneous leishmaniasis due to L. major: wet, rural or zoonotic cutaneous leishmaniasis [13,14]. After a short incubation period of less than 2 months, a red furuncle-like nodule appears at the site of inoculation (Fig. 32.38). After 2 weeks a central crust forms. The crust may persist (Fig. 32.39), or fall away revealing the underlying ulcer (Fig. 32.40). The ulcer and the raised, red margin enlarge over the next 2–3 months, and the lesion reaches a diameter of 3–6 cm. Multiple, small, secondary nodules (2–4 mm) sometimes occur around the lesion in lymphatics. Healing takes place in 2–6 months and leaves a scar. This type of cutaneous leishmaniasis is acquired in a rural area, where the infecting organisms are also rodent parasites and are poorly adapted to humans. It is an example of a zoonosis.

Fig. 32.38 Cutaneous leishmaniasis due to *Leishmania major*: early papules, one of which is starting to show central crusting.

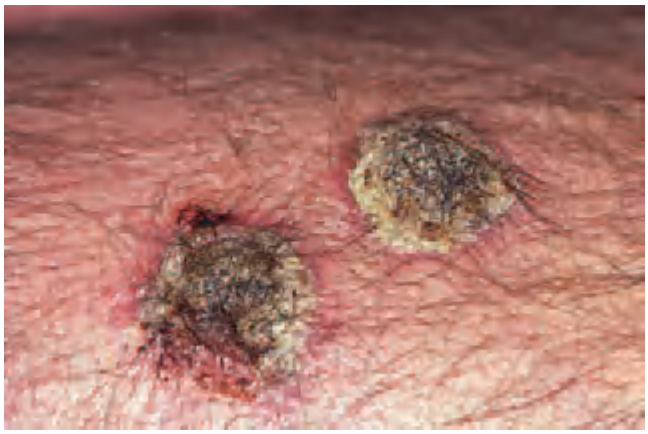

Fig. 32.39 Cutaneous leishmaniasis due to *Leishmania major* from Saudi Arabia, showing marked and persistent crusting.

Cutaneous leishmaniasis due to L. tropica: dry, urban or anthroponotic leishmaniasis [15]. After an incubation period of more than 2 months, a small, brownish nodule appears, which becomes a slowly extending plaque 1–2 cm in diameter in about 6 months. At this stage, shallow ulceration appears in the centre, which develops a closely adherent crust. Multiple secondary nodules occur much less frequently than in the 'wet' form. After 8–12 months, the lesion starts to regress and the ulcer heals, leaving a scar. The average time from nodule to scar is about 1 year, approximately twice as long as in the 'wet' form. Rare forms of viscerotropic infections by *L. tropica* have been described in war veterans who acquired the parasite in the Middle East and in cases of Indian kala-azar [16].

Cutaneous leishmaniasis due to L. aethiopica [11]. Lesions are most commonly central on the face, and single. Satellite papules accuminate into a large, spreading nodule that may not crust or ulcerate (Fig. 32.41). Lesions are seldom much inflamed, and heal over 2–5 years. If the sandfly bite has been on the mucosal border of the nose or mouth, primary mucocutaneous leishmaniasis (MCL) may develop, producing swelling of lips or nose, and persist for many years (Fig. 32.42), although without the gross destruction seen in Latin America caused by *L. brasiliensis*.

Fig. 32.40 Cutaneous leishmaniasis due to *Leishmania major* from Sudan. An ulcer with a raised edge.

Fig. 32.41 Cutaneous leishmaniasis due to *Leishmania aethiopica* from Kenya. A large nodule with many satellite papules and abundant parasites.

Cutaneous leishmaniasis due to L. donovani infantum [7]. Whereas infants infected with this parasite tend to get visceral leishmaniasis, adults are more likely to develop

Fig. 32.42 Nasal involvement, and marked inflammatory oedema in leishmaniasis due to *Leishmania aethiopica* in Ethiopia.

Fig. 32.43 Cutaneous leishmaniasis due to *Leishmania infantum*, from Spain. The fleshy nodule, with relatively little inflammation is characteristic.

simple self-healing cutaneous disease, without concurrent or subsequent visceral involvement. The appearance and evolution of the lesions is typically slow and mild, when compared with that of *L. major*, with which it coexists in North Africa [6] (Fig. 32.43). Solitary mucosal lesions have occasionally been reported [5].

In addition to the classical self-healing sores, there are two types of cutaneous leishmaniasis that are chronic, and may not heal spontaneously.

Fig. 32.44 Leishmaniasis recidivans (lupoid leishmaniasis) from Baghdad, showing active papules cropping in the edge of the scar of the healed sore. (Courtesy of Professor G. Rahim.)

Leishmaniasis recidivans: chronic leishmaniasis, lupoid leishmaniasis [10]. It has been estimated that approximately 4% of *L. tropica* infections from Iran and Afghanistan will develop this chronic form of the disease. Brown-red or brown-yellow papules appear, usually close to a scar of an old lesion of cutaneous leishmaniasis or actually in the scar. They coalesce and form a plaque closely resembling lupus vulgaris, even to the formation of apple-jelly nodules (Fig. 32.44). The lesions frequently worsen in the summer and may ulcerate or form concentric rings. Rare keloidal and verrucous forms on the lower limbs are described. A psoriasiform type also occurs and may cover large areas of the body.

The recidivans lesion is the result of a peculiar host reaction in which cellular immunity fails to sterilize the lesion, despite the presence of exaggerated hypersensitivity. Although not as destructive as lupus vulgaris, lupoid leishmaniasis may persist and spread slowly for many years [17]. Investigations to demonstrate the parasite or leishmanial DNA in the affected skin are commonly negative.

Diffuse cutaneous leishmaniasis: disseminated cutaneous leishmaniasis, leishmaniasis cutis diffusa. In the Old World this form of the disease is due to *L. aethiopica* and has certain characteristic features [11].

1 There is an initial lesion, which spreads locally, and from which the disease disseminates to other parts of the skin, often involving large areas (Fig. 32.45).
2 The lesions are nodules that do not ulcerate.
3 There is a superabundance of parasites in the lesions.
4 The histology is characteristic in that macrophages full of amastigotes predominate.
5 Internal organs are not invaded and there is no history of kala-azar.

Fig. 32.45 Diffuse cutaneous leishmaniasis due to *Leishmania aethiopica* in Ethiopia. The face is covered with infiltration and nodulation but there is no ulceration.

6 The leishmanin test and other tests of specific cellular immunity are negative.
7 The disease progresses slowly and becomes chronic.
8 Treatment produces only gradual improvement and relapse is the rule.

Under the influence of treatment, the histology changes towards the tuberculoid in a proportion of patients, and they may recover completely. Cases of coincident leishmaniasis and leprosy have been described, and show that the immune deficiency of each condition is specific [18].

Diagnosis. In endemic areas, or in travellers returned from endemic areas, the clinical diagnosis is not difficult in the case of typical sores. A positive diagnosis of cutaneous leishmaniasis (Old World and New World types) can be suggested, and in most cases confirmed, by the presence of one or more of the following criteria:
1 History of exposure to an endemic area in the previous weeks or months.
2 History of sandfly bites in the previous weeks or months.
3 History of high-risk activities such as sleeping outdoors, jungle or desert trekking.
4 Non-healing chronic nodular, violaceous ulcer for 4–6 weeks or longer.
5 Demonstration of amastigotes in Giemsa-stained smears from infected skin by direct microscopy.
6 Demonstration of intracellular amastigotes in the dermis of H & E sections of skin.
7 Presence of leishmanial granulomas in the dermis in H & E specimens.
8 Growth of promastigotes in Nicolle–Novy–MacNeal (NNN) culture medium from lesional specimens.
9 Demonstration of leishmanial DNA by the PCR.

Deeper, subcutaneous sores (the so-called volcano lesion), sores arising from lymphatic spread, or chronic sores in which scarring predominates may present difficulties. Confirmation is through demonstration of the parasite. Usually, this is best achieved by making a smear of material from the sore and staining it with Wright's, Giemsa or Leishman's stain on a microscope slide. The smear may be made from the exudate from the sore, and is often positive even if purulent because secondary bacterial infection is unusual. Alternatively, a slit-skin smear is made, as for leprosy (Chapter 29), being careful to avoid taking blood from the nodular part of the lesion. Parasites are usually readily seen in sores that have not yet started to heal, but are difficult to see thereafter. Alternatively, material may be obtained through a needle or with a dental broach [19].

Ideally, material should also be cultured on NNN or similar medium. At the time of taking the lesional skin biopsy for histological examination, a portion of it should be cultured, and dab smears made from the cut surface of the other portion before it is fixed. Leishmania are harder to see and identify in sections than in smears. In chronic leishmaniasis especially, histology may not be able to distinguish leishmaniasis from sarcoidosis, tuberculosis or other tuberculoid pathologies. However, in acute forms with or without the presence of amastigotes, the presence of a granuloma has a high diagnostic sensitivity.

In all forms of cutaneous leishmaniasis, the leishmanin test will be positive once the stage of crusting has been reached [19]. The test is negative in the diffuse anergic forms. The Leishmanin test also called the Montenegro test, particularly in Central and South America, is a suspension of 5×10^6 cultured promastigotes of *Leishmania* spp. (*L. major* is commonly used for cutaneous diagnosis in Old World leishmaniasis) per mL of 0.5% phenol saline: 0.1 mL is injected into the volar surface of the forearm and the result read at 48–72 h. The antigen is normally standardized so that an induration of 5 mm or more, measured by the ballpoint technique, is positive [1]. While interpreting the result in an individual patient, it is important to take into consideration the prevalence rate in the control population. This intradermal skin test is not useful for the diagnosis of current cutaneous leishmaniasis as a positive result may indicate previous sensitization. Moreover, there are also problems of cross-reactivity amongst different *Leishmania* spp. and therefore the Montenegro test is

not useful for particular epidemiological settings where infections by different *Leishmania* spp. overlap.

Molecular diagnostic tests to detect leishmanial DNA by PCR have been available for several years. Assays can be carried out by using nuclear DNA, and more recently the diagnostic sensitivity was significantly enhanced by using kinetoplast minicircle DNA [20]. The sensitivity of this test has been reported to be between 92% and 98% with 100% specificity by several authors [20]. A variety of clinical specimens, including cotton swabs and archival smears or paraffin-embedded skin sections, can be used as the DNA source for the PCR diagnosis. Ideally, the diagnosis of cutaneous leishmaniasis should achieve a species- and subspecies-specific level, as this has therapeutic and prognostic implications.

Treatment [21]. Most sores will heal spontaneously, but their duration cannot be predicted in an individual case. It is reasonable to try topical methods of treatment for simple sores, and to reserve the systemic use of pentavalent antimonials for problematic sores: these include sores where scarring would be disabling or severely disfiguring; sores that will not heal easily, for example on the lower leg or over a joint; sores involving mucosa or cartilage; or sores that might be due to parasites of the *L. brasiliensis* group.

Heating a sore to 40–42°C for several hours each day promotes healing but is technically difficult [22]. Small single sores may be frozen with carbon dioxide snow [23], curetted under local anaesthetic [24] or infiltrated with 1–2 mL sodium stibogluconate or meglumine antimoniate, on one or two occasions a few days apart. Careful attention to technique is essential [25]. Preliminary studies using the aminoglycoside aminosidine or paromomycin in an ointment look promising, but problems of formulation have yet to be solved [26].

Systemic treatment is with sodium stibogluconate or meglumine antimoniate by intravenous or intramuscular injection in a single daily dose of 20 mg antimony/kg, for as long as it takes to produce clinical and parasitological healing and a few days longer: usually 15–21 days [27]. Sores due to *L. brasiliensis* should be treated for the full 21 days [28]. *Leishmania aethiopica* is not sensitive to antimony at this dosage [29] and, when systemic treatment is justified, patients should be treated with pentamidine isethionate in a dose of 4 mg salt/kg once a week for as long as necessary [30]. Patients with diffuse cutaneous leishmaniasis require treatment for many months beyond clinical and demonstrable parasitic cure [30]. Leishmaniasis recidivans (lupoid) may respond to local infiltration after nodulectomy, or systemic antimonials. The additional use of steroids has helped some cases [14]. Severe scarring may require plastic repair. After healing, patients are normally immune to reinfection with the same species, although second sores in old age, or due to a parasite of a different zymodeme, have been reported.

It is clear that the available treatments for cutaneous leishmaniasis are far from being satisfactory. Even more, reported therapeutic failures with pentavalent antimonials have been described as an increasing problem in endemic regions for visceral leishmaniasis in India and also as an emerging problem in New World cutaneous leishmaniasis amongst returned travellers to the UK [31]. Novel approaches include combination therapeutic regimes using antimonials and immunostimulating agents. Intravenous treatment with pentavalent antimonials results in a number of common adverse reactions and side effects including hepatic, pancreatic, musculoskeletal and cardiac toxicity. Elderly patients seem to be more frequently and severely affected by these symptoms.

American cutaneous leishmaniasis and MCL

SYN. AMERICAN LEISHMANIASIS; SOUTH AMERICAN LEISHMANIASIS; ESPUNDIA; PIAN BOIS; UTA; CHICLERO'S ULCER; BUSH YAWS; PICATURA DE PITO

Aetiology and epidemiology. The site of development of leishmania in the gut of New World sandflies differs from that in Old World sandflies, and the parasites have been redesignated by the addition of the subgenus *vianna*, for example *Leishmania viannia brasiliensis* [32], but in this chapter the older, simpler terminology is retained, by which the parasites that cause disease in humans fall into the *L. brasiliensis* and *L. mexicana* complexes. American leishmaniasis is an endemic and mainly rural disease of damp, forested country in South and Central America [32]. It becomes epidemic among young people who go to work in the forests, 25% of young soldiers fighting in the jungle in certain areas and in villagers settled on land recently torn from the tropical forest. The optimum time for transmission is immediately after the rainy season.

Additionally, *L. b. brasiliensis* is becoming increasingly periurban [27], with a number of opportunistic hosts, including dogs and donkeys (whose true reservoir status is questionable). *Leishmania brasiliensis peruviana* is, by contrast, part of a mountainous zoonosis among peridomestic dogs, causing an endemic human infection that affects children especially. Vectors and reservoirs are given in Table 32.2. As increasing numbers of new species of parasite are identified, it is becoming clear that each is associated with its own complex of reservoir hosts and vector sandflies.

Pathogenesis. The pathology of the skin lesions does not differ significantly from that of Old World sores. The necrotic pattern, with ulceration of the overlying epidermis, is common [9]. Although recovery from an infection

confers lifelong immunity against reinfection with the same species of parasite, that immunity does not develop early enough or adequately to prevent the blood-borne metastatic spread of parasites of the *L. brasiliensis* complex, especially *L. b. brasiliensis* itself, to the mucosa of the nose, mouth, palate or larynx. Here, they may later start to multiply and be recognized immunologically, and cause severe destructive lesions, known as espundia (Portuguese: a sponge) [33]. Histology of the mucosal lesion [34] shows a collection of lymphocytes and plasma cells around small arterioles in the nasal submucosa. Occasional leishmania are present in the vascular endothelial cells. Oedema, congestion and proliferation of vascular endothelium progress, leading to desquamation and necrosis of the overlying mucosa and underlying cartilage. Endarteritis and thrombosis add to the tissue destruction. Vascular supply is so reduced that only fibrous tissue remains.

Clinical features [35]. The main types of American leishmaniasis are as follows.

Cutaneous leishmaniasis due to L. mexicana complex. The vector of *L. m. mexicana* bites humans reluctantly, so only those who spend long periods of time in the forest, such as chicle collectors, are at risk. The lesions behave like those of *L. major* or *L. tropica*. Most are on the side of the face or behind the ears (Table 32.3). Lesions on the pinna of the ear may invade cartilage, take many years to heal and destroy the pinna [36]. *Leishmania mexicana amazonensis* is extremely common in forest rodents, but the vector is not anthropophilic, so human infections are rare. A large proportion of them give rise to diffuse cutaneous leishmaniasis, which does not differ significantly from its counterpart in the Old World, due to *L. aethiopica* [29].

Cutaneous leishmaniasis due to L. brasiliensis complex [37]. Sores are often large deep ulcers, usually with a raised edge. Sores due to *L. b. guyanensis* are often fleshy and protuberant, usually on the limbs, often multiple, and resemble those of yaws, 'pian bois' [38]. This parasite and *L. b. panamensis* are especially associated with lesions along the draining lymphatics, but these may occur with any species. The lymphatic lesions may remain discrete small nodules, or may become inflamed and break through the skin to resemble the primary lesion. Lymphadenopathy is seldom marked.

American MCL [39,40]. Up to 40% of patients with sores due to *L. b. brasiliensis* and a very much smaller proportion with sores due to *L. b. panamensis* and *L. b. guyanensis* may develop mucosal lesions: 50% of mucosal lesions develop within 2 years of the appearance of the skin lesion, and 90% within 10 years. Delays of 35 years are recorded [33]. About 15% of patients with MCL give no previous history of a skin sore. The nasal mucosa is almost always affected, and in one-third of patients a second site is also involved, in the pharynx, palate, larynx or upper lip, in that order (Fig. 32.46). The usual initial lesion is a nodule on the inferior turbinate or septum, which causes stuffiness and obstruction. The destructive pathology perforates the septum and over years may destroy the nose, palate and lips (Fig. 32.47), which may become gross and protuberant, or scarred and constricted, causing difficulties in speech and eating. Death may supervene from secondary infection, starvation or laryngeal obstruction (Fig. 32.48). Spontaneous healing is virtually unknown.

Fig. 32.46 Mucosal leishmaniasis due to *Leishmania brasiliensis* in Brazil. The nasal septum anteriorly is most severely affected. (Courtesy of Dr L. Bakos, Porto Alegre, Brazil.)

Fig. 32.47 Severe mucocutaneous leishmaniasis from Brazil. (Courtesy of Professor P. Marsden, University of Brasilia, Brazil.)

Cutaneous leishmaniasis due to L. b. peruviana: 'uta' [35]. Lesions are less severe than those of *L. b. brasiliensis*. They heal spontaneously and are not known to cause MCL.

Fig. 32.48 Mucosal leishmaniasis from Brazil. A fatal case, showing the extensive laryngeal involvement. (Courtesy of Professor P. Marsden, University of Brasilia, Brazil.)

Diagnosis. The principles are the same as for cutaneous leishmaniasis of the Old World, but the differentials of syphilis, yaws, rhinoscleroma, sporotrichosis, histoplasmosis, leprosy and, especially, blastomycosis must also be considered. Lesions of sarcoidosis, lupus vulgaris and cutaneous T-cell lymphomas (CTCLs) can also resemble cutaneous leishmaniasis. For the diagnosis of MCL, the nasal lesion must be sampled, after careful cleaning, for culture, as well as examined by impression Giemsa smear and histology. Problems of contaminating infection can be avoided by inoculating some of the material into a hamster.

Treatment [12]. This is summarized in Table 32.3. Lesions due to *L. b. guyanensis* are particularly liable to relapse. Lesions due to *L. b. brasiliensis* should be treated systemically for a week beyond parasitological cure, in order to prevent MCL from developing [28]. Previously untreated patients with MCL respond to pentavalent antimonials in a dose of 20 mg/kg/day, if given daily for 3–4 weeks [41]. Only 20% of relapsed patients will respond to the drug. Amphotericin is the drug of second choice, given in a dose of 1 mg/kg on alternate days for 2 months. Treatment that is inadequate in dose or duration leads to relapse and drug resistance. Secondary infection should be treated. Corticosteroids are useful to prevent laryngeal oedema that can otherwise complicate the start of treatment of laryngeal disease.

Cutaneous leishmaniasis in the returned traveller. Common and rare forms of cutaneous leishmaniasis are increasingly being described in non-endemic regions of the world. A recent retrospective survey at the Hospital for Tropical Diseases in London disclosed more than 50 new cases including Old and New World cutaneous infections by *L. tropica*, *L. viannia braziliensis*, *L. major* and *L. donovani* complex. Patients with infections acquired in the New World manifested a more severe clinical picture and therefore sought medical referral at an earlier stage. The diagnosis was established by all four standard investigations including Giemsa smears for direct microscopy, H&E histology, parasitological culture and molecular diagnosis by PCR. Intravenous or intralesional treatment with sodium stibogluconate and other less frequently used agents resulted in cure for most of these patients. Educational strategies to increase the awareness of cutaneous leishmaniasis as an emerging problem in the UK are being directed at general practitioners, dermatologists and the public.

Visceral leishmaniasis

SYN. KALA-AZAR; 'DEATH FEVER'; DUM-DUM FEVER

Leishmania donovani donovani and its close relative *L. donovani infantum* are, by contrast with the other species of *Leishmania* that infect humans, normally viscerotropic, and cause a severe systemic infection, which may be accompanied by cutaneous manifestations.

Aetiology. There are four main zoogeographical zones in which visceral leishmaniasis is found (see Table 32.2). Transmission is peridomestic and tends to be stable in the Mediterranean focus. Dogs are the reservoir. Young children are most commonly affected. Infected adults tend to develop self-healing skin sores. In Brazil, peridomestic transmission from raiding foxes affects older children. A similar age group is affected in East Africa, where transmission takes place outside the houses in the evenings. In India, where the human is the reservoir, epidemics occur every 15 years or so and all age groups, previously uninfected, are susceptible. Travellers and tourists of any group age are susceptible in any of the four zones.

Pathogenesis. In over 90% of cases, the infection is subclinical and cutaneous hypersensitivity and immunity develop [42]. In the others, especially in the malnourished, the parasite invades and multiplies in reticuloendothelial cells of the spleen, liver, lymphoid tissue, bone marrow and gut submucosa. This reticuloendothelial bombardment is associated with the overproduction of polyclonal IgG, specific antibody production, and the formation of high titres of immune complexes and various autoantibodies. The spleen and, to a lesser extent, the liver become

Fig. 32.49 Post-kala-azar dermal leishmaniasis. Typical facial papules in a Kenyan arising 6 weeks after treatment and healing spontaneously. (Courtesy of Dr J.D. Chulay.)

enlarged, and hypersplenism ensues, causing anaemia, leukopenia and thrombocytopenia. Organ function is usually well preserved until late in the disease, but specific and non-specific indices of cell-mediated immunity are depressed, and secondary infections are common and often fatal [43].

Clinical features [44]. After an incubation period of weeks to months, sometimes exceeding a year, fever develops, either insidiously or abruptly. The commonest additional symptoms are fatigue, discomfort from the presence of the enlarged spleen and cough, diarrhoea and epistaxis. Gross splenomegaly is the dominant physical sign; hepatomegaly, lymphadenopathy in some endemic zones, and signs of malnutrition, including pedal oedema, red, straight hair in Africans, and wasting also occur.

In a few cases in Africa, a primary skin sore has been described, like those of cutaneous leishmaniasis. Rarely, there may be an accompanying mucosal lesion. In Indian people especially, the skin of the face, hands, feet and abdomen becomes hyperpigmented, even black: kala-azar means black sickness. Despite epistaxis and sometimes jaundice, there is no evidence of cutaneous bleeding. In Iran, patients have been seen with numerous skin lesions [45].

Post-kala-azar dermal leishmaniasis (PKDL) (dermal leishmanoid). In 5% of East African patients, and 20% of Indian patients, a rash develops after the visceral disease has healed, either spontaneously or following treatment. A small proportion of patients with PKDL give no previous history of visceral disease. In Africa [46] the rash begins during convalescence, appearing on the cheeks, chin, ears and extensor aspects of forearms, buttocks and lower legs (Fig. 32.49). Usually, the rash comprises discrete papules, which on histological examination show a tuberculoid histology with scanty parasites. The leishmanin test is positive. The rash heals spontaneously over a few months. Presumably it represents the acquisition of specific cellular immunity that is clearing up scattered parasites that remained in the skin. Both cellular immunity and pentavalent antimonials are less efficient in the skin than in the viscera.

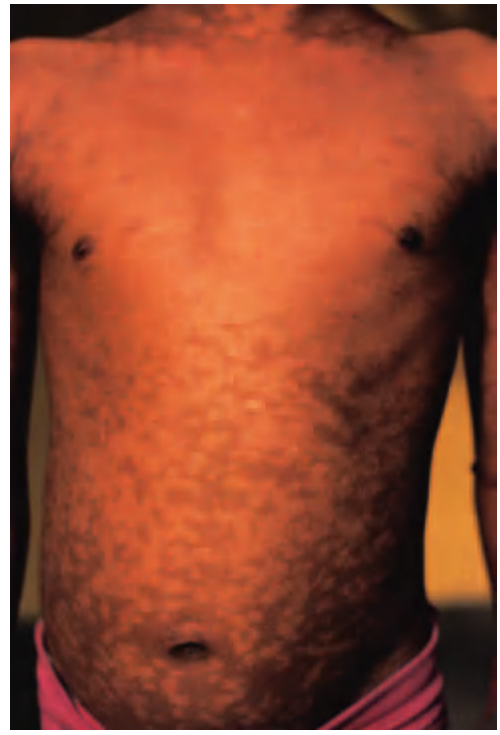

Fig. 32.50 Post-kala-azar dermal leishmaniasis in an Indian person showing the extensive hypopigmented macular rash.

In India, by contrast, the rash appears 1–2 years after recovery, as hypopigmented macules, similar in appearance and distribution to those of lepromatous leprosy (Fig. 32.50). After a variable period of years or months, diffuse nodulation begins to develop in these macules (Fig. 32.51). The rash is progressive over many years and seldom heals spontaneously. The tongue, palate and genitalia may be involved. There may be lymphadenopathy, but the viscera are spared and there are no features of relapse of the previous systemic infection. Presumably, this condition represents cellular immunity against a dermotropic mutant of *L. donovani*. PKDL is thought to represent the intraepidemic reservoir of infection of visceral leishmaniasis in India. Histology shows a poorly differentiated infiltrate of chronic inflammatory cells, with a variable number of leishmania in dermal macrophages [47]. The leishmanin test is usually negative, but becomes positive after successful treatment [48].

Diagnosis. In visceral leishmaniasis, parasites may be demonstrated in aspirates of spleen, bone marrow, liver or lymph node, in that order of likelihood (Fig. 32.52). In

Fig. 32.51 Post-kala-azar dermal leishmaniasis in an Indian person. A later stage than that shown in Fig. 32.50. Papules are beginning to develop.

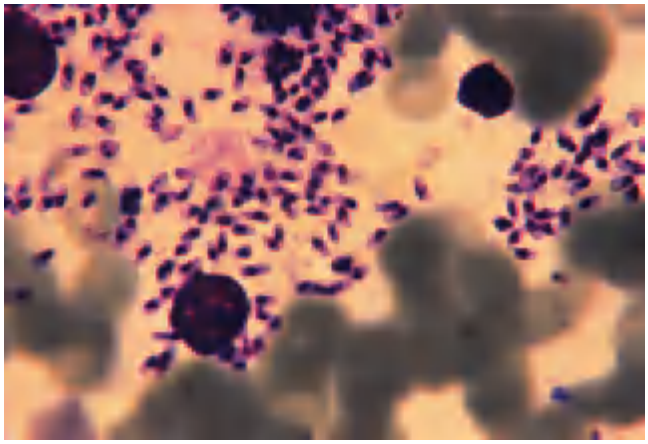

Fig. 32.52 Amastigotes of *Leishmania infantum* in a bone marrow smear from a patient with visceral leishmaniasis and the acquired immune deficiency syndrome. (Courtesy of Mr A.H. Moody, Hospital for Tropical Diseases, London, UK.)

PKDL, slit-skin smears are usually positive. Antibodies to *Leishmania* spp. may be demonstrated by a variety of techniques: indirect immunofluorescence, ELISA and direct agglutination tests are commonly performed [49]. The leishmanin test is negative, except in African PKDL.

Treatment. For visceral leishmaniasis, sodium stibogluconate is used, as for cutaneous leishmaniasis for 21–30 days, according to the endemic zone [27]. African PKDL does not require further treatment. Indian PKDL is treated with a further course of sodium stibogluconate.

Visceral leishmaniasis in patients with HIV infection [50]

The main area of overlap of these two infections is in southern Europe, especially Spain. Leishmaniasis may be acquired prior to or after the HIV infection, and may thus be primary or secondary to the HIV infection. In some patients, typical characteristics of fever and splenomegaly have not been present, and serological tests have been negative. On occasion, the parasite has been discovered by chance, for example in the biopsy of Kaposi's sarcoma, and disseminated dermatofibroma-like lesions containing amastigotes have been described in a patient with acquired immune deficiency syndrome (AIDS) coinfected with visceral *L. donovani* [51]. Aspirates of bone marrow and spleen show extremely heavy parasitization. Relapse and mortality rates are high. Treatment should be prolonged and monitored by splenic aspirates.

Toxoplasmosis

Aetiology. The disease is caused by *Toxoplasma gondii*, a tiny sporozoon often assuming a crescentic shape, first identified in 1908 in a North African rodent, *Ctenodactylus gondii*. Cats are definitive hosts and a form of *Toxoplasma* cyst can be found in their faeces. Rodents and birds are the intermediate hosts. Larger mammals including humans are infected incidentally, by eating raw, infected meat or by ingesting oocysts in contaminated food or water.

Pathogenesis. The organism tends to invade the reticuloendothelial system and the endothelium of the blood vessels, forming granulomas with necrosis of affected tissues. Toxoplasmosis causes four types of disease in humans [1]:
1 an acute febrile lymphadenopathy;
2 fetal infection, causing brain damage;
3 ocular disease, usually due to reactivation of fetal infection;
4 disseminated disease in immunocompromised patients, including those with HIV infection, causing fulminating encephalitis.

Skin changes are uncommon and non-specific. In the congenital disease [1], macular and haemorrhagic eruptions predominate. Occasionally, abnormal hair growth and exfoliative dermatitis have been seen. In the acquired disease, macular, maculopapular, papular and haemorrhagic eruptions also occur and may be followed by scarlatiniform desquamation. A wide variety of other lesions have been described including bullae, nodules, livedo annularis, urticaria and an eruption like pityriasis lichenoides; conclusive evidence of a causal relationship is frequently wanting. A dermatomyositis-like syndrome is described [2,3].

Diagnosis is made on clinical evidence, and may be confirmed by demonstration of the organism in biopsy of lymph node, liver or spleen, bone marrow, or in cerebrospinal and ventricular fluid. Usually, the diagnosis is made serologically. Several methods are available, among them:
1 the Sabin–Feldman dye test, positive early and declining over 1–2 years, which measures mainly IgG antibodies;
2 direct agglutination of formalinized parasites—useful for screening, detects IgM and IgG antibodies;

3 indirect fluorescence—simple and safe, can be used to distinguish IgM from IgG antibodies, as can an IgM ELISA.

Treatment. The sulphonamides and pyrimethamine (Daraprim) act synergistically and are effective [4]. Severe side effects may occur due to interference with folic acid metabolism. For this reason, infections in immunologically normal individuals are not usually treated.

Chapter 33

Diseases Caused by Arthropods and Other Noxious Animals

D.A. Burns

Mechanisms of skin injury by arthropods

Arthropods produce their effects on the skin by a variety of mechanisms [1–6], more than one of which may be implicated simultaneously.

Mechanical trauma

The puncture wound or laceration produced by the penetration of the skin seldom causes serious disturbance to the host. The nature of the trauma inflicted depends upon the structure of the mouthparts, which show wide variation between different species. There are two methods of feeding on blood: 'vessel feeders' insert the tip of their mouthparts into a capillary, and 'pool feeders' lacerate the skin, damage blood vessels and feed on the extravasated blood. Vessel feeders include sucking lice (Anoplura) and most mosquitoes, and pool feeders include stable flies and tsetse flies.

Injection of irritant, cytotoxic or pharmacologically active substances

An injected substance may contain pharmacologically active agents that produce local or, if in sufficient quantity, systemic effects. Salivary secretions and sting venoms may contain various enzymes such as hyaluronidase, proteases, peptidases and phospholipases; kinins; histamine-liberating agents; histamine; 5-hydroxytryptamine; or acetylcholine.

Injection of potential allergens

The vast majority of reactions to arthropod bites or stings depend upon the presence of specific antibodies to antigenic substances in the saliva or venom. Investigation of extracts of venom sacs and salivary glands from many species, using modern immunological techniques, has demonstrated the presence of numerous antigens, some specific for a single species, and others common to several related species or even to related genera.

The type of reaction provoked by an arthropod bite or sting in an individual patient largely depends on previous exposure to the same or related species. When an individual is bitten for the first time by a species whose salivary secretions contain no directly injurious substance, there is commonly no reaction. After repeated bites, sensitivity starts to develop, manifest by an itchy papule developing about 24 h after each bite and persisting for several days. With prolonged exposure, an immediate weal reaction occurs, to be followed by the delayed papular reaction. After a further period of exposure, the delayed reaction no

longer occurs, and eventually there is no reaction at all. The patient is then said to be immune. Mellanby [7] demonstrated this sequence of events with mosquito bites, and a similar response is seen with the bites of many other arthropods.

Some patients show a severe systemic hypersensitivity to arthropod allergens, manifest by anaphylaxis. The antigenic substances in the venoms of Hymenoptera (bees, wasps, hornets) are more likely to induce severe systemic hypersensitivity reactions than are the antigens of most other insects.

The capacity of a patient to respond to an antigenic stimulus is also an important factor in determining the reaction to an arthropod. The reactions of patients who are immunosuppressed, as a result of either disease or therapy, are modified. Examples of this include the occurrence of crusted scabies in immunosuppressed individuals, and the response to bites in patients with chronic lymphatic leukaemia, human immunodeficiency virus (HIV) infection, and Epstein–Barr virus-associated natural killer cell leukaemia/lymphoma (see p. 33.7).

Secondary infection

Bacterial infection may be introduced at the time of the bite, but commonly gains entry as a result of scratching, and may confuse the clinical picture. Compartment syndrome caused by streptococcal cellulitis complicating an insect bite has been described [8].

Invasion of the host's tissues

Certain flies cause myiasis, in which the host's tissues are invaded by larvae (see p. 33.8).

Contact reactions

Simple contact with the secretions of certain arthropods, or with their living or dead bodies, may provoke irritant or allergic contact reactions. For example, the secretions of blister beetles produce a severe irritant reaction, and repeated handling of cockroaches may induce contact urticaria and dermatitis.

Reactions to retained mouthparts

Persistent granulomatous papules or nodules may be provoked by retained mouthparts, for example those of ticks.

Transmission of disease

Many diseases have arthropod vectors, for example malaria (mosquitoes), leishmaniasis (sandflies) and typhus (lice).

Susceptibility to infestation or attack

There are a number of environmental and social factors that determine the range of arthropod species to which an individual is exposed.

Persons living and working in tropical climates tend to wear fewer clothes, and therefore expose larger areas of the body to bites and stings. Clothing itself is essential to the existence of the body louse, and areas of constriction of clothing affect the distribution of the skin lesions caused by certain mites (e.g. harvest mites).

Certain occupations carry an increased risk of reactions to arthropods [9]. Forestry workers, for example, may be exposed to the urticating hairs of the caterpillars of certain species of Lepidoptera, and dock workers handling foodstuffs may be attacked by mites infesting the cargo.

In some societies, humans are exposed to attack by the parasites of the domestic animals with which they cohabit.

Housing can influence exposure to arthropod attack in a number of ways. Overcrowded homes favour transmission of ectoparasites, such as lice and the scabies mite, and dilapidated housing provides an ideal habitat for bedbugs. Spiders and scorpions will take up residence in garages, outhouses and woodpiles.

The methods by which an arthropod is attracted to its host species include body heat, carbon dioxide in exhaled air (e.g. ticks, fleas, bedbugs), and displacement of air or vibrations caused by the host (e.g. fleas) [10]. Human sweat contains mosquito attractants, and anhidrotic subjects are unattractive to mosquitoes [11,12]. The human skin microflora may be responsible for producing compounds that attract mosquitoes and, as there is variation in the microflora between individuals, body odour probably contributes to susceptibility to biting [13]. Human odour also appears to play a part in attracting sandflies [14].

Pregnant women appear to be more attractive to mosquitoes than the non-pregnant [15,16].

There is also a suggestion of increased susceptibility to mosquito bites in patients with HIV infection receiving antiretroviral therapy and suffering from lipoatrophy [17].

Certain species of flies are attracted to skin ulcers and purulent material, in which they lay their eggs.

Insect pheromones play a part in attacks by large numbers of Hymenoptera. Honeybees, when stinging, emit an alarm pheromone from glands in their sting chambers, and this guides other bees to attack an intruder.

Histopathology of arthropod bites and stings [1–3]

The histopathological changes associated with arthropod bites depend upon a number of factors, including the arthropod involved, the type of immunological reaction provoked and the duration of the lesion.

In papular urticaria, there is prominent papillary dermal oedema and a perivascular chronic inflammatory infiltrate with a significant admixture of eosinophils.

Bullous reactions develop beneath a more or less intact epidermis, and may be multilocular.

Chronic reactions often have a pseudolymphomatous appearance. The dermis contains a dense inflammatory infiltrate of lymphoid cells and histiocytes, with an admixture of eosinophils and plasma cells, and the presence of atypical mononuclear cells with hyperchromatic nuclei. Secondary lymphoid follicles with germinal centres are sometimes formed. Multinucleated cells may also occur. If retained mouthparts are present, there may also be giant cells of foreign-body type.

Additional histopathological features associated with particular arthropods are noted in the relevant sections of this chapter.

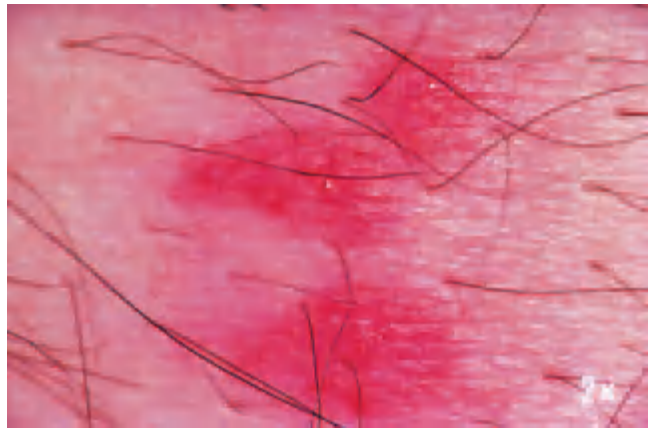

Fig. 33.1 Typical papular urticaria. In this case, in response to flea bites.

Clinical features of arthropod bites

The very large number of species of biting and stinging arthropods, their different feeding habits and the variation in individual patients' responses to the various irritants and allergens injected determine the diversity of clinical features. The type and distribution of lesions produced by individual arthropods are discussed in the relevant sections throughout this chapter.

The most frequently encountered response is papular urticaria (Fig. 33.1). Initially, an extremely itchy urticarial weal develops at the site of the bite, and this is succeeded by a firm pruritic papule, which usually persists for several days. The weal and papule may show a central haemorrhagic punctum, and the papule may be surmounted by a tiny vesicle. Lesions are often grouped in clusters, and develop in crops at irregular intervals.

The number and distribution of skin lesions produced by the bites depend upon the type of exposure and the feeding habits of the arthropod involved. New bites by the same species will often cause a recrudescence of activity in existing lesions.

Bullous reactions are common on the lower legs (Fig. 33.2), but may occur at other sites, especially in children. In the presence of lower limb venous hypertension, haemorrhagic or ulcerated lesions may develop. More severe local changes are sometimes found, with cellulitis and lymphangitis in the apparent absence of secondary infection.

Irritation is an almost inevitable symptom, and rubbing and scratching may increase the inflammatory changes and induce eczematization. When the bites are very numerous, or if the local reaction is severe, there may be fever and malaise.

Secondary infection is a common complication, and may be manifest as impetigo, folliculitis, cellulitis or lymphangitis.

Fig. 33.2 Bullous lesions in response to arthropod bites. (Courtesy of Dr F.A. Ive, Durham, UK.)

Anaphylactic shock is unusual except after Hymenoptera stings, but is occasionally seen with some other arthropods.

Bite reactions may persist for months. Tick attachment sites, in which the mouthparts may be retained, are the most likely to persist, but so may bites of mosquitoes and other insects.

Diagnosis

The diagnosis of insect bites is often self-evident, for example when the patient has spent the afternoon in the garden on a hot day in summer and subsequently develops typical lesions on exposed areas of skin. However, difficulty arises when the source of the bites is not immediately obvious.

The distribution of the bites may provide a clue to their origin, for example localization to the abdomen and thighs in cheyletiellosis or contact with sarcoptic mange in dogs, and involvement of the legs below the knees when the lesions are produced by cat or dog fleas. Patients should be asked about domestic pets—not only their own, but also those in the homes of close relatives who are visited regularly, as ectoparasites associated with pet animals are often the source of persistent arthropod bites. If the bites are not localized, but scattered all over the body, consider reactions to arthropods biting in the patient's bedroom, such as bird fleas, bird mites or bedbugs. Enquire if the patient has recently moved house. It may

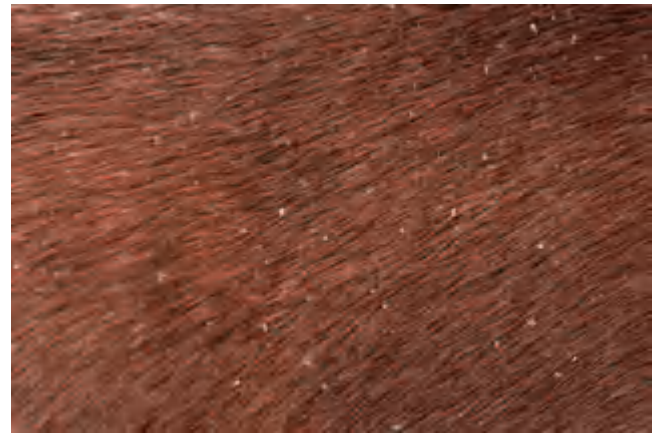

Fig. 33.3 Typical heavy scale in the coat of a dog suffering from *Cheyletiella* infestation.

be that the previous owners of the new home kept pet animals and have left a legacy of domestic flea infestation. Even if the house remained empty for a considerable time before the new owners took up residence, the flea population will be waiting in cocoons to emerge when the new occupants arrive. Adult fleas can survive starvation for variable lengths of time, depending upon species and environmental conditions [1,2]—a newly emerged and unfed dog flea, *Ctenocephalides canis*, will survive for approximately 60 days. In the absence of their natural hosts, such animal flea populations will not usually survive for more than a few months.

If the history and examination do not suggest a possible source for the problem, or if the dermatologist wishes to confirm a suspected source, the following procedures may be useful [3,4].

1 The patient's pet animals should be examined if possible for signs of skin disease. Cheyletiellosis and canine scabies produce characteristic changes on an affected animal [5]. Skin scrapings will confirm sarcoptic mange, and vigorous combing of scale from the coat of a dog suffering from cheyletiellosis (Fig. 33.3) will provide material in which *Cheyletiella* mites may be identified. If the animal cannot be examined, the patient should be provided with a sheet of black paper, and asked to collect brushings or combings from the animal's coat for subsequent examination.

2 If domestic infestation with cat or dog fleas is suspected, this can often be confirmed by examination of debris from the pet's bedding. The patient is supplied with a large polythene bag and instructed to place the pet's bedding in the bag and shake it vigorously for a few minutes. The bedding is then removed, and the bag is sealed and delivered to the dermatologist for microscopy of the debris. Macroscopically, flea eggs and faeces have a 'pepper-and-salt' appearance (Fig. 33.4), and the larvae are grub-like. For identification, adult fleas should be 'cleared' in 10%

Fig. 33.4 Typical 'pepper-and-salt' appearance of flea eggs and faeces in the debris from a cat's bedding.

potassium hydroxide for 24 h so that the majority of the pigment is removed and the anatomical details revealed. Cat and dog fleas are readily identified, but if unfamiliar species are encountered, the help of an entomologist with an interest in Siphonaptera should be sought. Correct identification of fleas is important so that proper control measures may be carried out [6].

3 If problems from bird fleas or bird mites are suspected, it is often of value to examine dust obtained with a vacuum cleaner from bedrooms. This is, however, time-consuming and requires some expertise.

4 It may be necessary to visit the patient's home to establish whether there are birds' nests under the eaves, which might be a source of fleas or mites, or to take specimens from household pets.

5 Mites that might have relevance to human dermatoses may be isolated from clothing, furnishings, or bedding by the techniques described by Hewitt *et al*. [7].

An entomologist is often invaluable in these situations, not only for identification of arthropods, but also to advise about their relevance to the situation. An arthropod discovered at the scene of the crime may only be an innocent bystander.

In some cases, in spite of extensive efforts, the source of the bites remains unknown, and the dermatologist can then only treat the problem symptomatically with oral antihistamines, topical antipruritics and insect repellents [8].

Class Insecta

Mosquitoes, gnats, midges and flies (Diptera)

The order Diptera is one of the largest of the insect orders. Diptera are two-winged flies with a single pair of membranous forewings, and with hindwings modified as balancing organs (halteres). Most feed on nectar, plant exudates or decaying animal and vegetable matter, but some are blood-sucking, and some have larvae parasitic on humans. To the dermatologist, the Diptera are important as biting insects and as the cause of myiasis, in addition to their capacity to transmit disease.

The Diptera are usually classified in three suborders, based on characteristics shown by larvae, pupae and adults —the Nematocera, the Brachycera and the Cyclorrhapha [1]. Detailed information on the morphology, biology and medical importance of Diptera is provided in comprehensive texts by Kettle [2], and Lane and Crosskey [3].

Suborder Nematocera

The Nematocera are small flies with long, many-segmented, filamentous antennae. With a few exceptions, the medically important species are blood-suckers.

Family Culicidae (mosquitoes)

Mosquitoes have worldwide distribution. They are responsible for the transmission of malaria, filariasis, yellow fever and dengue fever. Human malaria is transmitted exclusively by *Anopheles* species. Both male and female mosquitoes will imbibe sweet juices from flowers or ripe fruit, but only the females pierce the skin and suck the blood of vertebrate animals. Most mosquitoes are nocturnal feeders, but a few species are diurnal. The eggs of mosquitoes are deposited on or near water, and adults develop via aquatic larval and pupal stages.

Family Psychodidae (sandflies)

These are tiny (2–3 mm long), hairy flies with lanceolate wings and long legs. They are widely distributed, especially in the tropics and subtropics.

Genus Phlebotomus. Species of *Phlebotomus* are vectors of cutaneous and visceral leishmaniasis in the Old World. *Phlebotomus* species are also vectors of sandfly or papatasi

fever. *Phlebotomus* bites cause a condition known as harara in Israel and the surrounding countries.

Genus Lutzomyia. Lutzomyia species are vectors of cutaneous and visceral leishmaniasis and bartonellosis in the New World.

Family Simuliidae [3,4]

Popularly known as blackflies, this family contains approximately 1300 species, whose distribution is worldwide. Blackflies are small (2–6 mm) flies with a characteristic humped thorax, and short, broad wings. They breed only in areas of fast-flowing water, and bite during the day.

Over large parts of the tropics, several species of blackfly are responsible for transmission of onchocerciasis—principally the *Simulium damnosum* complex (several closely related species) in West Africa, *S. neavei* in East Africa, *S. metallicum* in Venezuela and *S. ochraceum* in Guatemala. In temperate regions, the greatest problem caused by simuliids is their painful bites, and some species are such a persistent nuisance at certain times of the year that they may make large areas unpleasant to live or work in. In Yugoslavia, the notorious Golubatz fly, *S. columbaschense* (*S. columbaczense*), which bred in the Danube at Golubatz, caused both mortality among livestock and human misery until environmental changes eliminated it. In North America, the most troublesome biting species are *S. venustum*, which is holarctic and occurs from Alaska to Greenland and south to Texas and South Carolina, and *Prosimulium mixtum*, which occurs in the north-eastern USA and eastern Canada.

S. posticatum (the Blandford fly), formerly named *S. austeni* Edwards, is widely distributed throughout Europe and European Russia. In England, it is found in an arc running from East Anglia through Oxfordshire into Dorset. In the Stour valley area of Dorset, particularly in the region of Blandford Forum, the fly is present in sufficient numbers in summer to cause a problem [5–7]. It had not been known as a pest in the UK prior to the 1960s. The eggs are laid in cracks in vertical river banks, a short distance above the water [8]. The larvae are concentrated in stretches of fast-flowing water immediately downstream of barrages and weirs, where they attach themselves to weeds or stones and feed on phytoplankton. Adults hatch in May, and are on the wing in May, June and early July. Females require a blood meal before oviposition, and although they will bite various wild and domestic animals, they appear to prefer humans and dogs.

Family Ceratopogonidae (gnats; biting midges; 'punkies'; 'no-see-ums')

These small flies (1–3 mm in length) have a worldwide distribution, and are notorious as biting pests. The biting midges of the West Highlands of Scotland (the commonest species of which is *Culicoides impunctatus*), for example, are an intolerable nuisance, and pose a problem to the Scottish tourist industry [9]. Males and females feed on nectar, but most females require a blood meal for maturation of the ovaries and egg production. There are four genera that suck blood: *Culicoides*, *Leptoconops*, *Austroconops* and *Forcipomyia* (subgenus *Lasiohelea*). They breed in rivers, swamps and marshes, and often occur in swarms, which will readily attack any mammal in their vicinity. A few species enter homes and bite at night.

The genus *Culicoides* is widely distributed. *Leptoconops* species are largely restricted to the warmer parts of the Old and New World. *Austroconops* contains only one species, which is restricted to western Australia. *Lasiohelea* species are principally associated with tropical and subtropical rain forests.

Suborder Brachycera

The Brachycera are large, stout-bodied flies with short antennae, often composed of three segments, and never more than six.

Family Tabanidae

Many species of three genera of this family will attack humans—*Tabanus* (horse flies), *Chrysops* (deer flies) and *Haematopota* (clegs). They are large flies, and have a worldwide distribution. Only females suck blood. Tabanid flies act as vectors for loiasis and tularaemia, and some species may transmit anthrax mechanically [10].

Family Rhagionidae (snipe flies)

Species of *Symphoromyia* occurring in the Palaearctic and Nearctic regions are vicious biters. *Atherix* is another blood-sucking genus in the Nearctic and neotropical regions, and *Spaniopsis* is troublesome in Australia.

Suborder Cyclorrhapha

The antennae are composed of three segments, with a bristle (arista) carried dorsally on the last segment. The Cyclorrhapha is a large group of flies whose taxonomy is complex. Several families are of medical importance.

Family Chloropidae (eye flies; frit flies)

These are small flies about 2 mm in length. The adults of some species are attracted to open sores, body secretions and the eyes, particularly eyes with a copious discharge. *Hippelates* and *Siphunculina* species are associated with humans and can act as mechanical vectors of yaws, conjunctivitis and streptococcal skin infection.

Family Muscidae (house flies; stable flies)

This family includes the familiar house fly *Musca domestica* and the lesser house fly *Fannia canicularis*. These do not bite, but may act as mechanical vectors of disease. The muscids *Stomoxys calcitrans* (stable fly) and *Haematobia* species (horn flies) have mouthparts modified for sucking blood. They usually feed on large quadrupeds, but can inflict painful bites on humans.

Family Hippoboscidae (flat flies; louse flies; keds)

Members of this family are blood-sucking ectoparasites of birds and animals. Several species of ked have been recorded as biting humans [11,12].

Family Glossinidae (tsetse flies)

Many species are vectors of trypanosomiasis. They are confined to Africa south of the Sahara.

Members of several other families of Diptera are important in that their larvae may cause myiasis (p. 33.8).

Clinical features [13,14]. The clinical features of the bites of insects of this large and diverse order are variable. The nature of the pharmacologically active substances injected, and the degree of acquired allergic sensitivity to the antigenic substances in the saliva, are the main factors that determine the reaction. For most of the Diptera, the allergic component is by far the more important. The nature of any injected toxins is usually unknown and the effects attributable to them are usually slight. The clinical picture will also be influenced by the biting habits of the species concerned.

The reaction to mosquito bites is determined by previous exposure, and the sequence of events following multiple bites was elucidated by Mellanby [14]. In an individual not previously exposed, the bites produce no response. With subsequent bites, a delayed reaction occurs, consisting of pruritic weals, which develop approximately 24 h after the bites and persist for several days. After repeated bites for several weeks, the response changes, with the appearance of an immediate weal at the bite site. This resolves after about 2 h, to be replaced by the delayed reaction. Further exposure provokes the immediate reaction, but not the delayed response. Eventually, tolerance is acquired, and no reaction occurs. Studies of the bite reaction in relation to age have shown an increase in immediate reactions from early childhood to adolescence, and a decrease thereafter. The appearance and intensity of delayed reactions decreases with age [15]. It has been proved conclusively that the mosquito salivary glands are the source of the antigens responsible for the bite reactions [16].

Anaphylactic reactions to mosquito bites are rare [17]. Gaig *et al*. [18] reported a patient with a serum sickness-like illness associated with mosquito bites. Severe local reactions are not uncommon, and in highly sensitive subjects bullae, cellulitis and eczematization are often seen, especially on the legs. Gravitational factors probably play a role in the development of bullae on the legs [19]. Exaggerated hypersensitivity responses to mosquito bites have been reported in patients suffering from chronic lymphatic leukaemia [20–23]. However, although the clinical picture and histological features are typical of arthropod bites, in many cases patients do not recall being bitten [22,24]. Exaggerated responses to mosquito bites have also been described in patients with HIV infection [25,26], and a chronic pruritic eruption in patients with acquired immune deficiency syndrome (AIDS) in South Florida has been attributed to mosquito bites [27].

In recent years, there have been a number of reports from Japan of severe hypersensitivity to mosquito bites preceding the development of malignant histiocytosis [28–30]. This has now been characterized as a disease in which there is a triad of hypersensitivity to mosquito bites, chronic Epstein–Barr virus infection, and natural killer cell leukaemia/lymphoma [31–33]. It affects predominantly Japanese in the first two decades of life. The skin lesions are bullae, which develop at mosquito bite sites, undergo necrosis and heal with residual scarring. Accompanying the skin lesions are systemic features, principally high fever and general malaise. Affected individuals die of haemophagocytic syndrome (malignant histiocytosis).

Multiple sandfly bites are responsible for the syndrome known as harara (urticaria multiformis endemica), which occurs in Israel and surrounding countries [34]. Skin lesions occur on exposed parts of the body, and are composed of urticated papules and papulovesicles, and bullous lesions, frequently with secondary infection.

The bites of Simuliidae, which may be very numerous, are on exposed skin. The sites of the bites are often marked by a small blood crust with surrounding ecchymosis. Within a few hours, small, pruritic papules develop, and these resolve after several days. However, severe reactions with marked oedema of the limbs and constitutional upset occasionally occur, and in some cases nodules and discoid eczematous areas persist at the sites of the bites for several months [35]. The bites of the Blandford fly occur most frequently on the legs, and women are principally affected [6,7]. The bites often produce a severe local reaction, with oedema and blistering, and may be accompanied by systemic manifestations, including pyrexia, arthralgia and meningism.

The biting midges of the family Ceratopogonidae generally cause small, papular lesions on exposed parts of the skin, but wealing and bulla formation may occur in sensitized individuals. Weal-like lesions, papules and persistent nodules have been described following bites from *Leptoconops torrens* in California [36].

Midges of the family Chironomidae are closely related to ceratopogonids. These midges do not bite, but

hypersensitivity to their larvae, used as aquarium fish food and as bait, is well recognized [37], and includes contact urticaria [38] and protein contact dermatitis [39].

The bites of keds may be followed by the development of persistent pruritic papules [12].

The bites of horse flies and stable flies are often very painful and frequently become secondarily infected.

Myiasis

Myiasis is the infestation of body tissues of humans and animals by the larvae of Diptera [1–6]. The various forms of myiasis may be classified from an entomological or a clinical point of view. Entomologically, flies may be classified into three myiasis-producing groups: obligatory, facultative and accidental. Obligatory myiasis producers always pass their larval stage parasitically in the body of an animal. Larvae of facultative myiasis producers usually develop on decaying flesh or vegetable matter, but may infest wounds. In accidental myiasis, the eggs or larvae of Diptera are ingested in food or drink, producing intestinal myiasis.

Clinically, myiasis can be classified according to the part of the body affected. Cutaneous myiasis includes wound myiasis and furuncular myiasis, in which larvae penetrate and develop within the skin. In nasopharyngeal myiasis, the nose, sinuses and pharynx are affected, and ophthalmomyiasis involves the eye, orbit and periorbital tissues. Intestinal and urogenital myiasis involve invasion of the alimentary tract or urogenital system.

The flies responsible for myiasis in humans include the following groups.

Family Muscidae

Eggs of *Fannia canicularis* (lesser house fly) and *Musca domestica* (house fly) may be deposited on ulcers and give rise to wound myiasis [7].

Family Calliphoridae (blowflies)

Genus Cochliomyia (Callitroga). These New World screwworms are distributed in North and South America. Cases of myiasis involve the larvae of only two species of *Cochliomyia*: *C. macellaria* and *C. hominivorax* (*americana*). The larva of *C. macellaria* is a facultative parasite, which may be responsible for secondary infestation of wounds. Larvae of *C. hominivorax* are obligatory parasites, which feed on living tissue and can penetrate unbroken skin [8–10], but they may also infest wounds.

Genus Chrysomya. The Old World equivalent of *Cochliomyia*. *Chrysomya bezziana*, the Old World screwworm, is important medically, as the larvae are obligate parasites in wounds.

Genus Cordylobia. Cordylobia anthropophaga, the 'tumbu' fly, is widespread in tropical Africa south of the Sahara [11], and most reported cases of tumbu fly myiasis are acquired in Africa [12,13]. There are, however, reports of myiasis acquired elsewhere, including Spain [14] and Saudi Arabia [15]. Tumbu fly myiasis occurring in two boys who had never been to Africa might have been acquired as a result of their father, who made frequent visits to Africa, bringing tumbu fly eggs back amongst his possessions [16]. *C.* (*Stasisia*) *rodhaini*, the only other species of *Cordylobia* known to infest humans, has a more limited distribution in tropical Africa, principally the rainforest areas. Extensive furuncular myiasis due to *C. rodhaini* has been reported in an Italian man who acquired the problem while working in Ethiopia [17]. Eggs are not laid on the host, but on sand or soil, especially if contaminated by urine or faeces. They may also be deposited on clothing and linen hanging out to dry. After hatching, the larva raises its cephalic end searching for a suitable host. In the wild, rats are the usual host, but around human habitation, dogs and humans are common hosts. The larva attaches itself by means of its oral hooks, and rapidly penetrates the skin. When development is complete, usually in 14–16 days, it drops to the ground to pupate.

Genus Auchmeromyia. Although strictly not a cause of myiasis, the larva of the fly *A. senegalensis*, the Congo floor maggot, is a blood-sucking parasite of humans. This fly occurs throughout tropical Africa, where it lives in native huts and lays its eggs in the soil of the floor. The larvae lie buried in the soil during the day, but emerge at night to feed on the sleeping occupants of the huts. Once engorged, they drop off the host and burrow back into the soil.

Larvae of members of the genera *Phormia* (black blowflies) [18–20], *Lucilia* (greenbottle) and *Calliphora* (bluebottle) may also be secondary invaders of wounds in man.

Family Sarcophagidae (flesh flies)

Genus Sarcophaga. There are occasional reports of members of this genus infesting wounds [21].

Genus Wohlfahrtia. These are similar to *Sarcophaga*. They are important myiasis-causing flies in camels and sheep. The larvae of *W. magnifica* may be deposited in the ear, eye or nose, and cause extensive destruction of healthy tissue. Delir *et al*. [22] reported an Iranian woman with a cavity in the left labium majus occupied by a number of *W. magnifica* larvae. *W. magnifica* occurs in south-eastern Europe, southern and Asiatic Russia, the Middle East and North Africa. *W. vigil* and *W. opaca* are North American species whose females deposit larvae on the skin of young animals, resulting in furuncular myiasis. Lesions are identical to those of *Dermatobia*. Human furuncular myiasis occurs only in young babies, as the larvae are unable to penetrate adult skin [23].

Family Oestridae

Genus Cuterebra (rodent or rabbit botfly). Rabbits and rodents are the natural hosts for the larvae of these flies, which are sometimes responsible for human furuncular myiasis [24–26]. Baird *et al*. [27] reviewed 54 cases of North American cuterebrid myiasis.

Genus Dermatobia (human botfly). Dermatobia hominis is the only species in the genus. It is a bluebottle-like fly found in the neotropical areas of the New World, extending from southern Mexico to northern Argentina. It occurs in areas where temperature and humidity are relatively high, principally lowland forests. *D. hominis* causes cutaneous myiasis in a wide range of mammalian hosts, including humans, and is particularly important as a parasite of cattle.

The female fly does not deposit her eggs directly, but uses other insects, such as day-flying mosquitoes and blood-sucking flies, as vectors to carry her eggs to the host. She grasps the insect vector in midair and deposits a number of eggs on its abdomen. When the vector subsequently feeds on a potential host, the eggs hatch and the larvae rapidly burrow into the skin (Fig. 33.5). Larval development lasts approximately 50–60 days, following which the larva emerges, drops to the ground and pupates. Human botfly myiasis should always be considered as a cause of boil-like lesions in patients who have recently returned from endemic areas [28–33].

Genus Gasterophilus (horse botfly). A form of migratory cutaneous myiasis known as 'creeping eruption' is caused by *Gasterophilus* larvae. The Gasterophilinae are mainly parasites of the alimentary tract of horses, but occasionally larvae of certain species of *Gasterophilus*, including *G. haemorrhoidalis* and *G. pecorum*, penetrate human skin.

Fig. 33.5 Third instar larva of *Dermatobia hominis* (the human botfly). Note the rows of backward-pointing spines.

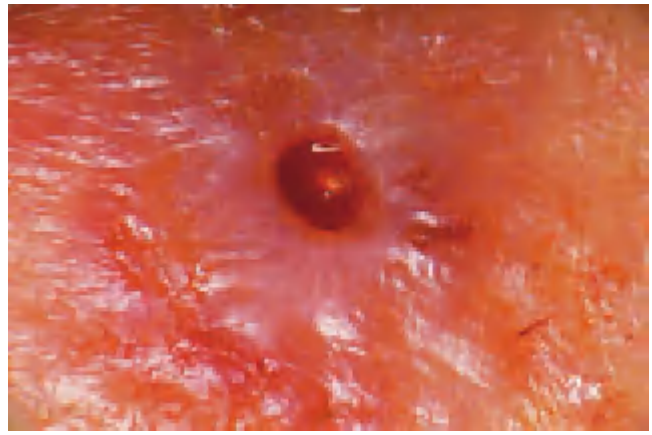

Fig. 33.6 Furuncle-like lesion produced by *Dermatobia hominis*. The tail of the larva is visible in the centre of the lesion.

Genus Oestrus (sheep nostril fly). Oestrus ovis, which develops in the nasopharyngeal passages of sheep and goats, and *Rhinoestrus purpureus*, which parasitizes horses, are occasionally responsible for human myiasis, especially ophthalmomyiasis [34,35].

Genus Hypoderma (warble flies). The larvae of *Hypoderma* species are obligate parasites of cattle. Man is an abnormal host for *Hypoderma*, and the larvae do not mature fully. After penetrating the skin, the larvae produce migratory subcutaneous swellings [36]. They may also invade the eye, producing severe damage. Marked eosinophilia may accompany infestation, and Starr *et al*. [37] reported a cattle rancher in whom an illness marked by pleuritis, pericarditis and myositis, and due to infestation with *H. lineatum*, mimicked the hypereosinophilic syndrome.

Fig. 33.7 Scanning electron micrograph of the spines on a *Dermatobia hominis* larva.

Clinical features [2,5,29]. The habits of the flies and their larvae determine the variations in the clinical manifestations for which they are responsible.

Traumatic or wound myiasis has been a serious complication of war wounds in tropical areas, and is sometimes seen in neglected ulcers or wounds in most parts of the world [38]. The eggs or larvae (maggots) can be seen, often in large numbers, in the suppurating tissues.

Obligatory cutaneous myiasis occurs in two main clinical forms; in both, there may be mild constitutional symptoms and eosinophilia. Both occur mainly on exposed skin—often the face, scalp, arms or legs. In the furuncular form, boil-like lesions develop gradually over a few days. Each lesion has a central punctum, which discharges serosanguineous fluid. The posterior end of the larva, equipped with a group of spiracles, is usually visible in the punctum, and its movements may be noticed by the patient (Fig. 33.6). The lesions are often extremely painful. The inflammatory reaction around the lesions may be accompanied by lymphangitis and regional lymphadenopathy. Once the larva has emerged, or has been removed, the lesions rapidly resolve. The flies causing furuncular myiasis in humans are *Dermatobia hominis*, *Cuterebra*, *Cordylobia anthropophaga*, *Cordylobia (Stasisia) rodhaini*, *Wohlfahrtia* species and *Hypoderma* species. The inflammatory nodular lesions produced by *Hypoderma* species are migratory.

The second principal clinical form is a creeping eruption, in which a tortuous, thread-like red line with a terminal vesicle marks the passage of the larva through the skin. The larva lies ahead of the vesicle in apparently normal skin. This form of myiasis is produced by *Gasterophilus* larvae.

Treatment. The larva of Cordylobia can often be expressed by firm pressure around the edges of the lesion, but the punctum may require enlarging surgically.

The larva of *D. hominis* has a bulbous anterior end equipped with rows of backward-pointing spines (Fig. 33.7), and cannot easily be expressed. Traditional methods

of treatment include occluding the punctum with pork fat [39,40], blocking the spiracles of the larva and stimulating premature extrusion. A similar result may be obtained with mineral oil, petrolatum or butter. Surgical management is most frequently recommended: the punctum is enlarged by cruciate incisions, and this enables removal of an intact larva [41]. The injection of lidocaine (lignocaine) underneath the nodule may be sufficient to push the larva out [42], and Li Loong *et al*. [43] also found that injection of 2 mL of 2% lidocaine into the blind end of the cavity facilitated non-surgical removal of the larva.

Fleas (Siphonaptera)

Fleas are small (1–8 mm long), wingless, laterally compressed insects whose adults are blood-sucking ectoparasites of mammals and birds. Over 1500 species and subspecies are known. The larvae of fleas are not parasitic, but feed on organic material that they find in the nest or dwelling-place of the host [1,2].

The order Siphonaptera contains three families of medical importance.

Family Tungidae

This family contains tropical species that burrow in human skin (see Tungiasis, p. 33.13).

Family Pulicidae

Members of this family occur throughout the world, and some species transmit plague and murine typhus [3]. Cat fleas have been shown to be vectors of *Bartonella henselae*, the pathogen responsible for cat scratch disease and bacillary angiomatosis [4,5]. Many species are important

only for the irritability of their bites. The species most frequently parasitizing humans are the human flea, *Pulex irritans*, and the cat and dog fleas, *Ctenocephalides felis* and *C. canis*, but other species will bite humans in the absence of their normal host. The tropical rat flea, *Xenopsylla cheopis*, is the vector of bubonic plague.

The adult female flea lays her eggs during feeding on the host, and the eggs fall to the ground. Flea larvae feed on organic debris in their environment, and an important food source is the faeces of the adult flea. The larvae subsequently form cocoons, and under suitable conditions of temperature and humidity the life cycle may be completed in a few weeks. However, the cocoon stage can sometimes last as long as a year, and the flea may emerge only in response to vibrations produced by the movement of possible hosts.

In a household occupied by infested pet dogs or cats, fleas in various stages of development are found in the animals' bedding, and on carpets and soft furnishings.

Family Ceratophyllidae

Species in this family are mainly parasitic on rodents and birds. Bird fleas overwinter in cocoons in birds' nests, and emerge in spring. At this time, they can become household pests, as they may gain access to bedrooms from nests under the eaves.

Flea infestation in humans

Infestation with the human flea, *Pulex irritans*, occurs mainly in congested communities with low standards of hygiene. It is now rare in developed countries. Cat and dog flea infestation in the home is, however, common.

Animal fleas are common throughout the world, and persons in contact with domestic animals are frequently bitten. Severe attacks are sometimes experienced by individuals moving into empty premises previously occupied by pet cats or dogs. The vibration caused by footsteps triggers the emergence of fleas from their cocoons. Attacks are more likely to occur when the fleas do not have access to their usual host. Household infestations with bird fleas may occur from nests or nest boxes on or near the house [6], and similar problems may occur in the workplace [7]. An outbreak of papular urticaria in a nursery school was traced to an infestation with dog fleas of a fox's burrow beneath the building [8]. Similar problems were caused by *C. felis* entering houses from raccoons which had bred in the cavity between two houses [9], and by *P. simulans* originating from a skunk in a basement [10].

Clinical features [11,12]. Flea bites usually provoke typical papular urticaria in a sensitized individual. Occasionally, the reaction is more severe, and bullae may occur. The lesions may be grouped in lines or irregular clusters.

Fig. 33.8 Typical distribution of cat or dog flea bites on the legs.

Cat and dog flea bites occur predominantly on the legs below the knees, and are most profuse around the ankles (Fig. 33.8), but they can also occur on the forearms. They are much more common in women than men, as trousers and socks protect the legs. Bites from bird fleas tend to be more extensive, as the sleeping occupants of bedrooms usually provide larger areas of exposed flesh.

Confirmation of flea infestation [13]. If flea infestation from pet animals is suspected, this can be confirmed by microscopic examination of debris from the animals' bedding material (p. 33.4).

The principal sign of flea infestation in an affected animal is the presence of dried concretions of flea faeces on the animal's coat. Some animals will also have signs of flea allergy dermatitis. In dogs, this is usually manifest as areas of crusting and alopecia, most frequently on the lower back and the base of the tail. In cats, the clinical picture of flea infestation is more varied, most commonly a miliary dermatitis due, at least in part, to excessive grooming.

If fleas from another source are suspected of causing bites, it may be necessary to examine samples taken with a vacuum cleaner from rooms, or to visit the suspect premises.

It is important to identify the flea species responsible for an infestation, so that efforts at eradication may be accurately directed at the source [14]. Cat fleas (Fig. 33.9), dog fleas and common bird fleas may be readily identified

Fig. 33.9 *Ctenocephalides felis*, the cat flea.

after 'clearing' in 10% potassium hydroxide for 48 h [3], but the help of an entomologist should be sought.

Treatment. In domestic cat and dog flea infestations, treatment should be directed at the household as well as the affected animal. There are several proprietary preparations available for the treatment of pets, and others specifically for use on the animals' bedding, household carpets and soft furnishings.

Pest-control companies will deal with flea infestation from other sources.

Fig. 33.10 Tungiasis, showing a characteristic lesion on the sole of the foot. (Courtesy of Dr N.H. Cox, Cumberland Infirmary, Carlisle, UK.)

Tungiasis

Aetiology. Tungiasis is caused by the sand flea *Tunga penetrans*, also known as the jigger, or chigoe. Originally a native of South America, it subsequently spread to Africa [1]. In recent years, tungiasis has reappeared in Mexico [2], where it was previously last recorded in 1948. The ease of world travel has contributed to tungiasis being encountered in non-endemic areas [1,3–8].

T. penetrans is the smallest known flea (1 mm long). Its larvae develop in dry, sandy soil, and development from egg to adult takes about 3 weeks in favourable conditions. The impregnated female flea burrows into the feet of large mammals, preferring humans and pigs. In humans, the fleas establish themselves between the toes, under the nails and on the soles. Once embedded in the skin, the flea's abdomen enlarges to the size of a pea, and large numbers of eggs are produced. The eggs are subsequently gradually extruded over a period of 2 weeks, and the female flea dies [9].

Pathology. Anatomical components of the flea are sufficiently distinctive to enable a diagnosis of tungiasis to be made histologically [10].

Clinical features [11,12]. The presence of the fleas causes intense irritation. At first, the site of penetration of the skin is visible only as a black dot, but soon an inflammatory nodule develops (Fig. 33.10). Secondary infection is common, and tetanus has often complicated tungiasis in the past. In severe cases, the feet may be honeycombed by multiple lesions, causing serious discomfort and disability.

Treatment. The flea should be completely removed from the skin. This can be accomplished by curettage and cautery of the residual cavity, or excision.

The unwary traveller may well acquire tungiasis, and those visiting endemic areas should be warned to wear stout shoes and not to sit on the ground.

Bees, wasps and ants (Hymenoptera)

The adults of many species in this large order of insects have evolved a sting apparatus, and constitute the Aculeata group. Some use the sting in defence, and others use it offensively in hunting for food. Males have no sting apparatus. Humans are frequently stung by these insects, with reactions varying from local discomfort to fatal anaphylaxis.

The Hymenoptera are readily recognized by the narrow isthmus connecting the abdomen to the thorax. Some of the more important families include the following.

Superfamily Apoidea (bees)

Family Apidae (honeybees)

Honeybees possess a barbed sting. When humans are stung, the bee is unable to remove the sting. The sting and venom apparatus are avulsed from the bee's abdomen in its struggles, but the venom apparatus continues to function and pump in more venom.

'Africanized' honeybees, the product of interbreeding between bees from southern Africa and European species, have caused significant problems in recent years [1]. These aggressive ('killer') bees, which have characteristics of their African antecedents, including strong colony-defensive behaviour, have migrated northward from Brazil to the southern USA.

Family Bombidae (humblebees; bumblebees)

The sting is not barbed, and the bumblebee is therefore able to sting repeatedly. Most species are inoffensive, and only sting defensively when severely provoked.

Allergic reactions to bumblebee stings are much less common than reactions to the stings of honeybees.

Superfamily Vespoidea

Family Vespidae (social wasps)

This family includes wasps, yellow-jackets and hornets. Species of *Vespa*, *Vespula* and *Polistes* inflict painful stings. Wasps can also sting repeatedly, as they either have small barbs or none at all on their stings.

Superfamily Bethyloidea

These are small, solitary wasps. They sometimes become abundant in houses. They are parasitic on the larvae of Lepidoptera and Coleoptera. *Scleroderma domesticum*, *Epyris californicus* and *Cephalonomia gallicola* may inflict troublesome stings [2,3].

Superfamily Scolioidea

Family Formicidae (ants)

Many ant species are equipped with powerful stings, including the Australian jumper and bull ants [4,5], and *Solenopsis*, the fire ant. Fire ants, so called because of the burning pain of their stings, have been particularly problematic in recent years in the USA. There are several native species of fire ant in the USA, but it is the red and black imported fire ants *S. invicta* and *S. richteri*, inadvertently brought to the USA from South America, which are troublesome pests in the southern states [2,6–11]. *S. invicta* is also well established in two locations of the Brisbane area of Australia [12].

The fire ant first uses its powerful mandibles to grip its victim, and drives its non-barbed sting into the skin. It then rotates about the point of attachment of the mandibles and inflicts further stings in a circular pattern [9–11,13].

Although largely outdoor insects, fire ants may move into dwellings, causing problems for the inhabitants [14].

Species of *Pogonomyrmex* (harvester ants) may inflict multiple painful stings [2,15].

The sting

The mechanism of the sting is essentially similar in all species, although there are variations in detail. It consists of a dorsal sharp stylet and two ventrolateral lancets,

which may or may not be barbed. These structures enclose the venom canal, which communicates posteriorly with the venom sac. The venom is produced by a pair of coiled glands, which discharge into the venom sac.

Venoms [16–29]

The composition of venoms is complex. Pharmacologically active and antigenic substances are both present, and an individual's reaction to the sting is determined partly by the quantity of the former, and partly by the degree of acquired hypersensitivity to the latter. Hymenoptera venom contains vasoactive amines, small polypeptides and larger protein molecules. The components of vespid (wasps, yellow-jackets and hornets) venoms include histamine, serotonin, mast cell degranulating peptide, wasp kinin, phospholipases, hyaluronidase and antigen 5. The three major allergens in vespid venoms are phospholipases, hyaluronidase and antigen 5. The venom of the honeybee contains histamine, mast cell degranulating peptide, melittin, phospholipase A_2, hyaluronidase and acid phosphatase. The three proteins in honeybee venom which are important allergens are phospholipase A_2, hyaluronidase and acid phosphatase. In addition, the polypeptide melittin is also antigenic. Bumblebee venom appears to be chemically and antigenically related to honeybee venom [23].

Study of fire ant venom was impeded for many years by the extreme difficulty in obtaining sufficient amounts. The venom is composed of 90–95% water-insoluble piperidine alkaloids [24], which are not allergenic but are responsible for the local reaction at the sting site. When commercial-grade venom became available, several potent allergenic proteins were identified [10,25]. Antigenic similarity between fire ant venom, and bee and wasp venoms, has been demonstrated [26].

Allergy to Hymenoptera venom is mediated by immunoglobulin E (IgE) antibodies. The antigenic substances in the venom of many Hymenoptera are more liable to induce high degrees of hypersensitivity of the immediate type than are the antigens of most other insects.

Clinical features [16,17,27,28]. Reactions to bee and wasp stings may be classified as local or systemic. Both may have a toxic or a hypersensitive mechanism. The typical local toxic reaction produced by pharmacologically active components of the venom is burning pain, which may be very severe, followed by erythema and oedema. This local reaction subsides in a few hours. The systemic toxic effects of multiple stings include hypotension, generalized vasodilatation, severe headache, vomiting, diarrhoea and shock, and the cumulative effect of a large number of stings may be fatal, particularly in children.

In some cases, hypersensitivity produces only a more intense local reaction manifest as increased oedema, usually developing within the first 30 min, but occasionally delayed for several hours. If a generalized anaphylactic reaction occurs, this is usually within a few minutes of the sting. The manifestations of a generalized reaction may be classified as cutaneous (pruritus, erythema, urticaria and angio-oedema), respiratory (laryngeal oedema, bronchospasm) or vascular (tachycardia, hypotension, shock). These features may occur separately or in combination, and in varying degrees of severity.

Occasionally, late-onset reactions to stings occur [18]. Some of these also appear to be mediated by venom-specific IgE [29]. In some patients, an urticarial reaction develops several hours after the sting, and in others a serum sickness-like reaction occurs, with urticaria, joint swelling and arthralgia.

A patient with a foreign-body granuloma and IgE pseudolymphoma following multiple bee stings has been reported [30], and another with an eosinophilic foreign-body granuloma after multiple self-administered bee stings as treatment in traditional Korean medicine [31].

At least one-third of individuals developing systemic reactions give no personal or family history of atopy [32]. A study of a large number of boy scouts, average age 13 years, suggested that the incidence of reactions was not higher in atopic subjects [33], and later work, relying on history alone, confirmed that the frequency of sting reactions is similar in atopic and non-atopic populations [34].

Studies of fatalities following Hymenoptera stings [35,36] have shown the major cause of death to be respiratory tract obstruction from massive oedema and secretion.

Skin lesions produced by fire ants typically occur in clusters [9–13]. The site of attachment of the mandibles may be marked by two minute haemorrhagic puncta. The initial reaction to the sting is the development of a weal, followed within a few hours by a vesicle. The fluid in the vesicle gradually becomes cloudy, and after 8–10 h the typical lesion is an umbilicated pustule on a red, oedematous base. The pustule subsequently ruptures, forming a crust, and after several days the lesions heal, frequently leaving small scars. Systemic hypersensitivity reactions may also occur, and feature generalized urticaria and angio-oedema, wheezing, nausea and vomiting, and hypotension [9,37,38]. These manifestations may increase in severity with successive attacks, and fatal anaphylaxis can occur [11].

Treatment [28,39,40]. Local reactions to Hymenoptera stings may be treated with oral antihistamines. The treatment of choice for anaphylaxis is intramuscular epinephrine (adrenaline) (in adults, a dose of 0.5 mL 1 : 1000 solution should be administered, and repeated after about 5 min in the absence of clinical improvement, or if deterioration occurs after the initial treatment), followed by chlorpheniramine (10–20 mg, intramuscular or slow intravenous) and hydrocortisone (100–500 mg, intramuscular

or slow intravenous) [40]. Patients at risk of an anaphylactic response to Hymenoptera stings should wear a device such as a warning bracelet, in case they are discovered unconscious following a sting. They should also carry a sting emergency kit, and receive instruction in self-administration of epinephrine.

The introduction of venom immunotherapy has reduced the risk of anaphylaxis in Hymenoptera-sensitive patients. It is thought to exert its beneficial effect by stimulating the development of IgG (blocking) antibodies against the venom allergens. This prophylactic measure is indicated in patients with a history of life-threatening reactions to stings, positive skin tests and presence of venom-specific serum IgE. However, such therapy should only be carried out in specialized units.

Conventional advice with regard to honeybee stings is that the sting should be immediately scraped off, never pinched. A study by Visscher *et al*. [41] suggests that the method of removal does not affect the quantity of venom received and is therefore unimportant; the sting should simply be removed as rapidly as possible.

Lice (Phthiraptera)

Lice are members of the order Phthiraptera. They are wingless, dorsoventrally flattened insects, which are obligate ectoparasites of birds and mammals. The Phthiraptera are highly host-specific and spend their entire lives on the host. Members of the suborder Anoplura are blood-sucking ectoparasites of mammals.

Humans are parasitized by three species of Anoplura: *Pediculus capitis*, the head louse; *Pediculus humanus*, the clothing or body louse; and *Pthirus pubis*, the pubic or crab louse. Head lice and clothing lice are morphologically almost identical, and are capable of interbreeding, but on the host they maintain their territorial preferences. *Pthirus pubis* is morphologically quite distinct from *Pediculus*. It is a louse that has no close relatives in the insect world, apart from a species living on gorillas. *Pthirus* is the correct zoological name for the crab louse—the name should

Fig. 33.11 *Pediculus capitis*, the head louse.

have been *Phthirus*, but a misprint was inadvertently accepted by the International Committee on Zoological Nomenclature [1].

Morphology and biology [1–10]

Pediculus capitis (head louse). The adult female is a greyish white insect 3–4 mm long (Fig. 33.11). The male is slightly smaller. The claws on the legs are adapted for clinging to hair.

During her lifespan of approximately 40 days, the female is capable of laying about 300 eggs at the rate of 7–10 daily. The eggs of the head louse are cemented to hair shafts with a chitinous cement material secreted by the female's accessory glands (Fig. 33.12). In temperate climates, in order to provide a suitable temperature for incubation, the eggs are attached to hair close to the surface of the scalp. They are oval, flesh coloured and have a lid (operculum) capping the free end of the egg. The operculum is pushed off by the emerging louse nymph. Once the louse has emerged, the empty egg case or 'nit' appears white, and is easier to see than the intact eggs close to the scalp surface. Eggs hatch in about 8 days and, following three moults, the louse nymph reaches maturity in approximately 10 days.

Pediculus humanus (clothing or body louse). This louse is almost identical in appearance to the head louse, and its development is similar. Its natural habitat is the clothing

Fig. 33.12 Head-louse eggs cemented to a hair shaft.

Fig. 33.13 *Pthirus pubis*, the crab louse.

of its host, and it only visits the skin to feed. Its eggs are cemented to clothing fibres, with a preference for clothing close to the skin. Seams are a favoured site for oviposition. It thrives in situations where normal hygiene is lacking. The clothing louse and its eggs will not survive high-temperature washing and ironing, and it is intolerant of temperature changes in its environment. It is therefore a parasite of individuals whose clothing is rarely changed or washed.

Pthirus pubis (pubic or crab louse). The crab louse is quite distinctive in appearance (Fig. 33.13) and habits from *Pediculus*. Its body is squat, and the second and third pairs of legs carry heavy, pincer-like claws. When static, the crab louse uses these huge claws to grip adjacent hairs close to the skin surface (Fig. 33.14). Its eggs are light brown in colour and, like those of the head louse, are cemented to the hair of the host (Fig. 33.15). It is adapted to living in hair of a particular density. Scalp hair, except at the scalp margins, is too dense, but the crab louse will colonize axillary hair, eyebrows, eyelashes, beard hair, and hair on the trunk and limbs, in addition to pubic hair.

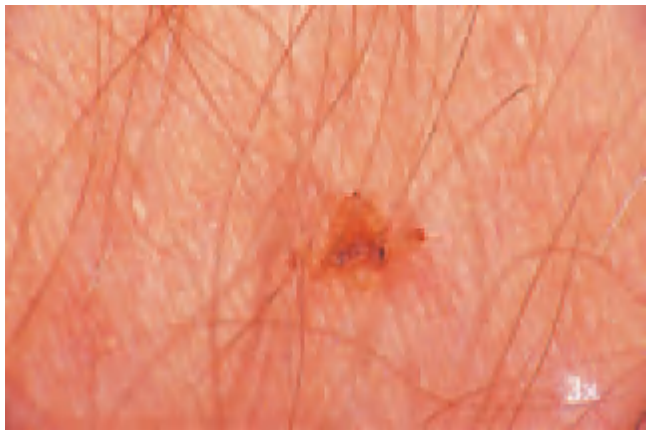

Fig. 33.14 Crab louse clinging to hairs on the abdomen.

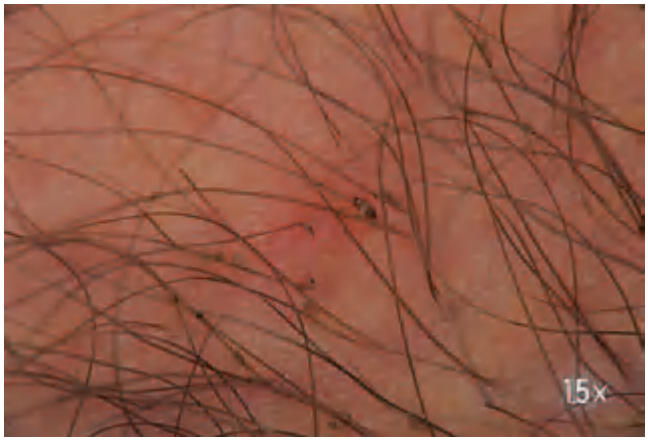

Fig. 33.15 Crab-louse eggs attached to abdominal hair.

It is mainly sedentary, but becomes active at night when the host is sleeping [11]. It moves by transferring its grip from one hair to another. The crab louse has difficulty moving when taken from its host, whereas head and clothing lice are quite mobile off the host.

Pthirus pubis is a specific parasite of humans, but its transfer to a dog has been recorded [12].

The Anoplura are vessel feeders (solenophages), introducing their mouthparts directly into a blood vessel to withdraw blood [13,14]. The components responsible for probing the skin and piercing a blood vessel are a group of stylets, which are kept withdrawn within the head unless the insect is feeding. In the front of the head is a small, snout-like tube, the haustellum, which is soft, eversible and armed with teeth. When the louse is about to feed, the haustellum is everted and the buccal teeth rotated outwards. The teeth cut into the epidermis, and the haustellum is driven into the skin. It eventually comes to rest with the buccal teeth fully everted, anchoring the mouthparts. Once fixed in the skin, a bundle of stylets is pushed forward through the opening in the haustellum by protractor muscles within the head of the louse [7] (Fig. 33.16). The

Fig. 33.16 Scanning electron micrograph of a crab louse, showing the protruded stylet bundle.

stylets are advanced into the dermis as a single bundle or fascicle, and probe for a small blood vessel. When the stylet bundle has pierced a blood vessel, feeding begins.

Head lice (pediculosis capitis)

Prevalence and epidemiology [1,2]. The head louse has a worldwide distribution, and head louse infection is common both in developed and developing countries. However, precise data on current prevalence are relatively sparse.

In England, in the past, head lice were common in industrial conurbations. In 10 industrial cities, in 1941, about 40% of boys and 50% of girls younger than school age had head lice [3]. In contrast, infection rates in rural communities were low. A survey of schoolchildren in 1975 [4] showed an overall prevalence of 2.44%, with the highest rates in the more deprived central areas of large conurbations. Once again, the infection rate was higher in urban than in rural areas. However, in the early 1980s, there was a resurgence of infection, and the increase occurred mainly in middle-class, often professional families, especially in suburban and rural areas [5]. Hence, in more recent years, the head louse has become classless and cosmopolitan. It is of interest to note that in a recent survey in Jordan, there was a significant association between social class and infection rates, there being much higher infection rates in lower socio-economic classes [6].

High rates of head louse infection have been reported from the USA, Canada and several other countries; a review by Gratz [1] provides a comprehensive survey of published information relating to prevalence.

Head lice are more common on children, particularly in the age range 3–11 years, than on adults, and most surveys have shown that girls are more frequently infected than boys. Behaviour patterns in girls and boys at different ages probably influence rates of infection [7]. For example, in primary schools children are organized into small groups around desks, and head-to-head contact is frequent. In addition, hair contact is probably more likely between girls than boys. Older children tend to be more independent and more separated from their peers. The contribution of hair length to infection is contentious. Some studies have not shown any correlation between hair length and louse infection rates, but in others children with longer hair have had higher infection rates. A recent survey from Israel, in which detection of infection was by means of a louse comb rather than by direct visual inspection, found a significantly higher infection rate in children with long and medium-length hair than in those with short hair [8].

Several authors have noted a low incidence of head louse infection in black Americans [9–11], although infection rates in black Africans are high [1]. This might be related to specialization in the louse with regard to modification of the legs to grasp hairs of different cross-sectional shape [12], and consequent restriction on transfer between white people and negroes, and vice versa. It has also been suggested that the use of pomades by black Americans provides an environment unsuited to establishment of infection [9]. However, head lice are quite common in the Indian subcontinent, where hair oils and creams are frequently used [13], and a survey in Brazil found the same prevalence in blacks as in whites [14].

It is thought that the majority of head louse infections are acquired by direct head-to-head contact. Spread of lice is encouraged by poverty, poor hygiene and overcrowding. Overcrowding is perhaps the most important factor. Lack of hygiene alone does not encourage head louse infection.

There are conflicting opinions about the importance of fomites in transmission of head lice [5,15], and in practice the putative role of caps, scarves, combs and brushes is difficult to confirm or refute [16].

In Australia, an examination, employing a vacuum cleaner fitted with a filter, of classroom floors in schools in which there was an overall prevalence of head lice of 20.9% did not reveal any lice on the floors [17]. Hence, there is no requirement for antilouse measures on carpets and floors.

Clinical features. Although many individuals are asymptomatic [18], scalp pruritus is the characteristic manifestation of head louse infection. Secondary bacterial infection may occur as a result of scratching, and concomitant head louse infection must always be considered in cases of scalp impetigo. Pruritic papular lesions may occur on the nape of the neck, and occasionally a generalized non-specific pruritic eruption develops [19]. In severe, neglected cases, pus and exudate may produce matting of the hair—a state that has been termed ‘plica polonica’, from its prevalence in Poland in the early part of the 20th century. Matting of the hair can occur in the absence of louse infection, and it has been suggested that the term should be discarded [20].

The empty egg cases (‘nits’) are easily identified, and occur in greatest density on the parietal and occipital regions (Fig. 33.17). However, on naked-eye inspection, they may be confused with peripilar keratin casts (‘pseudonits’; hair muffs) [21,22] or dried globules of cheap hair lacquer.

Detection of adult lice and nymphs provides evidence of an ‘active’ infection, whereas the presence of eggs and egg cases alone merely indicates that infection has occurred at some time. The most reliable method of diagnosing current active infection is by detection combing [23], which has been shown to be superior to direct visual examination of the hair and scalp [8,24,25]. This is an important criterion for several reasons:

1 It is recommended that individuals who do not have evidence of active infection should not receive chemical treatment [23].

2 Participants in clinical trials of pediculicides should have live lice or ‘lice and eggs’ present on the head before enrolment, not just eggs alone [26].

Fig. 33.17 Numerous head-louse eggs and empty egg cases.

3 Children who do not have evidence of active infection may be inappropriately excluded from school [27,28].

Treatment [2,26,29,30]. The acetylcholinesterase-inhibiting insecticides malathion and carbaryl (carbaril) have been extensively used to treat head louse infection in the UK, although use of the latter declined markedly a few years ago following the release of data suggesting a potential carcinogenic effect of long-term oral administration of carbaryl to rodents [31]. Thereafter, it became a prescription-only medicine. These insecticides replaced lindane, following evidence of the development of resistance to organochlorines [32]. Lindane has been withdrawn from use in the UK. Malathion and carbaryl are efficient pediculicides and have good, but not complete, ovicidal activity [32–36]. It is recommended that lotion (alcoholic basis) and liquid (aqueous basis) formulations of malathion and carbaryl should remain on the scalp for 12 h before being washed off. Both insecticides are degraded by heat, and a hot-air hair dryer should not be used after their application. Treatment should be repeated after 10 days, because of the incomplete ovicidal activity. The second treatment should deal with any nymphs which emerge from surviving eggs.

Also effective as pediculicides are pyrethrins synergized with piperonyl butoxide, and the synthetic pyrethroids permethrin and phenothrin [37–39].

The formulation of the marketed products influences their efficacy, because the vehicle may also have pediculicidal activity [26,40,41]. Lotion and liquid formulations are preferable to shampoos, as the latter expose the insects to relatively low concentrations of insecticide which, in the long term, will favour the development of resistance. Preparations with an aqueous basis are less likely to irritate an excoriated scalp than alcoholic solutions, do not irritate the bronchi of asthmatics and are not flammable.

There have been a number of recent analyses of the effectiveness of available chemical methods of head louse eradication. A comparative assessment of the pediculicidal and ovicidal activity of five products marketed for head louse treatment in the USA (containing lindane, 1.0% permethrin, 0.5% malathion, and pyrethrin synergized with piperonyl butoxide), carried out on lice and eggs harvested from healthy Kuna Indian children in Panama, showed that 0.5% malathion was the fastest-killing pediculicide and the most effective ovicide, and that 1% permethrin was also highly effective [42].

A group of general practitioners in Oxford, England, employed an evidence-based approach to answering the question 'In children attending primary care with nits, what is the most effective treatment for eradication?', using several UK sources of information, and opted for permethrin [43].

A Cochrane Library review of interventions for head lice identified 71 trials of pediculicides, of which only four met the criteria for inclusion in the review. The study concluded that permethrin, synergized pyrethrin and malathion were effective in the treatment of head lice [26].

Hence, these analyses support the effectiveness of malathion, synergized pyrethrin and synthetic pyrethroids.

However, there is now evidence of widespread malathion and pyrethroid resistance in the UK [44–46], and resistance to these insecticides in other parts of the world [47–52]. In addition, there is evidence of the emergence of carbaryl resistance in the UK [46]. The restricted use of carbaryl in the UK in recent years may be a factor which has contributed to the delayed emergence of resistance in comparison with malathion and synthetic pyrethroids, which have been widely employed in over-the-counter preparations. Similarly, a factor in the continued pediculicide efficacy of malathion in a study in south Florida, USA, is probably the commercial failure, and therefore limited use, of previously marketed malathion preparations [53].

Therefore, choice of chemical treatment for head louse infection should be guided not only by evidence of pediculicidal activity from well-conducted clinical trials, but also by local patterns of resistance [54]. If treatment fails, efforts should be made to determine if resistance is responsible. From a practical point of view, if a correctly applied pediculicide has failed to eradicate an infection, a different pharmacological class of agent should be used—for example, change from a synthetic pyrethroid to malathion, or vice versa.

Family members should be examined, and treated if they show evidence of active infection.

Physical treatment is an alternative to the use of chemical agents and, in the UK, the 'Bug Busting' (Community Hygiene Concern, London, UK) wet-combing method has been promoted as a treatment for head lice. The technique involves ordinary shampooing of the hair, followed by the application of generous amounts of conditioner, and combing using a fine-tooth comb to remove lice. This procedure is repeated every 4 days for 2 weeks [55]. Comparison of the effectiveness of the Bug Busting method with chemical means of control is limited to a pilot study conducted by Bingham *et al*. [25] and a randomized controlled trial conducted by Roberts *et al*. [26,56]. The latter demonstrated that malathion lotion was twice as effective as the Bug Busting method, in an area with established intermediate resistance to malathion.

A battery-powered device, the 'Robi comb', which kills lice as it is used to comb through the hair, is also available.

Other treatments which have been employed to eradicate head lice include crotamiton [57], and topical [58] and oral ivermectin [59,60]. Although the results of oral ivermectin treatment were not impressive, it is likely that this is because ivermectin has no ovicidal activity, and two doses separated by an interval of 10 days would be more effective.

Oral therapy with co-trimoxazole has been reported to be effective in eradicating head lice [61,62]. This is probably because the antibiotic is ingested by the louse and affects its symbiotic bacteria. These bacteria are essential for synthesis of B vitamins, without which the louse cannot survive [63].

Tea tree oil and lavender oil are said to have pediculicidal activity, but have not been formally assessed.

Empty egg cases persist for some time until they are gradually worn away by repeated washing, but are otherwise difficult to dislodge. It has been claimed that a cream rinse containing formic acid may facilitate their removal [64], although this is disputed [29].

In an attempt to prevent repeated reinfection, and to discourage 'prophylactic' use of insecticides, a head-louse repellent containing piperonal has been marketed in the UK [65].

Guidelines for the management of head lice have been issued by the United Kingdom Department of Health [66], the Centers for Disease Control and Prevention (CDC) [67], the American Public Health Association [68], and the Canadian Paediatric Society [69].

Fig. 33.18 Clothing lice and eggs.

Clothing/body lice (pediculosis corporis)

Prevalence and epidemiology [1–3]. Pediculosis corporis occurs throughout the world, although it is now uncommon in developed countries. The clothing louse is the louse of poverty and neglect, and flourishes in overcrowded, unhygienic situations on individuals who rarely remove their clothing. In the Western world today, those harbouring lice are mainly vagrants.

The number of lice and eggs on the clothing varies greatly. In most infected individuals the population is small, but in some there may be thousands of lice.

The clothing louse is the vector of epidemic typhus, trench fever and louse-borne relapsing fever. Epidemic typhus has been responsible for huge mortality in the past [4,5].

Clinical features [3,6]. In most infected persons, itching is the principal complaint. Pruritus is the result of sensitization to louse salivary antigens. Others, who have not become sensitized or have acquired tolerance to the bites, are asymptomatic. The body is often covered in excoriations, and there may be secondary bacterial infection. In those who have harboured clothing lice for long periods of time, the skin is often hyperpigmented (so-called 'vagabonds' disease', morbus errorum), and this is probably a postinflammatory phenomenon.

Lice and eggs should be sought in the clothing (Fig. 33.18).

Treatment. It is the clothing, not the patient, which requires treatment. Tumble-drying is a most effective means of killing both lice and eggs [2]. High-temperature laundering of undergarments and dry cleaning of outer clothing are also effective.

In dealing with large numbers of infected individuals, insecticides have been used to treat clothing. The emergence of lice resistant to dichlorodiphenyltrichloroethane (DDT) and lindane led to the introduction of malathion

dusting powder [7,8] and, more recently, permethrin-treated clothing has been shown to be toxic to clothing lice [9].

Crab lice (phthiriasis pubis)

Prevalence and epidemiology [1–3]. Crab lice are transmitted by close physical contact, usually sexual. Although crab louse infection appears to be a common disorder among sexually active young adults, recent prevalence data are lacking.

Because many patients with crab louse infection who attend genitourinary medicine clinics are found to be suffering from other sexually transmitted infections (STIs) [4–7], screening for other STIs is indicated.

Clinical features. Itching, mainly in the evening and at night, is the principal symptom. Close inspection of affected areas will reveal lice grasping hairs close to the skin surface, and louse eggs attached to the hair shafts. Louse faeces are often visible as rust-coloured speckles on the skin and hair, and the underclothes may be spotted with altered blood.

When crab lice are discovered on the pubic area, other hairy areas of the body should be examined, as these lice may colonize eyebrows, eyelashes (Fig. 33.19), beard, axillae, areolar hair and the scalp margins [8–12]. In heavy infections in men, the hair on the trunk and limbs may be extensively colonized. A case has been reported in which the presence of an enormous population of lice was attributed to inappropriate use of topical steroids [13].

Blue-grey macules (maculae caeruleae) are occasionally seen on the skin [14–16], but their precise pathogenesis is unknown. Bullous lesions attributed to crab lice have been reported [17,18].

In children, crab lice may colonize the eyelashes and scalp [19–22]. Infection in children is usually acquired by close physical contact with infected parents. As an isolated finding, it is not indicative of sexual abuse, although this may occasionally occur [23].

Fig. 33.19 Crab-louse eggs on the eyelashes.

Treatment [3,24–28]. Malathion, pyrethrins with piperonyl butoxide, pyrethroids and carbaryl may be used to eradicate crab lice. In view of the possibility of involvement of axillary and body hair, it is preferable to treat the whole of the trunk and limbs, and the scalp may also require treatment. Alcohol-based preparations may be irritating when applied to the scrotum, and an aqueous base is preferable. Treatment should be repeated after an interval of 7–10 days. All sexual contacts should also be treated.

Eyelash infection (phthiriasis palpebrarum) [29,30]. Although mechanical removal of lice and eggs with fine forceps [31] or epilation of the lashes with their attached eggs are obvious remedies, these procedures are uncomfortable, and are not recommended. Cryotherapy has been used to destroy crab lice on the lashes [32], and the use of fluorescein in concentrations of 10–20% is also said to be effective [33].

Any ointment might be expected to interfere with the respiratory function of the louse by blocking its spiracles, and the use of a thick application of petrolatum twice daily for 2–3 weeks has been recommended [34,35]. Yellow mercuric oxide ointment was frequently used in the past, and physostigmine ointment is also a popular remedy, particularly among ophthalmologists [30,36–38]. A drawback is the ocular effect of physostigmine, which causes pupillary constriction and paralysis of accommodation. Oral ivermectin, given as two doses a week apart, cured four patients with eyelash crab lice [39].

Argon laser phototherapy has also been employed [40].

Aqueous pediculicide preparations may theoretically be used to treat crab lice on the eyelashes, but proprietary preparations are not licensed for this purpose and, in an increasingly litigious society, it is therefore suggested that petrolatum is the treatment of choice.

Bugs (Hemiptera)

Family Cimicidae (including bedbugs) [1–3]

All the Cimicidae are blood-sucking, temporary ectoparasites of birds and mammals. Two-thirds of the species in this family are parasites of bats. It has been suggested that Cimicidae became adapted to feeding on humans when cave dwellers took up residence alongside the bats.

Genus Cimex. *C. lectularius* (the common bedbug) is cosmopolitan, and common throughout Europe, North America, North Africa, North India, Siberia, North China, South Africa, Australia and South America. In recent years, bedbugs have been scarce in the UK, but an increase in the number of cases referred to Brighton Public Health Laboratory Service in 1999 suggested that they might be becoming more common [4].

C. pipistrelli (the bat bug), originating in a bat roost in a house, was responsible for itchy skin lesions in one of the house occupants [5].

C. hemipterus (the tropical bedbug) is less tolerant of low temperatures than *C. lectularius*. This bug is confined to tropical and subtropical regions, including India, Burma, Malaya, South China and Central Africa.

Genus Leptocimex. *L. boueti* has a limited distribution in West Africa, where it parasitizes humans and bats.

Genus Oeciacus. Several species are usually found on birds and in their nests, for example *O. hirundinis*, the martin bug [6] and *O. vicarius*, the swallow bug. They may invade houses from nests under the eaves, and will bite humans readily, but it is unlikely that they can complete their life cycles on human blood, or take up residence in houses as bedbugs do.

Genus Haematosiphon. *H. inodorus*, the only species in this genus, is also known as the Mexican chicken bug. As the name suggests, its major host is the chicken, but it can be a serious pest in human domiciles if these are close to chicken roosts.

Ecology [1–3]. Bedbugs are 4–5 mm in length, with dorsoventrally flattened, oval bodies, the forewings reduced to

Fig. 33.20 *Cimex lectularius*, the bedbug. (Courtesy of Oxford Scientific Films.)

scale-like pads, and the hindwings absent (Fig. 33.20). The mouthparts are modified into a proboscis adapted for piercing and sucking.

Female bedbugs deposit their pearly white, flask-shaped eggs in the crevices of floors and walls, in furniture, bed frames and mattresses. Each female lays about 300 eggs in her lifetime. The eggs hatch after about 10 days: the nymphal stage lasts approximately 6 weeks, during which time the bug moults five times.

Bedbugs normally feed at night, usually about an hour before dawn, but they may feed during the day if circumstances are favourable [7]. Searching for a food source is erratic, and is probably at random at distances greater than a few centimetres, but in the final approach to the host, both temperature and odour play a part in guiding the bug. Feeding time is relatively short (3–12 min). During feeding, the bedbug injects saliva containing an anticoagulant and anaesthetic. In the absence of a suitable food supply, however, adult bedbugs can survive starvation, in ideal circumstances, for a year or more [8].

In the absence of its usual host, *C. lectularius* will attack other animals, and Cimicidae normally parasitic on other hosts are similarly prepared to attack humans, invading houses from birds' nests or chicken runs.

Clinical features. The bites of the bedbug are painless, and the attention of the victim is only drawn to the bites by the reaction they produce. They commonly occur on the face and neck, hands and arms, but may occasionally be generalized. In the individual not sensitized by previous exposure, there may be no symptoms at any stage, and only a purpuric macule indicates the site of the bite. Late-onset reactions may occur in some cases [9]. In sensitized subjects, intensely irritating weals or papules surmounted by haemorrhagic puncta are the characteristic reaction. In some cases in which the reaction is severe, bullae predominate [10,11].

The bites of other Cimicidae are essentially similar, but their distribution depends on the method of exposure.

Bedbugs as vectors of disease [12]. It is not known with certainty that bedbugs act as vectors for any disease, but their possible role in the transmission of hepatitis B and C, and HIV infection, has been investigated [13–20]. Hepatitis B virus persists for up to 6 weeks in the bedbug's body [13,17,18]. It has been suggested that mechanical transmission to humans could occur via infected bug faeces, or when bugs are crushed during feeding. Hepatitis C virus RNA was not detected in bedbugs after feeding on blood with a high viral titre [17].

Initially, it was suggested that bedbugs might act as vectors for HIV [19], but it was later concluded that this is unlikely [20,21].

Haematosiphoniasis [22]. Haematosiphoniasis is the name given to the cutaneous lesions caused by the bites of *Haematosiphon inodorus* (the Mexican chicken bug). Polymorphic lesions, consisting of weals, papules, vesicles, pustules and scabs, occur predominantly on exposed parts of the body.

Family Anthocoridae

The Anthocoridae are related to the Cimicidae. Bugs of this family are mostly predacious on other insects, but are known to bite humans occasionally. *Lyctocoris campestris* is a cosmopolitan species closely associated with humans, for example in haystacks and granaries [1]. *Anthocoris kingi* and *A. nemorum* will also bite humans [2]. Another anthocorid bug, *Dufouriellus ater*, attacked many workers in a clothing factory in north-east England [3].

Family Pentatomidae

Palomena prasina (the green shield bug), a member of this family, has been reported as the cause of perioral blistering in a small child [1].

Kissing bugs, assassin bugs and cone-nosed bugs (Reduviidae)

The majority of species of Reduviidae are predators on other insects, and are commonly called assassin bugs for this reason, but some attack humans and other animals. Most species are encountered in North, Central and South America, but some occur in Africa, the Middle and Far East, and in Australia. The subfamily Triatominae is the most important medically, and includes those species which feed exclusively by sucking the blood of vertebrate animals. Adult triatomines are large insects, commonly measuring 20–28 mm in length. They have an elongated head with a prominent proboscis and long, four-jointed antennae (Fig. 33.21).

Fig. 33.21 Cone-nose bug. (Courtesy of Oxford Scientific Films.)

The Triatominae are largely confined to the western hemisphere, with the majority of species being distributed in North, Central and South America. In the USA, *Triatoma sanguisuga* has the widest distribution, extending from the south-eastern and Mid-Atlantic states westwards, including Texas. Triatomines feed on a wide range of hosts, and domestic species feed on humans and domestic animals. They are of medical importance as vectors of *Trypanosoma cruzi* in Chagas' disease [1,2].

Ecology. In nature, triatomine bugs form colonies in the habitat of their host, for example a small mammal's nest or animal lair. In the south-western USA, infestations are often found in the nests of wood rats. Some species, however, have become totally domesticated, and live and breed in human dwellings, laying their eggs in cracks and crevices in the floors and walls. The young hatch as nymphs, which are miniature versions of the adults. Nymphs and adults hide in crevices during the day and emerge at night to feed.

Clinical features [3,4]. The bites of the predatory species of reduviid bugs (assassin bugs) are purely defensive, and are usually extremely painful [5,6]. The bites of the blood-sucking Triatominae, however, are painless—this is essential to the parasite if it is to feed undisturbed. In an individual not previously exposed to the bites, there will be little reaction, but with repeated exposure hypersensitivity develops, and reactions ranging from pruritic papules to haemorrhagic nodules and bullae may occur.

Thrips (Thysanoptera)

Thrips ('thunder flies') are tiny, winged insects, 1–2 mm in length, and usually yellowish brown or black in colour. The name 'thrips' is derived from the Greek, meaning 'wood louse'. The order Thysanoptera ('fringe wing') comprises about 5000 species, with a worldwide distribution. The majority feed on plant juices, and some are important agricultural pests [1]. Some species are predatory on other arthropods. A few species appear able to suck blood, and there are a number of reports that thrips bite [2,3].

Most thrips, however, are unable to penetrate the human epidermis, and probably cause itching and prickling sensations only by their movement on the skin surface and their efforts to obtain water from perspiration.

Clinical features. Thrips bites, which occur on exposed skin, produce tiny puncta and small, pink macules or papules [2,4]. Large numbers of American soldiers in Hawaii developed hypoanaesthetic papular lesions surrounded by blanched halos, which, it was suggested, were caused by Cuban laurel thrips [5]. However, attempts to reproduce lesions by placing live thrips in contact with the skin were unsuccessful, and the cause of this distinctive dermatosis remains unknown [6].

Beetles (Coleoptera)

Beetles are insects whose forewings are modified to form hard wing cases for the membranous or reduced hind wings. There are over 370 000 known species, but it is likely that many more await discovery. They are mainly terrestrial and the majority feed on decaying animal or vegetable matter, but some are predaceous on other insects. Several species may provoke skin lesions and are of interest to the dermatologist.

Vesicating species [1–4]

Family Meloidae (oil beetles, blister beetles)

Most of the beetles in this group only cause problems when crushed on the skin, but some may emit their vesicating fluid without being crushed. The family is large and widely distributed. Many species contain the irritant cantharidin, which commonly is called 'Spanish fly'. Contact with the skin produces an irritant dermatitis and bullae. Cantharidin has an undeserved reputation as an aphrodisiac, which is unfortunate for a chemical capable of producing severe toxicity. It has been used in blistering plasters and hair restorers, and in the treatment of warts and molluscum contagiosum.

Lytta vesicatoria is perhaps the best known of the blister beetles. It is a large, bright metallic green beetle, which lives mainly in the Mediterranean region, but is sporadically found further north, occasionally as far as England.

Other vesicating species include *Epicauta* spp. (USA, Mexico, India, Sudan, Senegal) [5], *Mylabris* spp. (Nigeria, India) [6,7], *Psalydolytta* spp. (Gambia) [8] and *Cylindrothorax melanocephala* (Gambia) [8].

Family Staphylinidae (rove beetles) [9–11]

The genus *Paederus*, found worldwide, includes many species containing a vesicant, pederin, which is chemically distinct from cantharidin. Pederin is released when the beetles are crushed, provoking an acute irritant contact dermatitis. A major outbreak of vesicular dermatitis on Okinawa in 1966 was traced to contact with the beetle *Paederus fuscipes* [12], and a number of other reports have documented *Paederus* dermatitis from several parts of the world [13,14], including an outbreak which occurred in a military unit training in the Arizona desert during heavy rain and flooding [15]. A plague of whiplash rove beetles (*P. australis*) forced evacuation of an aboriginal community in the Northern Territory of Australia [16]. *P. sabaeus* has been responsible for several outbreaks of dermatitis in Africa at the end of the rainy season [17–19].

Histopathological changes of *Paederus* dermatitis include intraepidermal and subepidermal blistering, epidermal necrosis and acantholysis [20].

It has been proposed that the biblical third, fourth and sixth plagues of Egypt might have been related to rove beetles and the bullous lesions they cause [21].

Family Oedemeridae [3]

Oxycopis vittata has been reported as causing a blistering dermatitis in Puerto Rico [22].

Sessinia species (coconut beetles) have caused blistering in the Gilbert Islands [7].

Thelyphassa lineata produced a bullous dermatosis in a large number of New Zealand Army personnel [23], and there is a report of blister beetle dermatosis in Hawaii caused by *T. apicata* [24].

Family Paussidae

Cerapterus concolor, an inhabitant of ants' nests, can eject a blistering liquid when disturbed [25].

Family Tenebrionidae (darkling beetles)

Many species inhabit wood, flour and grain stores. *Tribolium castaneum* (the 'rust-red flour beetle') has caused a pruritic eruption in workers handling infested jute packing bags [26]. The secretion of *Tribolium* species is mainly composed of quinones.

Species of *Blaps* can eject defensive secretions which are irritant and cause blistering.

Clinical features [2–4]. Usually, lesions are produced only when the beetle is crushed on the skin. A weal forms rapidly and is followed by a blister after 12–24 h. The blisters are sometimes linear 'whiplash dermatitis'. A characteristic feature is the development of kissing lesions, where a blister comes into contact with another area. Blisters induced in a small child by *Mylabris bifasciata* were associated with severe systemic manifestations of cantharidin poisoning [6].

Allergenic species

Family Dermestidae [27]

The beetles in this cosmopolitan family feed on hides, woollen materials and stored food. The adult beetles are not known to be directly injurious to humans, but their larvae are covered with hairs, which may cause skin lesions.

Papular urticaria in a child, caused by the larvae of *Dermestes maculatus* Degeer, has been reported, but it was uncertain whether the reaction to the hairs was irritant or allergic [28]. *Dermestes peruvianus* was responsible for dermatitis, vasculitis, cervical lymphadenopathy and pulmonary nodular interstitial infiltrates in a man whose bed was colonized by the beetles [29].

The irritating hairs from the larvae of carpet beetles (*Anthrenus* spp.) may also cause skin lesions [30,31]. There is also a report of the damaging effect of *Anthrenus* larvae on paraffin-embedded tissue specimens, especially the sectioned surfaces of hyperkeratotic lesions [32].

Clinical features. The skin lesions are not distinctive. Dermatitis, urticaria and papular urticaria may occur.

Cockroaches (Dictyoptera)

Cockroaches are members of the order Dictyoptera, suborder Blattaria. They belong to one of the primitive orders of insects, being allied to crickets, grasshoppers, preying mantids and stick insects. Cockroaches were originally adapted to hot climates, but a number of species have established themselves in cool climates by living inside warm human habitations. They are active nocturnally, and are attracted to any organic material that may serve as food. This theoretically makes them potential mechanical vectors of pathogenic organisms.

The main pest species are *Periplaneta americana*, *P. australasiae*, *Blatta orientalis* and *Blatella germanica*.

Clinical features [1,2]. Inhalation of cockroach allergens is thought to play a part in some cases of allergic asthma, chronic rhinitis and conjunctivitis, and cockroach-specific IgE may be found in the serum of atopic subjects with a history of exposure to cockroaches. Three major allergens have been identified in crude extracts of *B. germanica* and *P. americana* [3], and work with the German cockroach (*B. germanica*) indicates that it is the cast skins and whole bodies of German cockroaches that contain the clinically relevant allergens; egg shells and faeces have little antigenic activity [4].

There are, however, few reports of skin lesions attributed to cockroaches. Contact urticaria and dermatitis have been described in laboratory workers and others handling cockroaches constantly [5–7], and urticated papules developed in a medical records clerk exposed to copious insect debris containing fragments of *B. germanica* when clearing old case notes from a derelict hut [8].

Locusts (Orthoptera)

Sensitivity reactions, manifest as asthma and allergic rhinitis, are a recognized occupational hazard in those working with laboratory colonies of locusts [1,2]. The principal allergen appears to derive from the peritrophic membrane, which is present in the gut and surrounds faeces [2].

Contact urticaria to locusts has been reported by Monk [3] in a laboratory research worker who handled a large number of locusts. The patient produced a positive reaction to locust antigen on prick testing and a wealing reaction at the site of contact with a live locust.

Similarly, urticaria and worsening of asthma on exposure to grasshoppers have been described in an atopic research laboratory worker [4].

Butterflies and moths (Lepidoptera)

Many members of this large order are of importance to the dermatologist because of the irritant properties of the hairs or spines of the caterpillars and sometimes of the adults. Skin lesions in the majority of cases are produced by a combination of mechanical and pharmacological effects [1,2]. The offending caterpillars are distributed through many different families [1,3]. Some of the species that have been recorded as causing damage to human skin are shown in Table 33.1.

Aetiology of skin lesions [1,2,16,17,26–29]. The term 'lepidopterism' is applied to the ill effects on humans of a structure or product of some part of a moth or butterfly at any stage of its life history. Some authors apply the term 'erucism' to injurious effects from caterpillars, and 'lepidopterism' to ill effects from adults. In the majority of cases, damage to human skin and mucosae occurs as a result of epithelial penetration by the 'hairs' (setae) of caterpillars. In addition to a foreign-body reaction, there is often an effect from venom. Setae develop from trichogen cells of the epidermis. They are hollow, and may function as sensory receptors or communicate with a poison gland cell and contain venom. They commonly have barbs, which hold them in place when they have penetrated the skin. In some families of moths, the caterpillars have clumps of much smaller setae known as 'dart hairs' or 'spicules', which are pointed at both ends and carry fine barbs. The point of attachment to the caterpillar is very narrow and easily fractured; hence, contact with the caterpillar may release huge numbers of these tiny darts. Such dart hairs are present in a number of species, including the brown-tail moth (*Euproctis crysorrhoea*) (Fig. 33.22) and the pine processionary caterpillar (*Thaumetopoea pityocampa*).

Table 33.1 Some Lepidoptera species responsible for skin damage.

Superfamily Noctuoidea
Family Lymantriidae (tussock moths)
- *Euproctis crysorrhoea* (the brown-tail moth): the most important urticating species in the UK [4]
- *E. edwardsi* (the mistletoe brown-tail moth) [5,6]
- *E. similis* (the yellow-tail moth) [7,8]
- *E. flava* (the oriental tussock moth)
- *Lymantria dispar* (the gypsy moth) [9]
- *Orygia pseudotsugata* (the Douglas fir tussock moth) [10]

Family Arctiidae (tiger moths)
- *Hyphantria cunea* [11]

Superfamily Notodontoidea
Family Thaumetopoiedae (processionary caterpillars)
- *Thaumetopoea* (*Cnethocampa*) *processionea* [12]
- *T. pinivora* [13]
- *T. wilkinsoni* [14]
- *T. pityocampa* [15–17]

Superfamily Zygaenoidea
Family Megalopygidae (flannel moths)
- *Megalopyge opercularis* [18,19]

Family Cochlididae (Eucleidae; Limacodidae)
- *Sibine stimulea* [20]

Superfamily Bombycoidea
Family Saturniidae
- *Hylesia* species [21,22]
- *Automeris io* (the bull's-eye moth) [23]
- *Hemileuca maia* (the buck moth) [24]

Family Lasiocampidae
- *Lasiocampa quercus*
- *Eriogaster lanestris* (the small eggar moth) [7]
- Dendrolimus punctatus [25]

Fig. 33.22 Caterpillar of *Euproctis crysorrhoea*, the brown-tail moth. (Courtesy of D. Fox/Oxford Scientific Films.)

Setae are also woven into cocoons, and the webs of the silk-spinning caterpillars.

Spines are an extension of the cuticle of the caterpillar and contain venom. The spines either have a terminal plug of inspissated material at their open ends, which is released by pressure, or a weak point at which the spine fractures to allow the venom to escape. Poisonous spines occur particularly on the caterpillars of the moth families Cochlididae (Eucleidae; Limacodidae), Saturniidae and Megalopygidae.

The venoms present in the setae and spines of caterpillars of a number of families of Lepidoptera have been studied, but not fully elucidated. Some contain histamine, histamine liberators, serotonin and proteases [14,30–33]. Lamy *et al*. [34] isolated a protein, thaumetopoein, from pine processionary caterpillar hairs. This has a direct effect on mast cells, leading to degranulation, and explains the urticating properties of these caterpillars. However, IgE-mediated hypersensitivity also appears to be responsible for some reactions to *Thaumetopoea*, and it has been suggested that the hairs should be considered as important airborne insect allergens [35].

In some species—for example, moths of the genus *Hylesia* (family Saturniidae)—irritating setae are carried by the adults. This genus is notorious for causing outbreaks of 'butterfly itch', 'moth dermatitis' or 'Caripito itch' [21] in tropical South America.

Clinical features [1,2,36]. Irritation may be experienced immediately after contact with the offending caterpillars, or may be delayed for hours or even days, depending on the species. Itching is followed by the development of small urticarial papules, sometimes surmounted by vesicles. Alexander [37] noted marked bruising in children who had been in contact with *E. crysorrhoea* caterpillars. Urticaria and eyelid oedema may also occur, and in severe eruptions there may be constitutional symptoms of malaise and mild pyrexia. The severity and distribution of the eruption depend mainly on the route and intensity of exposure, but the most common sites are the exposed parts of the body. Lesions usually resolve in a few days. When contact with caterpillars is suspected as the cause of a dermatosis, Sellotape stripping of affected areas and subsequent microscopy may be used to demonstrate setae [38].

Contact with *Megalopyge* caterpillars [18,19] produces immediate, intense, burning local pain accompanied by a spreading erythema around the puncture sites. The affected area becomes oedematous, and there is often lymphangitis and regional lymphadenopathy. The local changes may be accompanied by pyrexia, headache, nausea and vomiting, particularly in children [39].

In the eye, caterpillar setae may cause a variety of changes, ranging from conjunctivitis to ophthalmia nodosa [40,41] and even panophthalmitis.

Class Arachnida

Arachnida are readily distinguished from insects, as the adults have no wings or antennae and possess four pairs of legs. Unlike insects, where the body is divided into three segments (head, thorax and abdomen), arachnids have only two, the cephalothorax, from which the legs arise, and the abdomen.

The Arachnida are classified in seven orders, only three of which are of medical importance:

1 Araneae (spiders)
2 Scorpiones (scorpions)
3 Acari (ticks and mites)

Spiders (Araneae)

The appearance of many of the larger spiders inspires terror or disgust, but very few of the many thousands of species are dangerous to humans. Spiders are, for the most part, shy and avoid contact with humans. Almost all are venomous and bite, but only a few have chelicerae strong enough to penetrate human skin, and in most cases the bites are trivial. The European tarantula, *Lycosa tarantula*, which inspired the tarantella in Italy in the Middle Ages, inflicts a temporarily painful but harmless bite. Some lycosid spiders in South America, for example *L. antibucana*, cause severe swelling and lymphangitis. In the USA, the term 'tarantula' is erroneously applied to the large 'bird' or 'crab' spiders of the family Theraphosidae, which attack only when vigorously provoked, and whose bite may be painful but is not dangerous. Some colourful species kept as pets, for example *Brachypelma smithi*, are among several that have urticating hairs capable of causing prolonged pruritus. Many spiders whose bites are dangerous and sometimes fatal are small, inconspicuous and unimpressive.

The clinical syndrome following the bite of a spider is known as arachnidism. The form of arachnidism caused by species of the family Loxoscelidae is known as loxoscelism, and that by widow spiders (*Latrodectus* species) latrodectism.

Fig. 33.24 *Atrax robustus*, the Sydney funnel-web spider (defensive posture). (Courtesy of Mantis Wildlife Films/Oxford Scientific Films.)

Air transport of crates of fruit and other materials may introduce exotic species to countries in which they are unable to multiply but can survive long enough to attack humans.

Arachnidism [1–4]

Family Theridiidae

Genus Latrodectus (widow spiders). Spiders of this genus are widely distributed throughout the world. *Latrodectus mactans* (Fig. 33.23), the black-widow spider, occurs throughout subtropical and tropical regions. Other species have a similar, but more limited range, but some extend to the temperate regions of Russia and Canada.

The female of *L. mactans* is glossy black, with a body length of 1.5 cm and a leg span of up to 5 cm. She normally spins her web in empty burrows or under stones, but may be found in dark corners of barns, garages, store rooms or outdoor lavatories. She bites humans only in self-defence. *Latrodectus* venom is considered to be one of the most potent toxins, exceeding that of snake venoms, but the dose injected is minute in relation to the body weight of a human victim. The toxins of all species of *Latrodectus* which have been studied appear to be closely related, and the symptoms from envenomation are similar.

Latrodectus hasselti, the red-back spider, is common in Australia [5]. A report from Fremantle documented 150 admissions for red-back spider bites over a 6-year period from 1982 to 1987 inclusive, and estimated the annual cases at between 830 and 1950 [6].

Latrodectus geometricus, the brown-widow spider, bites reluctantly, but is occasionally troublesome to vineyard workers in South Africa.

Clinical features (latrodectism) [1–3,7–10]. In the days of the outdoor lavatory, *Latrodectus* webs were often spun across the toilet seat, and this led to the frequent occurrence of bites on the buttocks and genitalia. The bite of *Latrodectus* species is fairly painless, but within a few minutes increasingly severe pain develops and becomes generalized. Cramp-like or colicky abdominal pain is particularly common. Puncta may be visible at the site of the bite, and there is local erythema and oedema. There is frequently profuse sweating, and neuromuscular involvement causes paraesthesiae, incoordination and paralysis. The pain begins to subside within 24 h, and other symptoms resolve within 2–3 days, although weakness and lethargy may persist for longer. However, without treatment the bite may be fatal in young children or in the elderly and frail.

Treatment. Species-specific antivenoms are available for *Latrodectus* bites, and there is evidence that red-back spider antivenom prevents toxicity of other widow spider venoms [11,12].

Family Dipluridae

Genera Atrax/Hadronyche (funnel-web spiders). The family Dipluridae contains several genera in Australia and New Zealand [5]. Funnel-web spiders are large, aggressive spiders (Fig. 33.24), which are nocturnal and predominantly insectivorous. They are widely distributed along the eastern seaboard of Australia. *Atrax robustus*, the Sydney funnel-web, normally lives under rocks and logs, but the spread of the Sydney suburbs into its habitat has provided similar hiding places under houses. Some species of *Hadronyche* inhabit trees.

Clinical features [4,13,14]. The bite of funnel-web spiders is invariably painful. From the majority of bites, especially those of female spiders, no general symptoms follow, and recovery is uneventful. However, the large amount of venom from male spiders may cause severe systemic

symptoms. Nausea and vomiting are early features, accompanied by abdominal pain, profuse sweating, piloerection, muscle fasciculation, lacrimation, excess salivation, dyspnoea and pulmonary oedema. Several fatalities were recorded prior to the development of an antivenom.

Treatment. The compression bandage-splinting method of first aid is effective in delaying onset of envenomation and may enhance local inactivation of venom. Severe reactions will require hospital admission and full supportive measures. Funnel-web spider antivenom is very effective.

Family Loxoscelidae

Genus Loxosceles ('fiddleback', 'violin', 'brown recluse' spiders). There are a number of species of *Loxosceles* in North and South America, with 13 in the USA, five of which are known to induce human skin necrosis: *reclusa*, *laeta*, *deserta*, *arizonica* and *rufescens* [4]. The most notorious is *L. reclusa*, the brown recluse spider, which is tan to brown in colour, with a dark-brown, violin-shaped marking on the dorsum of the cephalothorax—hence the names 'fiddleback' and 'violin' spider. *L. reclusa* is active mainly at night. Its natural habitat is in dark areas beneath rocks and in holes and caves. It is also found in homes, in areas that are dark, dirty and undisturbed, such as attics, cupboards and garages.

Loxosceles laeta also occurs widely in South America. *Loxosceles rufescens* is widespread in southern Australia.

Clinical features (loxoscelism) [1–4,8,15]. There are two distinct clinical forms of loxoscelism: necrotic cutaneous loxoscelism, and the much less frequent viscerocutaneous loxoscelism. The clinical manifestations depend upon the age and health of the victim, the amount of venom injected and the site of the bite—fatty areas such as the proximal thigh and the buttocks show more cutaneous reaction and extensive involvement of the entire subcutaneous layer.

In necrotic cutaneous loxoscelism, there is local damage to the skin and subcutaneous tissues, but systemic symptoms are mild. The bite of the spider is usually relatively painless. However, after an interval of minutes or hours, severe pain develops at the site, accompanied by erythema, oedema and a central bulla. In severe envenomation, a 'target' lesion is seen—central blue/purple discoloration surrounded by an ischaemic halo and an outer ring of erythema (the 'red, white and blue' sign). After 3 or 4 days, the central area becomes necrotic, and an eschar develops. The eschar is eventually shed, leaving an ulcer which may take a considerable time to heal. The size of maximum necrosis appears to be predictive of time to complete healing [15].

In viscerocutaneous loxoscelism, systemic involvement is indicated by pyrexia, severe malaise, restlessness and headache. Within 24 h of the onset of general symptoms, ecchymoses, jaundice, haematuria and haemoglobinuria indicate massive intravascular haemolysis, which may result in death [16].

Treatment [4,8,17]. Rest, application of ice compresses, and elevation (RICE therapy) help to reduce inflammation and pain. Although dapsone is said to be beneficial [17], its use is controversial [4].

Family Lycosidae (wolf spiders)

There are a few reports of bites by members of the genus *Lycosa* [4,18,19]. They usually cause only local pain, swelling and erythema, without cutaneous necrosis or significant systemic symptoms.

Other venomous species [3–5,20–23]

Spiders of several other families may cause unpleasant bites. Sac spiders of the genus *Chiracanthium* (family Clubionidae), which are found in many parts of the world, may cause local pain, oedema and small areas of necrosis [4,20]. *Tegenaria agrestis* (family Agelenidae), the hobo spider (previously known as the aggressive house spider), is a cause of necrotic arachnidism in the north-west USA [4,21,22]. Members of the families Gnaphosidae, Salticidae (jumping spiders), Sparassidae (huntsmen spiders) and Oxyopidae (lynx spiders), all occasionally bite humans, but the effects are usually mild, unless there is secondary bacterial infection.

Scorpions (Scorpiones)

Scorpions are arachnids of the order Scorpiones, and are widely distributed in the tropics and subtropics. Their poisonous stings are responsible for considerable morbidity and mortality [1–3]. The venom is carried in the curved sting at the tip of the tail, which is swung over the scorpion's head to strike its prey. The principal components are neurotoxins [3,4], but some venoms also contain 5-hydroxytryptamine, histamine and kinins.

Many scorpions are quite harmless, and their stings of little consequence. Most of the dangerous species belong to the family Buthidae [5]. Species of *Androctonus* and *Buthus* are important in the Middle East and North Africa, and *Centruroides* species cause problems in the southern USA and Mexico. *Tityus* species are responsible for numerous episodes of envenomation in Brazil [6]. Throughout the world, many of the deaths from scorpion stings are in infants and young children.

Australia has a number of species of scorpions (Fig. 33.25), but their stings are relatively innocuous [7].

Fig. 33.25 Australian scorpion (*Urodacus* species). (Courtesy of Mantis Wildlife Films/Oxford Scientific Films.)

Clinical features [8–12]. The effects of scorpion stings may be local or systemic, and they vary according to the species responsible. The local effects are usually immediate severe burning pain and hyperaesthesia, and there may be marked swelling. Systemic effects include restlessness, profuse sweating, muscle spasms, difficulty with speech, marked increase in salivary and lacrimal secretion, nausea, vomiting, convulsions, hypertension, cardiac arrhythmias, myocarditis and pulmonary oedema. Death is usually due to respiratory or cardiac failure.

Treatment [7,9,12]. Ice packs should be applied, and the injection of local anaesthetic around the sting site will help to reduce the pain. Specific antivenoms are available.

Ticks (Acari)

Ticks are large acarines, which are blood-sucking ectoparasites of vertebrates. They are important vectors of diseases such as tick-borne relapsing fever, a number of viral and rickettsial infections, and Lyme disease.

Morphology and biology [1]. Ticks are typical arachnids, possessing mouthparts referred to as the capitulum, an unsegmented body, and four pairs of legs in the adult. Larval ticks have three pairs of legs.

There are two major families: the Ixodidae (hard ticks) and the Argasidae (soft ticks). The term 'hard' refers to the dorsal chitinous shield or scutum, which is present in the Ixodidae but not in the Argasidae. In Ixodidae, the scutum covers the whole dorsum in the male, but only a small

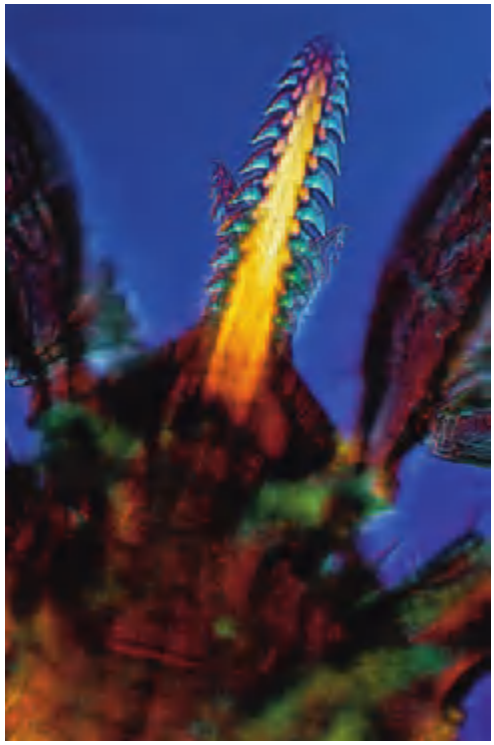

Fig. 33.26 Mouthparts of an *Ixodes ricinus* nymph, showing the toothed hypostome (interference contrast microscopy).

Fig. 33.27 Scanning electron micrograph of tick mouthparts.

anterior part in the female. In argasids, there is little difference between the sexes. The mouthparts of ixodid ticks project forwards and are easily visible from above, whereas those of the argasid ticks can only be seen from below. A conspicuous component of the mouthparts is the toothed hypostome (Figs 33.26 and 33.27).

Ixodid ticks have four stages in their life cycle: egg, larva, nymph and adult. The larva and nymph require blood meals before further development can occur, and the adult female (Fig. 33.28) also requires a blood meal before egg laying. The female lays one large batch of eggs and then dies. Some ixodids use one host for larval, nymphal and adult stages (one-host ticks), whereas others require two or, more usually, three separate hosts.

To find suitable hosts, the larvae, nymphs and adults climb low vegetation and raise the first pair of legs ('questing'), which carry sense organs (Haller's organ). These organs are sensitive to a number of stimuli, including the carbon dioxide in the exhalations of a potential host. If the host brushes past the vegetation, the tick will immediately grasp the animal's coat.

Argasidae undergo several nymphal stages, and the adult female feeds a number of times during her lifetime,

Fig. 33.28 *Ixodes ricinus*, the sheep tick (engorged female). (a) Dorsal view. (b) Ventral view.

(a)

(b)

laying several batches of eggs. Ixodid ticks feed on the host for several days, whereas argasids visit their hosts nocturnally to feed for only a few minutes. Argasids are mainly parasites of birds, bats and humans. Most ticks are essentially parasites of wild animals, and humans are incidental hosts.

When attaching itself to the host, the tick uses its toothed chelicerae to cut into the epidermis, before thrusting the hypostome into the opening and gradually penetrating the dermis. The hypostome becomes anchored by a protein cement, produced by the salivary glands, which forms a cone around the hypostome and interlocks with its teeth [1,2]. Argasids, being rapid feeders, do not attach themselves as securely as ixodid ticks.

Ticks as vectors of disease [1,3,4]. Within the large family of ixodid ticks, there are several genera of medical importance, including *Dermacentor*, *Haemaphysalis*, *Rhipicephalus*, *Amblyomma*, *Hyalomma* and *Ixodes*.

Dermacentor species act as vectors for a number of diseases, including Rocky Mountain spotted fever, Siberian tick typhus, Colorado tick fever and several types of viral encephalitis.

Haemaphysalis species may also carry Rocky Mountain spotted fever, Siberian tick typhus and Colorado tick fever.

Rhipicephalus sanguineus (the brown dog tick) transmits *Rickettsia conorii*, the causative organism of boutonneuse fever (Mediterranean spotted fever). *Rh. sanguineus* is normally confined to the tropics, but it may be encountered in temperate climates in centrally heated houses [5]. Ticks of the genus *Amblyomma* transmit *Rickettsia africae*, the organism responsible for African tick-bite fever [6].

Ixodes species are important vectors of certain haemorrhagic fevers and viral encephalitis, and also of Lyme disease (Chapter 27). They may also transmit babesiosis to humans [7]. The principal vectors of Lyme disease are the sheep tick *Ixodes ricinus* in Europe, and *I. dammini* (East coast) and *I. pacificus* (West coast) in the USA.

Various species of Argasidae may also act as vectors of disease, the most important being *Ornithodoros* species, which transmit tick-borne relapsing fever. In Israel, *O. tholozani* (the cave tick), which is endemic in the Middle East, is the vector of *Borrelia persica*, a causative agent of relapsing fever [8].

Pathology [3]. At the point of penetration of the tick mouthparts, there is coagulation necrosis of the epidermis and papillary dermis [9]. Surrounding the hypostome is the homogeneous cement [10]. The punctured epidermis shows parakeratosis, spongiosis and frequently pseudoepitheliomatous hyperplasia. There is marked dilatation of upper dermal blood vessels, and a dense perivascular infiltrate of neutrophils and lymphocytes. Histology of the bite site several weeks after removal of the tick shows a perivascular and periadnexal infiltrate of lymphocytes, plasma cells and histiocytes [11,12]. Foreign-body giant cells may also be present in the infiltrate. If the hypostome has been damaged during removal of the tick, fragments of the mouthparts may be seen.

Clinical features [3]. In the case of ixodid ticks, it is usually the parasite itself that attracts the patient's attention. Larvae, nymphs or adults may be discovered attached to the skin, and humans usually become accidental hosts when walking through, or sitting in, an area which contains ticks [13]. Larval ticks, sometimes referred to as 'seed ticks', are very small, and may go unnoticed unless present in large numbers [14,15]. An engorged adult female tick is the size of a large pea.

A papular urticarial response to ticks has been reported in berry pickers [16], and the author has seen papular urticaria developing within a few days of contact with numerous larval ticks of *I. ricinus*.

Autoeczematization has been reported in association with a tick-bite granuloma [17].

Temporary alopecia may develop around the sites of tick attachment to the scalp [12,18].

Bullae [19] and extensive bruising [20] at the feeding sites of argasid ticks have been reported, and anaphylaxis may be provoked by ixodid bites [21].

In boutonneuse fever, there is an eschar (tache noire; black spot) at the site of the bite of the infected tick, accompanied by a maculopapular rash, and African tick-bite fever is associated with multiple inoculation eschars, often located on the legs [6].

The bites of the cave tick, *O. tholozani*, produce characteristic deep red crusted papules or nodules, with a central punctum [8].

The colour of engorged ticks has led patients to suspect they were melanomas [22].

Tick paralysis [23,24]

Tick paralysis is an ascending flaccid paralysis probably caused by a neurotoxin injected by the feeding tick. Occasionally, bulbar paralysis, respiratory failure and death occur. The site of action of the toxin appears to be in the region of the neuromuscular synapse. If the tick is removed, all the signs usually resolve rapidly, but sometimes recovery is slow. Children are more frequently affected than adults.

Tick paralysis occurs in particular localities in association with specific ticks [3]. Offending species include *Dermacentor andersoni* and *D. variabilis* (USA); *Ixodes holocyclus* (Australia); *I. pilosus* (South Africa); *I. ricinus*, *I. hexagonus*, *Rhipicephalus sanguineus* (Europe).

Lyme disease

See Chapter 27.

Tick removal

Various methods for removal of ticks have been suggested, including the application of iodine, ether, chloroform, petrol and kerosene. Sherman [25] suggested a few drops of clear nail varnish, and Dolan and McKinsey [26] 2% lidocaine jelly. Karras [27] also found viscous lidocaine to be effective.

Ticks should not be removed by a sudden forcible movement, as this will often leave the mouthparts embedded in the skin. Gripping the tick with forceps or tweezers, as close to the skin as possible, and gentle traction usually succeeds when other methods have failed [28].

Mites (Acari)

Family Sarcoptidae

Scabies

Scabies in humans and other animals is caused by mites of the family Sarcoptidae, which includes *Sarcoptes scabiei*, the scabies mite, and *Notoedres cati*, a mange mite of cats.

The *Sarcoptes* causing scabies in humans and sarcoptic mange in many other animals are physiological variants of a single species, *S. scabiei*. Their host specificity is not complete, but they usually survive for only a short period on another host.

Human scabies

Human scabies has played a modest, but not insignificant role in history, and the story of scabies has been related in detail by Hebra [1], Beeson [2], Heilesen [3], Friedman [4] and Parish [5].

Morphology and biology of the scabies mite [3,6–12]. *Sarcoptes scabiei* var. *hominis* has an ovoid body, flattened dorsoventrally. The adult female measures approximately 0.4 mm long by 0.3 mm broad, and the smaller male 0.2 mm long by 0.15 mm broad. The body is creamy white and is marked by transverse corrugations, and on its dorsal surface by bristles and spines (denticles). There are four pairs of short legs; the anterior two pairs end in elongated peduncles tipped with small suckers. In the female, the rear two pairs of legs end in long bristles (setae) (Fig. 33.29), whereas in the male bristles are present on the third pair and peduncles with suckers on the fourth.

Copulation occurs in a small burrow excavated by the female. After copulation, the fertilized female enlarges the burrow and begins egg laying. The burrow is not confined

to the stratum corneum, but is inclined downwards into the epidermis. Eggs and mite faeces are deposited behind the female in the burrow. Approximately 40–50 eggs are laid by each female during a lifespan of 4–6 weeks, during which time she does not leave the burrow. Six-legged larvae emerge from the eggs after 3–4 days and escape from the burrow by cutting through its roof. The larvae then dig short burrows (moulting pockets) in which they transform into nymphs. After further moults, adult males and females develop.

The mites show a preference for certain sites in which to burrow, and appear to avoid areas with a high density of pilosebaceous follicles. The average number of adult female mites on an individual suffering from the common form of scabies is about 12 [13–15]. Only in crusted (Norwegian) scabies are large numbers of mites present.

Prevalence and epidemiology [1–4]. Scabies affects all races and social classes worldwide, but accurate figures of its prevalence are difficult to obtain. A recent study has suggested that the prevalence is increasing in the UK, and that scabies is more prevalent in urban areas, the north of the country, in women and children, and that it is commoner in the winter than the summer [5]. The prevalence of scabies in developed countries shows cyclical fluctuations for which there is, as yet, no satisfactory explanation. War conditions are associated with a high prevalence, as in the Second World War. However, the number of cases was already rising before the outbreak of war. By the early 1950s it was declining, and it remained low until the mid-1960s, when there was a further upsurge [6–8]. The interval between the end of one epidemic and the beginning of another is approximately 10–15 years.

One suggested cause of the increased frequency of scabies in the 1960s was sexual promiscuity, but some authors believe this is unlikely, in view of a lack of correlation with trends in sexually transmitted diseases [7,9]. A proposed explanation for the epidemic cycles is the 'herd immunity' theory [2,7]. This suggests that an epidemic of scabies confers a degree of immunity, so that a further epidemic will not occur until a new, susceptible population has arisen. However, the persistent high prevalence of scabies in many underdeveloped countries, without any marked cyclical variation, is evidence against this view.

Scabies is most common in children and young adults, but may occur at any age, and in the UK in recent years it has become frequent in the elderly in residential and nursing-home environments. In a questionnaire survey of dermatologists in UK hospitals, respondents estimated that approximately 30% of all cases of scabies they encountered occurred in institutions such as care homes and hospitals [10]. Although some outbreaks are related to cases of crusted scabies, others appear to originate from residents who have ordinary scabies with many burrows, and therefore a large mite population, or from infected carers. Close contact between residents and carers in these homes is common—for example, carers often hold the hands of residents to provide support when walking.

The overall sex incidence is probably equal.

Whereas all racial groups are susceptible, there are some differences in prevalence, which are probably related to customs and social factors rather than inherent susceptibility. Some reports suggest that black Americans appear less susceptible [11,12], but this has been disputed [13]. In a study of a multiracial population in Hawaii [14], scabies was far more frequent in white people and Hawaiians than in Japanese and Filipinos, and this was thought to be related to family size and social customs.

Overcrowding, which is common in underdeveloped countries and is almost invariably associated with poverty and poor hygiene, encourages the spread of scabies.

Scabies is usually transmitted by close physical contact, such as prolonged hand-holding or the sharing of a bed. Indirect spread by clothing or bedding is unimportant, as demonstrated by the meticulous studies of Mellanby [15,16]. It is often suggested that fertilized female mites are responsible for transmission, although there is no firm evidence to support this contention, but it seems unlikely in view of their relatively small numbers and inclination to remain within their burrows. There are far greater numbers of immature mites on the skin surface, and their involvement in scabies transmission would appear more plausible.

A study from Sheffield, UK [17], showed that scabies was introduced into households mainly by schoolchildren and teenagers, especially by girls. The authors suggested

that the high incidence of scabies in teenage girls could be due to contact with younger children in large families, and the habit of holding hands. The commonest sources of infection were friends and relatives outside the home, and schools did not appear to play any appreciable part.

Away from the host, scabies mites survive for 24–36 h in room conditions (21°C and 40–80% relative humidity) [18], and live mites have been demonstrated in dust samples collected in the homes of infected patients [19].

Immunology [1–5]. Allergic sensitivity to the mite or its products appears to play an important role in determining the development of lesions other than burrows, and in producing pruritus. However, the sequence of immunological events is unclear and requires further elucidation.

Evidence suggests that both immediate and delayed-type hypersensitivity are involved. Skin tests with mite extracts have given equivocal results, although positive immediate-type reactions to intradermal tests have frequently been obtained in patients within a few months of scabies infection. Normal IgE levels were reported in one series of scabies patients [6], but later studies have shown significantly elevated levels in many individuals [7–10].

Involvement of delayed-type hypersensitivity in the production of inflammatory papules and nodules is suggested by the histological changes and predominance of T lymphocytes in the cutaneous infiltrate [11,12].

Other immunological findings include high serum IgG and IgM, and low IgA [6,9] with levels returning to normal after treatment. IgM and C3 deposits have been demonstrated at the dermal–epidermal junction in the region of burrows [13,14], and circulating immune complexes have been found in the serum after treatment of scabies [15].

The frequency of human leukocyte antigen (HLA)-A11 was found to be higher among patients with scabies than in a normal population in Norway [16].

Clinical features [1,2]. Itching is usually the most obvious manifestation of scabies. It is generally worst at night and when the patient is warm. The onset occurs 3–4 weeks after the infection is acquired, and coincides with a widespread eruption of inflammatory papules. Reinfection of a previously cured individual, however, provokes immediate symptoms [3].

The pathognomonic lesions of scabies are burrows, which appear as slightly raised, brownish, tortuous lesions (Fig. 33.30). The point of entry of the mite, the most superficial part of the burrow, has a slightly scaly appearance, and at the distal end there may be a tiny vesicle, adjacent to which is the female mite. There may be few or many burrows, and in patients with a good standard of hygiene they may be difficult to find. Burrows occur on the wrists, the borders of the hands, the sides of the fingers and the finger web spaces, the feet, particularly the instep

Fig. 33.30 Numerous scabies burrows on the palm.

and, in males, on the genitalia. They are often present on the palms and soles of young children and the elderly. In adults other than the elderly, burrows may occur on the palms in women, but they are less frequently found on the palms in men, particularly heavy manual workers. Burrows on the trunk are uncommon in adults, but may be found in the elderly and in infants. They may be seen on the head and neck in babies, but rarely in adults. The scalp was, however, involved in an adult who was applying a topical steroid for seborrhoeic dermatitis [4], and scalp involvement in ordinary scabies may be a reason for relapse [5]. The reason for this pattern of distribution of burrows is not understood, but the mites appear to prefer non-hairy skin and areas of low sebum production.

The pruritic papules that accompany the development of hypersensitivity occur predominantly around the axillae, in the periareolar regions, on the abdomen, particularly the periumbilical region, and on the buttocks and thighs. Histology shows epidermal spongiosis, with intraepidermal microabscesses containing neutrophils and eosinophils, and a dermal perivascular infiltrate of eosinophils, histiocytes and lymphocytes [6,7]. Indurated, inflammatory nodules sometimes occur, particularly on the axillae, groins, scrotum and penis. They are intensely itchy, and may persist for weeks or months after the scabies has been effectively treated [8–10]. The histological changes seen in these lesions may simulate lymphoma, with a dense, pleomorphic dermal infiltrate composed of plasma cells, eosinophils, lymphocytes, histiocytes and reticulum cells [6,11]. T lymphocytes are the predominant cells in the dermal infiltrate of both papular and nodular lesions [12,13].

Inflammatory papules or nodules, sometimes surmounted by burrows, on the male genitalia are characteristic of scabies (Fig. 33.31). The genitalia of males suspected of suffering from scabies should always be examined, as these lesions may provide an important diagnostic clue if burrows are difficult to find.

Fig. 33.31 Inflammatory papules on the penis in scabies.

Nail involvement in crusted (Norwegian) scabies is frequent, but it is uncommon in ordinary scabies [14]. Its presence may be a reason for relapse [15].

In addition to these primary manifestations, secondary features may frequently confuse the clinical picture. Eczematous changes are common, and may be widespread and severe. The inappropriate use of topical steroids may further modify the clinical picture to mimic other dermatoses (see crusted scabies)—so-called 'scabies incognito' [16]. Secondary infection, manifest as folliculitis or impetigo, may also be severe and extensive. In the tropics and subtropics, where nephritogenic strains of β-haemolytic streptococci may be responsible for secondary sepsis, glomerulonephritis occurs as a complication of scabies, but this must be exceedingly rare in temperate climates.

A bullous pemphigoid-like eruption may occur in association with scabies [17–24], and in many of the reported cases immunofluorescence studies showed immunoglobulin deposition in the basement-membrane zone of the bullous lesions. The demonstration of circulating antibodies against BP180 and/or BP230 in two patients with scabies and bullous lesions [23] indicates that scabies may induce true bullous pemphigoid.

Cutaneous vasculitis is an unusual presentation of scabies [25–27].

Scabies in babies. The clinical features of scabies in infants and young children differ in certain respects from those in

older children and adults [28,29]. In addition to the more extensive distribution of burrows mentioned above, vesicular and vesiculopustular lesions on the hands and feet are frequent, extensive eczematization is often present, and there may be multiple crusted nodules on the trunk and limbs.

Bullous lesions have been described in a child [30].

Scabies in the elderly. Burrows commonly occur on the palms and soles, and may be very numerous. Truncal papulosquamous lesions, often surmounted by burrows, are common. Secondary eczematization is often troublesome.

Diagnosis. The typical history of pruritus with nocturnal exacerbations, and the distribution of the eruption of inflammatory papules, should suggest the diagnosis. The presence of genital lesions in males is pathognomonic. Absolute confirmation can only be made by the discovery of burrows and microscopical examination. A burrow is gently scraped off the skin with a blunt scalpel, and the material placed in a drop of 10% potassium hydroxide or mineral oil on a microscope slide. The presence of mites, eggs or fragments of egg shells confirms the diagnosis.

Epiluminescence microscopy may facilitate diagnosis [1], the mite in its burrow resembling a 'jet with contrail'.

Occasionally, burrows are difficult or impossible to find, and the diagnosis can then only be presumptive, based on the history, distribution of the papular eruption and the presence of contact cases within the family. However, in difficult diagnostic situations and atypical cases, polymerase chain reaction has been employed as a diagnostic tool [2].

Treatment [1–3]. There have been many suggested remedies for scabies. Sulphur has been used for centuries, and sulphur ointment is still employed by some dermatologists. Used excessively, or in high concentration, it may cause irritation, but 10% sulphur in yellow soft paraffin is, in general, safe and effective. A concentration of 2.5% may be used for scabies in infants and young children [4]. Rotenone, an extract of Derris root, was employed in the 1940s [5,6], but frequently produced scrotal dermatitis.

There are several currently available scabicides. The choice of therapy is determined not only by efficacy and potential toxicity, but also by considerations such as cost, ease of application, the presence of secondary eczematization and the age of the patient.

Although for many years a hot bath and vigorous scrubbing of the sites of burrows was considered essential, Mellanby *et al*. [7] demonstrated that this was not necessary.

Benzyl benzoate. Although benzyl benzoate is now synthesized, it occurs naturally in balsams of Peru and Tolu; balsam of Peru has been used as a scabicide in the past. In

1937, the Danish dermatologist Kissmeyer [8] reported the effectiveness of benzyl benzoate in the treatment of 8000 cases of scabies, and it rapidly became popular [7,9–11]. Employed as a 25% emulsion, it should remain on the skin for 24 h. There are a number of suggested treatment regimens, but little has been published on their comparative efficacy. Most involve two or three applications, either within 24 h, on successive days or separated by intervals of a week. Benzyl benzoate is irritant, and patients should be warned about overuse.

Monosulfiram [12,13]. A 25% solution in industrial methylated spirit is diluted with two or three parts of water to form an emulsion immediately prior to application, as the suspension is unstable. It should be applied once daily for 2 or 3 days. Monosulfiram is chemically similar to disulfiram (Antabuse) and an Antabuse effect, with flushing, sweating and tachycardia, may occur if alcohol is ingested during or soon after treatment [14]. Monosulfiram-impregnated soap has been used as a prophylactic measure in communities where scabies was endemic [15–17]. Monosulfiram is no longer available in the UK.

Malathion. Malathion 0.5% in an aqueous base is employed as a scabicide [18,19]. It should be left on the skin for 24 h, with a second application after an interval of a week.

Permethrin. Permethrin 5% dermal cream is an effective scabicide [20–22]. It should be washed off after 8–12 h, with a second application after an interval of a week.

Gamma benzene hexachloride (lindane). A single application, washed off after 12–24 h, is usually recommended, but it has been demonstrated that a 6-h application is equally effective [23]. Topical lindane is absorbed through the skin, especially if the barrier function of the epidermis is compromised [24–27]. There are a number of reports of adverse neurological effects, principally seizures, attributed to lindane [24,26,28–31], but toxicity was usually the result of excessive topical application or accidental ingestion. A comparison of percutaneous absorption of lindane and permethrin concluded that 5% permethrin cream is at least 40 times less likely to cause toxic effects than 1% lindane lotion [32]. However, critical assessment of lindane as a scabicide led to the conclusion that it is safe if used correctly [33,34].

There are anecdotal reports from several parts of the world, including the UK and USA, of lindane treatment failures, suggesting the emergence of lindane-resistant scabies mites.

Lindane is no longer available in the UK.

Other topical treatments include thiabendazole [35,36] and crotamiton [37]. Both have limited scabicidal activity, and several applications on consecutive days are required.

Ivermectin [38,39]. Ivermectin is structurally similar to the macrolide antibiotics, but does not have antibacterial activity. It is, however, active against a number of ecto- and endoparasites. It has been extensively employed in veterinary medicine, and in humans is used to treat filarial disease, principally onchocerciasis. It is not licensed for use in scabies in humans. Glaziou *et al*. [40] compared oral ivermectin with topical benzyl benzoate for the treatment of scabies, and found that the former produced a higher cure rate. A comparison of the effectiveness of topical permethrin with oral ivermectin showed that a single application of permethrin is superior to a single dose of ivermectin, but two doses of ivermectin (with a 2-week interval between) are as effective as a single application of permethrin [41]. Comparison of ivermectin with lindane showed that they are equally effective [42]. It has also been reported that a specially formulated topical ivermectin preparation was effective in treating scabies [43]. Oral ivermectin has proved particularly useful in the treatment of crusted scabies (see below).

Ivermectin is apparently a safe drug with a low incidence of adverse effects. Many of the reported adverse effects have occurred in individuals given ivermectin for the treatment of filariasis, in whom serious reactions were thought to be related to death of the parasites [44]. A report suggesting a pattern of excess deaths in elderly people in a residential unit, who were given ivermectin to control a scabies outbreak, raised concerns about its safety [45]. However, the conclusions of this report were challenged [46,47], and other authors' findings regarding its safety are reassuring [48,49]. It also appears to be safe in children [50].

A single dose of 200 μg/kg body weight will be effective in many cases of ordinary scabies but, presumably because of a lack of ovicidal activity, higher cure rates are obtained with two doses separated by an interval of a week.

Because it is effective, inexpensive and easy to administer, ivermectin might prove particularly useful in the management of institutional outbreaks of scabies (see below). Leppard and Naburi [51] controlled an outbreak of scabies in a prison in Tanzania by giving ivermectin to 1153 prisoners.

In the Cochrane systematic review of the treatment of scabies, 13 randomized trials are included, assessing the effectiveness of benzyl benzoate, crotamiton, lindane, ivermectin, permethrin and sulphur [3]. No randomized controlled trials investigating malathion were identified.

In one small trial, ivermectin was associated with a significantly higher clinical cure rate at 7 days than placebo. Permethrin appeared to be more effective than

crotamiton for clinical and parasitic cure rates. Permethrin appeared to be better than lindane for clinical cure rates in two small trials, but had no advantage in the largest trial. There appeared to be no difference in clinical cure rates between crotamiton and lindane or benzyl benzoate and sulphur.

One small-scale placebo-controlled study suggested that ivermectin might be an effective treatment for scabies. Two small-scale studies, one comparing ivermectin with benzyl benzoate and the other ivermectin and lindane, found no difference in effectiveness between these drugs.

It was suggested that permethrin is the preferred treatment for scabies at the present time (based on comparisons with lindane and crotamiton)—the choice being based on 'small studies together with professional opinion and traditional reviews'.

A survey of dermatologists in the UK revealed that the majority used permethrin cream for treating scabies, and about half reported treatment failures with malathion [52].

In addition to the adverse effects of scabicides already mentioned, contact dermatitis to mesulphen, a scabicide used in Italy [53] and toxic epidermal necrolysis attributed to monosulfiram [54] have been reported.

Liquid scabicides are most conveniently applied with a 2-inch (5-cm) paintbrush. Scabicides should be applied to the whole body, except the head and neck, although the latter should be included if there is clinical evidence of involvement, and a non-irritant agent employed. Patients should be provided with written instructions explaining their treatment regimen and a warning against excessive use. They should be advised that itching will persist for a few days, but will usually resolve within 2 weeks. A topical antipruritic, such as crotamiton combined with hydrocortisone, may be used on residual itchy areas. All members of the family and close physical contacts should be treated, whether symptomatic or not. Disinfestation of clothing and bedding, other than by ordinary laundering, is not necessary.

Secondary infection should be treated with a systemic antibiotic. If eczematization is severe, a non-irritant scabicide should be used.

Treatment of infants and young children. Benzyl benzoate should be diluted with two or three parts water if used on infants and young children. Prolonged or repeated applications of benzyl benzoate or lindane should be avoided. Permethrin cream is probably the treatment of choice.

Scabicides in pregnancy. The literature is replete with cautionary advice relating to the use of scabicides in pregnancy, but having indicated which scabicides are best avoided authors rarely commit themselves to stating what they recommend. This is understandable in view of concern about potential toxic effects on the fetus, but to the present author's knowledge there is no documented evidence that any of the currently available scabicides has been responsible for harmful effects in pregnancy, and all must have been used on innumerable pregnant women.

Scabicides and breastfeeding. Published information regarding scabicides and breastfeeding is sparse [55]. There do not appear to be any data on levels of scabicides in human milk following their use on lactating women, hence any advice tends to be based on studies of percutaneous absorption and measurement of plasma levels. It would appear preferable to stop breastfeeding for a few days after treatment, to allow plasma levels of any percutaneously absorbed scabicide to fall, thereby reducing the likelihood of its ingestion in breast milk by the neonate.

Crusted scabies

SYN. NORWEGIAN SCABIES

The appellation 'Norwegian' derives from the description in Norway by Danielssen and Boeck [1] of a type of scabies in which huge numbers of mites were present in lepers. Hebra referred to this as 'scabies Norvegica Boecki' [2]. It has been suggested that 'Norwegian' should be discarded and replaced by 'crusted' [3,4].

Crusted scabies is an infection with *Sarcoptes scabiei* var. *hominis* in which the mite population is enormous, and may number millions. The grossly thickened horny layer is honeycombed with cavities which contain large numbers of mites, and these are shed into the environment of the patient [5]. An undiagnosed case of crusted scabies may be the source of an outbreak of common scabies.

Aetiology and pathogenesis [6,7]. In common scabies, there are few mites, probably because scratching destroys the burrows. A good standard of hygiene may also help to control the mite population. In crusted scabies, the host's response to the mites is modified, allowing them to multiply.

Patients with skin anaesthesia secondary to sensory neuropathy or spinal injury [8] obviously do not perceive itch and therefore do not scratch, but many patients with crusted scabies show no demonstrable sensory loss. However, in many, itching is either absent or mild. Patients who are mentally retarded or suffer from dementia may develop crusted scabies [9], and Down's syndrome is a frequent association [3,10–13]. The reason for this association with mental abnormality is not completely understood, but lack of appreciation of pruritus may be important.

In some patients who are physically severely incapacitated, as a result of paresis [14,15] or severe arthropathy, the main reason for the development of crusted scabies is probably a physical inability to scratch in response to itching. It has also been described as a complication of dystrophic epidermolysis bullosa [16], in which an inability to scratch because of an absence of fingernails may have been a contributory factor, and in a patient with epidermolysis bullosa simplex [17].

Crusted scabies may develop in patients who are immunosuppressed, either as a result of disease [18,19] or therapy [20–22]. In recent years, there have been numerous reports of its occurrence in patients with HIV infection, and it is also an indicator of human T-cell lymphotrophic virus type I (HTLV-I) infection [23–25]. Crusted scabies has also resulted from inappropriate use of potent fluorinated topical steroids [26–28]. Suppression of sensitivity to the mites reduces itching, so there is less scratching and destruction of burrows.

The occurrence of crusted scabies in an otherwise healthy pregnant woman has been reported [29].

Clinical features. Large, warty crusts form on the hands and feet (Fig. 33.32), and the palms and soles may be irregularly thickened and fissured. Masses of horny debris accumulate beneath thickened and discoloured nails (Fig. 33.33). Erythema and scaling occur on the face, neck, scalp (Fig. 33.34) and trunk, and may generalize. The

Fig. 33.32 Crusted (Norwegian) scabies.

Fig. 33.33 Grossly dystrophic nails in crusted scabies.

extent of the erythroderma and the warty plaques varies greatly, and either may predominate. It has been suggested that *Staphylococcus aureus* colonizing burrows might play a part in initiating the erythroderma [30]. Itching is often absent or slight, but may occasionally be severe. Generalized lymphadenopathy is present in some cases, and blood eosinophilia is common.

Crusted scabies may masquerade as hyperkeratotic eczema, psoriasis, Darier's disease [31] and contact dermatitis [32].

The diagnosis is readily confirmed by examination of scrapings, which will be teeming with mites and eggs.

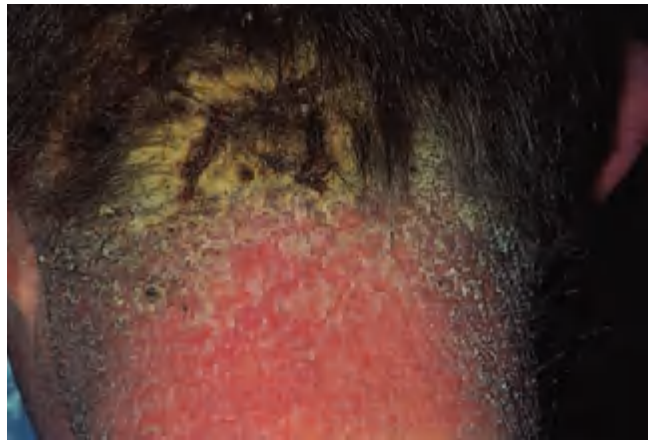

Fig. 33.34 Severe scalp involvement in crusted scabies.

Treatment. A patient with crusted scabies should be admitted to hospital for treatment. They may be treated with topical scabicides, but prolonged therapy involving several applications is often required, and incomplete response is not uncommon. In recent years, ivermectin has become the treatment of choice for crusted scabies, either alone or in combination with a topical agent [33–37]. Although there has not been a comparative study of various regimens which have been employed, it is likely that the most effective is two doses of ivermectin (200 μg/kg body weight), separated by an interval of a week, combined with a topical scabicide. The nails should be cut short, and a topical scabicide applied beneath their free edges.

Institutional outbreaks of scabies. There are numerous reports of outbreaks affecting both patients and medical personnel in hospitals and residential homes, and many of these are associated with undiagnosed cases of crusted scabies. Nursing and medical staff in contact with such a patient may develop the common type of scabies, but frequently the first lesions seen are pruritic papules on the limbs, without any clinical evidence of burrows. The presence of papules and nodules surmounted by burrows, on the abdomen, buttocks and limbs of several contacts of a case of crusted scabies has been described [38].

The management of an institutional outbreak of scabies requires control measures to deal with all residents/patients and health care workers [39–41]. In this situation, all the patients or residents should be examined to detect any cases of severe or crusted scabies, and such individuals should be isolated until cured. Any personnel coming into contact with such a patient should wear long-sleeved gowns and gloves. All individuals on an affected ward or in a residential home, and all medical and nursing staff and their families, should receive prophylaxis with a topical scabicide. Bedding should be laundered. It has

been suggested that during treatment of institutional outbreaks, particular attention should be paid to the nails, in view of the subungual persistence of mites [42]. Cases of crusted scabies should be treated as outlined above.

Animal scabies

Transmission of animal scabies to humans is probably rare, because of the relative host specificity of the mites [1]. However, recurrent exposure to animal scabies mites can produce troublesome and diagnostically puzzling lesions.

Many varieties of *Sarcoptes scabiei* have been incriminated, including the following:

1 The mites causing sarcoptic mange in horses, cattle, buffalo, pigs, camels, monkeys, sheep and goats [2–7].

2 *Sarcoptes scabiei* var. *canis* commonly causes transient skin lesions in those in contact with infested dogs [8–14]. Exceptionally, scrapings from human skin have shown mites and eggs, and symptoms have persisted after contact with the animal has ceased [15]. Canine scabies has been experimentally transferred to humans [16]. Affected animals have areas of scaling and hair loss on the ears, face and limbs [17].

3 *Notoedres cati*, the cause of sarcoptic mange in cats, is almost unknown in the UK, but where it is endemic in the cat population, as in India [18] and Japan [19], human skin lesions may occur.

Clinical features. Skin lesions resulting from contact with animal scabies vary in extent and distribution, according to the mode of exposure. The eruption is usually composed of small, pruritic weals or papules, which are frequently excoriated and resemble human scabies, but without burrows. Lesions from contact with sarcoptic mange in dogs and notoedric mange in cats usually occur at sites of contact with the animal, principally the chest, abdomen, thighs and forearms.

Treatment. If contact with animal scabies is suspected, the diagnosis can only be confirmed by examining the suspect animal and obtaining skin scrapings from it. Affected animals should be treated by a veterinary practitioner.

Human skin lesions are self-limiting, and will resolve once contact with the affected animal has ceased, or it has been treated.

Family Knemidokoptidae

Knemidokoptes mutans causes scaly leg in domestic poultry, and *Mesoknemidokoptes laevis* is a closely related mite which causes depluming itch in poultry; both have caused skin lesions in humans [1].

Family Psoroptidae

Mites of the family Psoroptidae cause mange in domestic animals. Species of *Chorioptes* and *Psoroptes* from cattle, horses and sheep have occasionally affected humans [1]. *Otodectes cynotis* is a common parasite in the ears of cats and dogs, and has been discovered in the ears of a patient suffering from otitis externa [2]. It was also considered to be responsible for a pruritic dermatosis in a patient whose dog was infested [3].

Family Listrophoridae

Listrophorus gibbus, a common parasite of the domestic rabbit [4], has been reported as causing papular urticaria in a child [5].

Mites of stored products [1]

Family Acaridae

These mites attack flour, grain, dried meat, cheese and dried fruit.

Acarus siro is the most important pest of storage premises, and is found on flour, grain, and occasionally cheese. It may cause skin lesions on those who handle these products.

Tyrophagus putrescentiae [2–4] is mostly found in stored food with a high fat and protein content such as dried eggs, ham, herring meal, cheese, nuts and copra. *Tyrophagus longior* is found on cheese, grain, hay and copra [5].

Suidasia nesbitti is particularly associated with wheat pollards and bran, and has been recorded as causing dermatitis in humans [6].

Rhizoglyphus species occur on flower bulbs and have caused dermatitis in persons handling stored bulbs.

Family Carpoglyphidae

Carpoglyphus passularum (*lactis*) is found on all kinds of dried fruit, and may cause dermatitis [7,8].

Family Glycyphagidae

Glycyphagus domesticus is a widely distributed species, often found in large numbers on plant and animal remains in houses and stables. It has also been found in flour, wheat, hay, tobacco, cheese and ham. *Glycyphagus destructor* is often abundant in hay, straw and grain.

Pathogenesis of food-mite dermatitis. It has been suggested that the dermatitis caused by these mites, which are not haematophagous, results from irritation by mite products, either faecal or secretory [3]. However, the pathomechanics of the response do not appear to have been studied in detail.

Dockers and warehouse workers handling stored products are most at risk, but shopkeepers and domestic workers are occasionally affected.

Clinical features [9]. The eruption provoked by these mites is sometimes called 'copra itch' or 'grocer's itch', and is often composed of minute, intensely pruritic papules or papulovesicles on exposed parts of the body, principally on the head and neck, and forearms, but occasionally more widespread. The appearance of the eruption on the face may suggest an acute contact dermatitis.

House-dust mites (HDM)

Dermatophagoides pteronyssinus, the HDM, was first discovered by Trouessart in dust shaken from tanned mammal skins [1]. It was subsequently established that it is widely distributed in the human environment in house dust and beds [2,3]. It occurs worldwide, and has been reported from all inhabited continents [4]. It is commonly associated with *Euroglyphus maynei* and *D. farinae*, which are related species in the same family, the Pyroglyphidae. In the USA, *D. farinae* appears to be more plentiful in house dust than *D. pteronyssinus* [5].

The largest numbers of mites are found in houses that are damp and inadequately heated [4]. Numbers vary seasonally, increasing in early summer to reach a maximum by early autumn. In the UK, numbers are low in winter and increase in spring, when temperature and relative humidity rise [6].

The main food of *D. pteronyssinus* is human skin scales [7]. Xerophylic moulds, especially *Aspergillus penicilloides*, are essential for the growth and survival of *D. pteronyssinus*. The moulds digest lipid in the scales which is toxic to the mites.

The major HDM allergens (Der p1 and Der f1) are present in the faecal pellets.

Role in atopic eczema [9–11]

The role of the HDM in the pathogenesis of atopic eczema remains controversial, although there is increasing evidence of involvement of HDM allergen in the disease [8–12].

Several studies have indicated that, in many individuals, the condition can be improved by techniques designed to reduce exposure to HDM allergen [13–18], although the benefits on clinical status appear to be greater in children than in adults [19], and it is not possible to predict which patients will benefit.

One study demonstrated that the houses of patients with moderate to severe atopic eczema had more HDMs than controls [20].

Measures to reduce the HDM allergen load include regular vacuum cleaning of carpets, or their removal, bedding covers made of material such as microporous Gore-Tex, and the use of acaricides, including benzyl benzoate and permethrin [21].

Hepple and Macmillan [22] have attributed a case of purpuric dermatosis to HDM allergy.

Pyemotes mites

Pyemotes mites are all primarily parasites of insects or their larvae. They only affect humans when the latter come into contact with the food of their natural hosts.

The mite *P. tritici* preys on the larvae of many species of insect infesting grain, straw or hay, and stored foodstuffs. Another species, *P. ventricosus* preys on the larvae of wood-boring beetles, including the common furniture beetle *Anobium punctatum*. There has been some confusion about nomenclature of *Pyemotes* species [1].

Pyemotes mites have been responsible for attacks of dermatitis in those shovelling grain or coming into contact with infested straw [2] and husk rice [3]. The dermatitis has been referred to by a number of terms, including 'barley itch', 'grain-shovellers' itch', 'grain itch', 'straw itch', 'cotton-seed dermatitis' and 'acarodermatitis urticarioides'. *Pyemotes* dermatitis has been reported in shop workers coming into contact with wheat used for decorative purposes [4–6]. Dermatitis in workers in a food-mixing shed at a piggery was attributed to *P. herfsi* [7], and *P. zwoelferi* was incriminated in dermatitis acquired by contact with a package of everlasting flowers [8]. Dermatitis in a fisherman handling crab pots made of cherry wood was probably caused by *P. beckeri* [9].

An outbreak of dermatitis in a small hospital in Queensland, Australia, was attributed to *Pyemotes* mites originating in an adjacent grain storage facility [10].

Clinical features [11,12]. The lesions are urticated papules surmounted by vesicles; occasionally they may be bullous. They are often very numerous, and their distribution depends upon the mode of exposure. In grain handlers, they are usually on the forearms and neck, but they may be profuse around the waist and in the groins.

Family Tydeidae

Dermatitis in eight woodworkers in Perugia, Italy, was attributed to contact with *Pronematus davisi* mites on wood imported from North America [1]. This mite has a worldwide distribution, and is widespread in North America, where it usually lives under bark.

Plant mites

Some mites of the family Tetranychidae ('spider mites') cause cutaneous irritation or urtication in humans [1–4]. These mites are phytophagous and occur on every type of crop and ornamental plant. The name 'spider mites' is derived from the silk webbing they produce from palpal glands.

Cheyletiella mites

Biology and epidemiology. Species of *Cheyletiella* mites are non-burrowing, obligatory parasites of certain mammals, predominantly dogs, cats and rabbits. The entire life cycle is completed on the host. Each egg is attached to a hair shaft by means of a fine thread, which is woven around it into a cocoon-like structure by the female mite. The adult mite develops via a larval and two nymphal stages. Adult mites move rapidly over the skin surface in pseudotunnels in keratinous debris. They use their hook-like

Fig. 33.35 Lesions on the abdomen produced by *Cheyletiella* mites from a pet dog.

Fig. 33.36 *Cheyletiella yasguri*.

palpi to attach themselves to the host while feeding on tissue fluids [1,2].

Cheyletiella mites were first reported as attacking humans by Lomholt [3] of Copenhagen, and in 1938 a case was reported from England [4]. It gradually became apparent that *Cheyletiella* infestation of dogs, cats and rabbits was common in most European countries, in the USA [5], in Canada [6] and in Australasia [7,8]. The distribution of these mites is likely to be worldwide. Many earlier reports incorrectly identified the species as *C. parasitivorax* when it was probably *C. yasguri*. It is now clear that *C. parasitivorax* is predominantly a parasite of rabbits, *C. yasguri* of dogs, and *C. blakei* of cats [9,10]. The three species are morphologically very similar, but distinguishable by the shape of a special sensory organ on the dorsal surface of genu I [10–12].

It is not clear from the limited information available whether the incidence of these mites is increasing, or whether infestation is becoming more frequently recognized. An investigation in the Netherlands [13] of 41 households, in which two or more cats were kept, showed *Cheyletiella* infestation of the animals in 27; 20% of the human contacts had skin lesions. Any age, breed or sex of animal may be affected. In dogs, cheyletiellosis is particularly common in boxers.

Most affected animals are asymptomatic, but some may suffer from pruritus. The most obvious sign of infestation is excessive dandruff, especially on the back, which is often known as 'walking dandruff' by veterinary dermatologists [14].

Clinical features in humans [15–17]. The typical clinical picture is of a large number of intensely itchy papules (Fig. 33.35). Surmounting the papules there may be tiny vesicles, and older lesions may show small areas of necrosis. Bullous lesions may occur [18,19]. The distribution of lesions corresponds to areas of contact with an infested animal, the abdomen and thighs being frequently involved as a result of an animal sitting on its owner's lap. The chest and arms may also be affected from carrying the animal.

In a patient with an extensive eruption, intradermal skin testing with an extract of *Cheyletiella* mites produced both immediate and delayed hypersensitivity responses [20].

Confirmation of the diagnosis [21]. The diagnosis may be confirmed by examination of combings from the animal's coat for the presence of mites. The suspect animal should be placed on a sheet of black paper, and the coat, particularly along the back, vigorously combed, preferably with a fine-toothed comb. The debris collected can then be examined microscopically (Fig. 33.36).

Treatment. The affected animal should be treated by a veterinary practitioner. Human skin lesions may be treated with a topical antipruritic. Once an animal has been treated effectively, there will be no further lesions on its owner.

Harvest mites (Trombiculidae)

Harvest mites belong to the family Trombiculidae. More than 1200 species of trombiculids have been described, and many may attack human beings or livestock [1]. They are parasitic as larvae, but free-living as nymphs and adults. The larvae may cause troublesome dermatitis (trombidiosis; scrub itch), and some are important vectors of rickettsial disease. They have many common names throughout the world, for example orange tawny (Ireland), chigger, red bug (USA).

The eggs are laid in soil. The six-legged larvae which emerge climb onto low vegetation to wait for suitable vertebrate hosts. On the host, the larvae move to areas where the skin is thin, such as the ears, axillae, groins and genitalia. There they pierce the skin with their cheliceral claws and inject saliva, which has cytolytic properties, into the epidermis [2]. This action forms a tube-like canal (stylosome), through which the mites feed on tissue fluids and cell debris. Once engorged, they fall to the ground and develop into eight-legged adults via a nymphal stage. Nymphs and adults feed on vegetable debris and the eggs of insects and other arthropods.

Neotrombicula autumnalis, the European harvest mite, is widely distributed throughout Europe. In the UK [3], the larval mites are most numerous from May to October, with a peak in September. The most favoured natural host is the rabbit. *Neotrombicula autumnalis* is not known to transmit disease.

Eutrombicula alfreddugesi and *E. splendens* are the most common chiggers attacking man in the USA, and *E. batatas* is an important dermatitis-producing species in South America.

In South-East Asia, Australia and the Pacific Islands, trombidiosis is commonly caused by *E. wichmanni*, and species of *Odontacarus* and *Schoengastia* [4,5].

Species of *Leptotrombidium*, including *L. akamushi*, *L. pallidum* and *L. deliense*, are important vectors of scrub typhus (tsutsugamushi disease), caused by *Orientia tsutsugamushi* [6]. *L. akamushi* has a wide distribution, ranging from Japan and China southwards through South-East Asia to Indonesia and eastwards throughout the Philippines to New Guinea. *L. deliense* occurs in China, the Indian subcontinent, Malaya, Indonesia, the Philippines, New Guinea and Australia. The natural hosts of *L. akamushi* and *L. deliense* are rodents and insectivores. *L. subquadratum* has been reported as a cause of pruritus and dermatitis in dogs and humans in South Africa [7].

Clinical features [4,8,9]. Humans are infested while working in or walking through grass or low vegetation. The response to the bites of harvest mites appears to be determined by the irritant effect of the mites' saliva and an acquired hypersensitivity to salivary antigens. Within a few hours, erythematous macules appear at the sites of the bites, and these gradually develop into extremely itchy papules or papulovesicles.

The distribution of lesions is determined by the preference of mites for thin skin, and the clothing of the host. Lesions commonly occur around the feet and ankles, the groins and genitalia, the axillae, the wrists and antecubital fossae, and areas constricted by clothing, such as the waistline. In heavy infestations, the whole body may be covered in lesions.

Chigger bites on the penis in children are responsible for a seasonal acute hypersensitivity reaction in the USA known as the 'summer penile syndrome' [10].

Trombiculid mite bites have provided evidence to implicate a suspect in a murder investigation [11].

Bird, rodent and reptile mites (Gamasida)

Family Dermanyssidae [1,2]

Dermanyssid mites are haematophagous parasites of birds and mammals. *Dermanyssus gallinae* (Fig. 33.37), the poultry mite, is a common parasite of domestic and wild birds. Poultry keepers, veterinary practitioners and others in direct contact with birds are sometimes attacked. Other dermanyssid mites responsible for dermatitis include *D. hirundinis* and *D. americanus*. Avian mites may enter buildings from birds' nests via windows, ventilation grilles or air conditioners, causing skin lesions on the occupants [3–7]. Mites on cage birds may cause similar problems [8]. Lucky *et al*. [9] reported itchy papular lesions related to contact with pet gerbils infested with *D. gallinae* and *Ornythonyssus sylviarum* (see below), and reviewed other reported cases of avian mite bites.

Liponyssoides sanguineus, the house mouse mite, is an ectoparasite of small rodents. It is of medical importance because it is the vector of *Rickettsia akari*, the agent causing rickettsial pox.

Family Macronyssidae [1]

Members of the Macronyssidae are haematophagous ectoparasites of birds, mammals and reptiles.

Fig. 33.37 *Dermanyssus gallinae*: comparison in size with the head of a match.

Ornithonyssus sylviarum (the northern fowl mite) and *O. bursa* (the tropical fowl mite) are pests of domestic and wild birds, and occasionally attack humans [10–13].

Ornithonyssus bacoti, although known as the tropical rat mite, is cosmopolitan, occurring in both tropical and temperate areas of the world. There are a number of reports of its effects on humans [14–17], including two groups of medical students in Lübeck, Germany [18] and Taegu, South Korea [19].

Ophionyssus natricis, a snake mite, caused skin lesions in a family owning a pet python [20].

Clinical features [2]. The clinical effects vary according to the route and severity of infestation and the degree of the host's response. Most commonly, there is a profuse eruption of small, intensely itchy weals or papules, sometimes grouped, and often asymmetrical. The lesions may have a central punctum, and vesicles occasionally occur in the centre of the papules, especially in children. Because of the intense pruritus, excoriations are common, and secondary infection may occur.

There is no characteristic distribution, as this is determined by the situation in which the bites are acquired. Those handling infested poultry tend to have lesions on the hands and forearms, whereas persons attacked by mites in bedding have more extensive bites. Occasionally, lesions are grouped adjacent to areas of tight clothing around the waistline.

In heavy infestations, the causative mites are often noticed by those affected, and any specimens obtained should be sent for identification to an entomologist familiar with Acari. When mite infestation is suspected, but no specimens are available, it may be necessary to visit the patient's home or workplace to determine the source of the problem.

Follicle mites (Demodicidae)

Demodex folliculorum (Simon), the follicle mite, is an obligate parasite of the human pilosebaceous follicle. It was first discovered in cerumen by the anatomist Jakob Henle in 1841, but it was the dermatologist Gustav Simon who provided the first complete description of the parasite, under the name *Acarus folliculorum*, in 1842 [1,2]. The generic name *Demodex* was created for it in 1843 by the zoologist Richard Owen.

Morphology and biology [1,3–5]. *D. folliculorum* measures 0.3–0.4 mm in length, and has an elongated, striated abdomen, giving it a worm-like appearance (Fig. 33.38). A morphologically distinct species, *D. brevis* Akbulatova, has been recognized [6]. *D. folliculorum* occupies the hair follicle, and the smaller *D. brevis* the sebaceous and meibomian glands.

The lifespan of *D. folliculorum* is thought to be approximately 2 weeks [5]. The heart-shaped eggs hatch to produce hexapod larvae, and the eight-legged adults develop via two nymphal stages.

Follicle mites show a predilection for areas of high sebum production [7] and they have been shown to contain lipase [8]. They are most numerous on the forehead, cheeks, nose and nasolabial folds, but they are also found on the scalp, in the external ear, in eyelash follicles and meibomian glands, and on the upper chest and nipples. They have also been discovered on the penis, mons veneris, buttocks and in ectopic sebaceous glands in the buccal mucosa [9]. *D. folliculorum* assumes a head-down position in the follicle, often with the tip of the abdomen protruding from the follicular orifice. Follicle mites are quite motile, and migrate from follicle to follicle. Most infested follicles contain two to six mites, but occasionally they are much more numerous. Mites have been isolated from individuals of all ages, except neonates [10]. Transmission to infants probably occurs as a result of close maternal contact. The prevalence of both *D. folliculorum* and *D. brevis* increases with age [11,12] and it is likely that with adequate sampling techniques, mites could be discovered in some follicles in the entire adult population. The skin-surface biopsy technique is a useful method of assessing the population density and distribution of *Demodex* mites [13–15].

Fig. 33.38 *Demodex folliculorum*, the follicle mite.

Pathogenicity. *D. folliculorum* has been implicated in the pathogenesis of a condition named pityriasis folliculorum [1–3]. This was originally described as occurring predominantly in middle-aged or older women who rarely washed their faces, but used large quantities of make-up

and cleansing creams. The lack of washing and use of facial cosmetics were considered to be aetiological factors, but a similar appearance has subsequently been described in women who washed their faces regularly [4,5]. This dermatosis is characterized by diffuse facial erythema and follicular plugs, which impart a 'nutmeg-grater' appearance to the skin. In reported cases, skin scrapings have contained unusually large numbers of *Demodex*, and the condition has responded to treatment with topical acaricides.

The question of the pathogenic role of *Demodex* in rosacea has prompted much debate in the past [6,7]. Although recent studies employing skin-surface biopsy have shown statistically significant increases in the density of *Demodex* mites in the facial skin of patients with rosacea compared with controls [8–12], it is still not clear whether rosacea merely provides a suitable environment for multiplication of the mites, or whether the mites play a role in initiating the disease. Skin biopsies taken from patients with rosacea, following topical therapy with sulphur, failed to show any correlation between clinical improvement and reduction in mite population [13]. In large studies of the histopathology of rosacea [14,15], *Demodex* was conspicuously absent from areas of inflammation in sections in which it was found.

It has been suggested that a local delayed hypersensitivity response to *Demodex* antigens might be partly responsible for the inflammatory component of rosacea [14], and the observation that most T cells in the granulomatous infiltrate surrounding extrafollicular *Demodex* are helper–inducer T cells [16] lends support to the hypothesis that the pathogenesis of rosacea involves a cell-mediated immune response.

Although extrafollicular *Demodex* or fragments of *Demodex* may be found in the granulomatous lesions of rosacea [17,18], its role in their induction has not been established. The mite may simply be displaced because the hair follicles have been destroyed by the inflammatory process.

A view that the beneficial effects of metronidazole in rosacea might be mediated through an action against *Demodex* [19] was not supported by the finding that mites can survive high concentrations of this drug *in vitro* [20].

Rosacea-like eruptions in which large numbers of mites could be demonstrated and which responded to therapy with acaricides [2,21–24] or metronidazole [25] have been described. The effectiveness of acaricidal treatment can be evaluated by skin-surface biopsy [26].

Demodex has been implicated in the causation of papular and papulopustular lesions in immunosuppressed individuals, including children with leukaemia [27–29], a patient with tumour-stage mycosis fungoides [30] and patients with HIV infection [31–34].

Facial lesions attributed to *Demodex* have been described in immunocompetent children, in the form of a localized scaly patch [35], and rosacea-like and pityriasis folliculorum-like lesions [36].

Demodex is present in eyelash follicles, and has been implicated in the pathogenesis of blepharitis in some patients [37–39], although its importance as a cause is disputed [40].

The observation of fungal spores [41] and *Mycobacterium leprae* [42,43] within *Demodex* mites has led to the suggestion that the mites may act as vectors for these organisms.

Class Chilopoda (centipedes) and Diplopoda (millipedes)

Centipedes

Centipedes are elongated arthropods, with bodies composed of many segments, each bearing one pair of legs. They are nocturnally active carnivores, and feed on insects. Some of the giant species also feed on small mice and birds. The first pair of legs is modified, and provided with powerful hollow claws, which are used to grip prey and inject venom from poison glands in the basal segments of the legs.

The claws of smaller species of centipedes are unable to penetrate human skin, but some tropical and subtropical species, principally members of the orders Scutigeromorpha and the giant Scolopendromorpha, can inflict painful 'bites' [1–6]. The bites cause local pain, erythema and oedema, which may persist for several hours. Systemic symptoms include nausea, dizziness and pyrexia.

Fig. 33.39 Giant millipede. (Courtesy of M. Fogden/Oxford Scientific Films.)

Millipedes

Millipedes also have multisegmented bodies, and most segments bear two pairs of legs (Fig. 33.39). They feed mainly on decaying vegetable matter, and are generally regarded as harmless, but some large tropical species can cause injury to humans when acting defensively. The injurious effects of the defensive secretions of the giant spirobolid millipedes of tropical and subtropical zones are well known to the indigenous populations of these areas.

Millipedes have numerous 'repugnatorial' glands distributed along the body segments, which provide a chemical defence system, and it is the corrosive secretions of these glands which may cause burns on the skin. In the majority of species, these secretions ooze out and form droplets around the foramina of the glands, but a few species (*Spirobolida*, *Spirostreptida* and *Rhinocrichus*) are capable of squirting the fluid for some distance [7,8]. Millipede secretions contain benzoquinones and hydroquinones.

Clinical features of millipede burns [1,7,9–11]. Children often try to pick up millipedes, and are therefore at most risk of burns from the corrosive defensive secretions. If millipede secretions enter the eye, they produce a severe irritant conjunctivitis. Contact with the skin produces a local burning sensation and a yellowish-brown stain, which gradually darkens to deep mahogany or purple-brown. This colour is produced by oxidation of the quinones in the secretions. The lesions blister within a day or two, but in the absence of secondary infection, will heal and desquamate in 10–14 days. The discoloration may persist for months. In dark-skinned individuals, persistent hypopigmentation is a common sequel.

Treatment [7]. Skin lesions should be washed with copious amounts of water to remove any remaining secretions, and the area cleaned with alcohol (a solvent of

benzoquinones) if available. Blisters should be treated with a topical antiseptic. Ocular injuries should be dealt with by an ophthalmologist.

Other noxious or venomous invertebrates

Leeches (Hirudinea)

Leeches are classified in the phylum Annelida (segmented worms), class Clitellata, in which they constitute the order Hirudinea. Fresh-water leeches were a popular method of bloodletting in Europe in the 18th and 19th centuries [1,2]. Although several species of leeches were used, the medicinal leech, *Hirudo medicinalis*, was the most popular. A large specimen of *H. medicinalis* may measure about 12 cm when fully extended. The body tapers towards each extremity, where it is provided with a muscular disc or sucker. Within the anterior sucker is the mouth, bordered by three jaws. Leeches attach themselves to the skin using these powerful jaws, and feed until engorged, when they release their grip and drop to the ground. Their saliva possesses anticoagulant, fibrinolytic, vasodilator and probably also anaesthetic properties. Some of the substances introduced by leeches during feeding are antigenic, and if sensitization to these substances develops, the reaction to the bite may be urticarial or bullous [3]. Multiple pseudolymphomas have occurred following application of leeches to the legs [4].

In recent years, there has been a revival of interest in the use of leeches for therapeutic purposes. They are being employed in microvascular surgery to salvage replants or skin flaps whose viability is threatened by venous congestion [5,6], and also for drainage of large haematomas. Unfortunately, the use of leeches carries the risk of introducing wound infection, most frequently with *Aeromonas hydrophila*, a Gram-negative rod, but occasionally other organisms are involved [7–10]. *Aeromonas* is part of the normal gut flora of the leech, where it is thought to be essential to aid digestion of a blood meal, as proteolytic enzymes are virtually absent from the leech gut. *A. hydrophila* is frequently susceptible *in vitro* to third-generation cephalosporins, aminoglycosides, trimethoprim–sulfamethoxazole, chloramphenicol, tetracyclines and several of the quinolones. It is often resistant to most penicillins, first-generation cephalosporins, amoxicillin–clavulanic acid, vancomycin and erythromycin [11,12]. Many plastic surgeons who use leeches employ antibiotic prophylaxis to protect against wound infection.

Jellyfish, sea anemones, corals (Cnidaria)

The phylum Cnidaria [1–3] includes the jellyfish, sea anemones and corals. All are aquatic, and the majority are marine. Three of the four classes of the phylum have a medusa or 'jellyfish' stage in their life cycles. Cnidarians have tentacles bearing batteries of stinging cells (nematocysts) which are used for defence and capturing prey. Within each nematocyst is a spirally coiled thread that can be everted, uncoiled and forcibly ejected. In contact with prey, or with human skin, the nematocysts are discharged and the threads inject a venom. The nature and toxic effects of the venom vary with species. Many species inflict at least some discomfort on humans, and some are potentially dangerous [3–6].

Class Hydrozoa. This class includes the fire corals and free-floating members of the subclass Siphonophora. The Siphonophora are colonial organisms in which a number of individuals, specialized for different functions, are

structurally associated. Perhaps the best known siphonophoran is *Physalia*, the Portuguese man-of-war. This has the local name of 'bluebottle' in Australia. It has an air-filled float, which acts as a sail, and trailing tentacles. The nematocysts occur in 'batteries' or 'sting buttons' along the tentacles, and contact with them results in extrusion of numerous nematocysts and the inoculation of venom.

Class Cubozoa. Often referred to as 'box jellyfish'; several species are dangerous to humans [3]. The most notorious is *Chironex fleckeri*, which has been responsible for a number of deaths in Australian waters. Other dangerous species include *Carybdea rastoni* (the 'jimble'), and *Carukia barnesi* (the 'Irukandji') [7]. Another box jellyfish named 'Morbakka' has caused problems in the Moreton Bay area of South Queensland, Australia [8].

Class Scyphozoa. The medusa is the dominant form of the life cycle. Jellyfish of this class are distributed worldwide, and some have medical significance.

Class Anthozoa. This class contains several thousand species, including the sea anemones, the soft corals and the stony or true corals. Several species of sea anemone are known to inflict painful stings [2,3,9,10].

The reef-forming corals may cause injury to the skin with their nematocysts, or with their calcareous outer skeletons [11].

Clinical features [3,12,13]. Contact with *Physalia* tentacles usually results in a linear erythematous eruption accompanied by severe local pain. Because of the arrangement of 'sting buttons' of nematocysts, there is a beaded pattern of local small weals. In humans, pain and skin lesions are usually the limits of toxicity, but occasionally more severe reactions occur [14]. Haemolysis and acute renal failure in a 4-year-old girl [15], and fatalities, have been reported [16,17].

The local effects of box jellyfish tentacle contact are immediate severe pain, and linear weals with a white, ischaemic centre. Larger weals may have a typical 'cross-hatched' or 'frosted-ladder' pattern corresponding to the architecture of the tentacles. Partial or full-thickness skin necrosis may result. Box jellyfish may be responsible not only for local lesions, but also for severe systemic effects, which may result in death [3,7].

In addition to acute skin lesions, which are regarded as toxic in nature, there may be persistent or recurrent eruptions at the original sites of cnidarian envenomation [18–23], attributed to delayed hypersensitivity. Recurrent episodes may be single or multiple, and may take the form of erythema, urticarial lesions, papules or plaques. A delayed hypersensitivity response to jellyfish antigens has been demonstrated by a positive patch-test reaction to a nematocyst preparation from *Olindias sambaquiensis* [24].

Fig. 33.40 Seabather's eruption. (Courtesy of Dr R. MacSween, Kingston, Ontario, Canada.)

Other reported sequelae of jellyfish stings include erythema nodosum [25], cold urticaria [26] and Mondor's disease [27].

Envenomation by fire corals usually produces immediate burning or stinging pain, followed by urticarial lesions at the site of contact. These may in turn be followed by a localized vesiculobullous eruption, and subsequently chronic granulomatous and lichenoid lesions [28–30]. Stinging of an aquarium shop worker by a stony coral, *Euphyllia picteti*, has been reported [31].

Seabather's eruption [32–37]. Itchy, erythematous papules and weals occur predominantly under swimwear, and lesions are usually concentrated in tight-fitting areas (Fig. 33.40). The organisms become trapped under the bathing costume, and discharge of nematocysts is triggered. It is probable that a similar clinical picture can be produced by different coelenterates in different waters. In Florida, the Gulf of Mexico and the Caribbean, *Linuche unguiculata* (thimble jellyfish) appears to be responsible, and evidence has recently been presented that all three free-swimming stages of this jellyfish can cause seabather's eruption [38]. Specific IgG antibodies against *L. unguiculata* antigen have been demonstrated by enzyme-linked immunosorbent assay (ELISA) in patients with seabather's eruption [39]. Cases in the Long Island region, New York, have been attributed to larvae of the sea anemone *Edwardsiella lineata* [32].

Pathology. The acute changes in the skin resulting from cnidarian stings consist of intracellular oedema of keratinocytes, many of which have pyknotic nuclei, and a lymphocytic infiltrate in an oedematous superficial dermis [40]. Nematocysts were visible penetrating the epidermis in a 5-year-old child who suffered fatal envenomation from *Chironex fleckeri* [41].

Histology of recurrent reactions shows a spongiotic vesicular dermatitis with a dense perivascular lymphohistiocytic infiltrate, often containing large numbers of eosinophils [20,42]. There is oedema of the papillary dermis. Immunohistochemical studies suggest that Langerhans' cells and helper T lymphocytes play a central role, and that type IV delayed hypersensitivity is involved in the pathogenesis of the lesions [42]. Epithelioid granulomas and large $CD30^+$ lymphocytes were present in a delayed reaction to a fire coral [43].

Treatment [3,44,45]. Inhibition of further discharge of nematocysts is an important aspect of first aid for some cnidarian stings. Vinegar inhibits discharge of the nematocysts of all the box jellyfish, and should be poured over the affected area of skin as soon as possible. However, in other jellyfish discharge is not inhibited, and may be provoked by vinegar.

The application of cold packs has been shown to provide relief of mild to moderate pain resulting from stings by *Physalia* and a number of species of jellyfish. An antivenom is available for use in *Chironex fleckeri* envenomation.

In Australia, protective clothing in the form of Lycra 'stinger suits' is extremely useful in the prevention of jellyfish envenomation.

Sea mats (Bryozoa)

The Bryozoa are small, sedentary, colonial animals, which usually form mat-like encrustations on rocks, seaweeds or other surfaces. *Alcyonidium gelatinosum* occurs in the North Sea, where it can cause severe occupational dermatitis in fishermen who may have to remove large quantities from their nets. 'Dogger Bank itch' is an acute papular, occasionally bullous, contact dermatitis on the hands, arms and face [1–6], which may have a photoallergic component [7]. Hypersensitivity to another bryozoan, *Electra pilosa*, has also been described [7,8].

Sea urchins (Echinoidea)

The Echinoidea, or sea urchins, form part of the phylum Echinodermata, which also includes the starfishes and sea cucumbers [1–3]. Sea urchins are usually spherical or ovoid, and are enclosed in a shell of closely fitting plates supplied with numerous moveable spines. The spines are formed by calcification of a cylindrical projection of subepidermal connective tissue. Situated between the spines are three-jawed pedicellariae, some of which are venomous. They are used to seize prey, and also in defence. In some species of sea urchins, the spines are also venomous.

Pathogenesis of skin lesions. Many species can cause unpleasant lesions of different types [4,5]—intense local pain and swelling following envenomation by spines or pedicellariae; secondary infection of the spine puncture wounds; development of implantation epidermoid cysts from fragments of epithelium driven into the wounds by the spines; late development of granulomatous skin lesions; synovitis, and joint damage if the spines penetrate joint cavities [6]. Occasionally, systemic upset accompanies the local changes.

Pathology [7]. In chronic lesions, a granulomatous inflammatory reaction predominates, with foreign-body or sarcoidal types the most frequent. Non-granulomatous chronic inflammation may also occur.

Clinical features [1,3–5]. Envenomation by sea urchins produces immediate burning pain, which may be very intense and persist for several hours. The degree of local swelling is variable, but is sometimes severe. In the absence of secondary infection, the puncture wounds heal within a week or two.

Delayed granulomatous reactions usually develop several months after the original injury, and take the form of bluish papules or nodules at the sites of penetration of the spines. On the digits, there may be diffuse fusiform swelling and limitation of movement. These lesions are very persistent if not treated.

A patient with a pruritic erythematous eruption on the knees and ankles following injury by a sea urchin produced a positive patch-test reaction to an extract of sea-urchin spines [8].

It has been suggested that *Mycobacterium marinum* may play a pathogenic role in some cases of sea urchin granuloma [9].

Treatment [4,5]. Immediate treatment consists of careful removal of spines and pedicellariae. Immersion of the affected area in hot water will provide pain relief. Local inhabitants in certain areas where sea-urchin injuries are common apply hot candle wax to the area [10]. The spines are difficult to remove surgically, but erbium–yttrium-aluminium-garnet (Er:YAG) laser ablation has proved effective [11]. If the spines have penetrated a joint, surgical exploration is advisable. The granulomatous lesions may be treated with intralesional steroid.

Sponges (Porifera) [1,2]

Tedania ignis (the fire sponge) is capable of producing a severe dermatitis, and has also been reported as inducing erythema multiforme-like lesions of the face, palms and soles 10 days after contact [3]. Dermatitis may also be caused by several other sponges, including *Neofibularia nolitangere* (the poison bun sponge) and *Microciona prolifera* (the red sponge).

Mollusca

The only important venomous univalve molluscs are cone shells of the genus *Conus* [1–3]. All the species of this genus possess a venom apparatus, and several species have caused human injury.

The stings are painful puncture wounds, with local ischaemia, cyanosis and numbness, the numbness quickly spreading to involve the whole body. The sting of some species, particularly *C. geographus* [2,4], may be fatal.

The very small floating mollusc *Creseis acicula* Rang has been incriminated as a cause of stings in bathers in Florida [5].

The tiny blue-ringed octopus (*Hapalochlaena maculosa*), a member of the Cephalopoda class of molluscs, and found mainly in Australian coastal waters, has been called the world's most deadly octopus. When agitated, the blue rings become very prominent. The bite of this octopus contains salivary toxins that may cause severe systemic symptoms culminating in death, usually from respiratory failure [6,7]. Cutaneous problems following *H. maculosa* bites include intense pruritus and urticaria [3,6,8].

Erythema, oedema and a burning sensation followed the bite of *Octopus apollyon*, succeeded by a persistent erythematous plaque and lymphoedema [9].

Noxious or venomous vertebrates

Venomous fish [1–3]

Numerous species of fish are capable of inflicting painful or even dangerous stings by means of dorsal or caudal spines provided with complex venom glands.

Venomous species are not confined to tropical waters. The lesser weever fish, *Echiichthys vipera* [4,5], the spiny dogfish (*Squalus acanthias*) and several species of stingray occur on the Atlantic coasts, and can inflict serious stings.

In warmer waters, species of stingray, scorpionfish, catfish [6], rabbitfish, stonefish [7], the aptly named 'bearded ghoul', stargazers and toadfish are potentially dangerous. In many cases, injuries are the result of the victim inadvertently stepping on the fish in shallow water. The tail of the stingray carries serrated spines containing venom glands surrounded by an integumentary sheath. Treading on the fish results in a reflex 'whip' of the tail, which drives the spines into the skin, usually on the leg [8]. Several of these venomous species bury themselves in the sand in shallow waters, with their spines protruding, and are therefore a hazard to bathers.

Clinical features. Injuries commonly occur on the feet or legs, as a result of the victim stepping on the fish. Fish stings are usually immediately painful. They present as painful lacerations or puncture wounds. Intense pain may continue for several hours, and swelling and erythema around the wounds may simulate an infective cellulitis. With some species, systemic symptoms may occur. Stingray spines may cause lacerations, or may be driven into the skin and break off. If the integumentary sheath ruptures, envenomation occurs. In severe stingray wounds, the affected area appears dusky or cyanotic, and later becomes erythematous or mottled, with necrosis of underlying fat and muscle [9].

The inflammatory infiltrate in one case of stingray envenomation contained numerous mononuclear cells, many of which were TIA+, suggesting that an immunological reaction might contribute to the delayed healing commonly seen after stingray injury [10].

Treatment. The venom of the weever fish, like that of the stingray, stonefish and other venomous fish, is an unstable protein which is heat-labile, and hot water is very effective in treating the stings [3,11–13]. The injured part should be immersed in hot water (someone other than the

victim should gauge the temperature), and this will diminish the pain. An antivenom is available for stonefish stings.

Snake bites

The highest incidence of snake bites is in South America, West Africa, the Indian subcontinent and South-East Asia [1,2]. In India, there are an estimated 10 000–50 000 deaths a year, and in Burma, snake bites cause about 1000 deaths a year [3].

The effects of snake envenomation vary according to the composition of the venom—for example, bites of the spitting cobra (*Naja nigricollis*) produce local swelling and necrosis, haematological abnormalities and complement depletion [4]; the venom of the Malayan krait (*Bungarus candidus*) contains a toxin (bungarotoxin) that interferes with transmission at the neuromuscular junction [5]; marked coagulation disturbances occur after envenomation by Australian brown snakes (genus *Pseudonaja*) [6]. Surveys of deaths from snake bite in Australia [7,8] have shown that the majority were due to brown snakes.

Treatment [8]. The first-aid and field management of victims of snake bites in Australia changed when the compression bandage–splinting method of first-aid treatment was introduced by Sutherland [9], and shown to be effective [10]. This method consists of the application of a firm compression bandage to the limb that has sustained the bite, and its immobilization by splinting. The centripetal flow of venom is markedly impeded by this procedure. The offending snake should be killed if possible, and kept for identification by a qualified herpetologist. If the snake cannot be identified, venom detection kits are used on swabs taken from the bite site to determine the appropriate antivenom. Unfortunately, there is limited availability of antivenoms in other parts of the world [3].

Other animal bites

An enormous variety of other animals may occasionally bite humans. Most bites cause a variable degree of crushing and tearing of the skin, and the devitalized tissue readily becomes infected by the wide range of microorganisms found in the mouths of animals.

Dog and cat bites

The highest incidence of dog bites occurs in school-aged children [1], and boys are bitten twice as often as girls. In contrast, wounds caused by cats occur more commonly in girls [2].

Most infections which develop from dog and cat bites are polymicrobial, and include aerobic (*Staphylococcus* species, *Streptococcus* species and *Corynebacterium* species) and anaerobic (*Bacteroides fragilis*, *Prevotella*, *Porphyromonas*, *Peptostreptococcus*, *Fusobacterium* species and *Veillonella parvula*) organisms. Cat scratch disease, caused by *Bartonella henselae*, can follow a bite from a cat. There are a number of other potentially pathogenic organisms, including those described below.

Capnocytophaga (formerly dysgonic fermenter type 2) [3–10]

Capnocytophaga canimorsus is part of the normal oral flora of healthy dogs, cats and a number of other animals.

The majority of reported *Capnocytophaga* infections have been associated with exposure to animals, about 80% following exposure to or bites from dogs. Previous splenectomy and alcoholism are predisposing factors, but infection may occur in perfectly healthy persons.

The spectrum of illness ranges from local wound infection to fulminant septicaemia. Skin lesions include a localized eschar at the site of the bite, cellulitis, non-specific macular or maculopapular lesions, erythema multiforme [4], petechiae, purpura fulminans and symmetrical peripheral gangrene. The more severe changes occur as a consequence of septicaemia and disseminated intravascular coagulation [8–10].

Confirmation of infection depends upon identifying intracellular bacilli on direct microscopy by Gram staining of blood films and buffy coats, and isolation from blood and tissue cultures [5]. The organism is sensitive *in vitro* to most penicillins, cephalosporins, erythromycin, tetracyclines and clindamycin.

Eugonic fermenting bacteria (EF-4)

Organisms belonging to this *Pasteurella*-like group are frequently present in the oral and nasal fluids of dogs. EF-4 bacteria have been isolated from abscesses caused by animal bites [11], but only rarely cause any human pathology.

Pasteurella multocida [3,5,12,13]

This is an aerobic Gram-negative coccobacillus, which is also a normal component of the oral flora of dogs and cats. Bites or scratches which become infected are usually complicated by inflammation and a purulent discharge. Abscess formation, tenosynovitis, septic arthritis and osteomyelitis may also occur.

Pasteurella multocida is sensitive to penicillins, cephalosporins, tetracyclines and ciprofloxacin.

Seal finger [14–16]

Seal finger may be encountered wherever sealing takes place, especially around Greenland, Newfoundland and Spitzbergen, but it also occurs in the Falkland Islands and South Georgia. In Denmark, the disease occurs sporadically from the bites of seal pups, but it is also acquired by handling dead animals. A case has been reported in a veterinary surgeon from Norfolk, UK, after he had performed a necropsy on a seal [15]. It is common in the spring in seal trainers at the New England Aquarium in Boston, Massachusetts, and although the aetiological agent has not been established with certainty, *Mycoplasma* species were isolated from an infected seal trainer, who responded to treatment with tetracycline [16].

The usual clinical picture is of a painful, swollen, slightly erythematous finger. There are usually no constitutional symptoms. Many cases resolve spontaneously with no sequelae, but in others joint involvement may lead to synovitis, osteitis, fibrosis of periarticular tissues and disfiguring arthropathy.

Rodent bites

There are a number of reports of anaphylaxis following rodent bites [17–19].

Human bites

Human bites are quite common, clenched fist injuries ('fight bites') being the most prevalent, and may introduce dangerous bacterial infection [3]. Necrotizing fasciitis caused by group A streptococci has resulted from a human bite on the calf (at a Bavarian Oktoberfest!) [20]. Transmission of herpesvirus types 1 and 2, and of hepatitis B and C, has also been documented. An epidemic of hepatitis B was traced to a carrier in a residential institution for the mentally retarded who regularly bit his fellow residents [21]. Biting is also a possible transmission mode for HIV infection [22].

A traumatic neuroma following a human bite on the forearm has been reported [23].

The possibility of physical abuse should be considered in children with human bites. However, most bites in children are inflicted by other children [24].

Treatment [1,25,26]. All animal and human bites are potentially dangerous, and thorough irrigation with normal saline, exploration and debridement are required. Prophylactic antibiotics are given in some cases. If infection develops, appropriate antibiotics for *Pasteurella multocida*, staphylococci and streptococci should be administered.

Rabies should be considered as a possible sequel to any animal bite if this occurs in countries in which the disease is endemic.

Chapter 34

Disorders of Keratinization

M.R. Judge, W.H.I. McLean & C.S. Munro

The molecular genetics of keratinizing disorders

Classification of keratinizing disorders. The term 'disorders of keratinization' refers to a broad spectrum of skin disorders where there is abnormal differentiation of the epidermis and/or appendages, often with aberrant formation of the cornified envelope [1]. These disorders may have associated epidermal fragility, and there is clinical and pathological overlap with inherited and acquired blistering disorders (see Chapters 40 and 41). Epidermal and/or adnexal defects may exist in isolation or can also be associated with additional extracutaneous features. The pathogenesis of many of the acquired disorders included in this chapter is poorly understood and may prove to encompass a variety of infective, inflammatory or other causes. However, many disorders of keratinization are inherited as single-gene Mendelian traits, and understanding their aetiology has permitted re-evaluation of their classification. Traditionally, this group of diseases has been classified according to clinical, histological and ultrastructural findings. As the majority of the genetically determined disorders are uncommon in the population, the morphological approach has been beneficial to the practising clinician and offers a logical pathway to diagnosis when confronted with a patient with an

unknown disorder. Remarkable advances have been made in molecular genetic technology during the past decade or so, stemming from the development of the polymerase chain reaction (PCR) technology and related techniques from the late 1980s onwards [2]. This technology facilitates rapid amplification and DNA sequencing (decoding) of genes and parts thereof, using minute amounts of patient DNA as the starting material. This, coupled with the recent advances in the mapping and near-complete sequencing of the entire human genome, have led to a rapid increase in understanding the basic molecular defects responsible for inherited disorders of keratinization, and these advances have made possible a new, molecular mechanism-based approach to their classification, which complements the pre-existing morphological classification system (Table 34.1). These molecular genetic and biological insights have in many cases confirmed the accuracy of the original clinical distinctions. As knowledge increases, however, the association of mutations in one gene with a distinct phenotype has become more complicated, as illustrated below.

Genotype–phenotype correlation. A good example of phenotypic heterogeneity arising from mutations in a single gene is that of keratin K1. Heterozygous dominant negative mutations in suprabasal keratins K1 and K10 were initially reported to be the genetic basis of bullous ichthyosiform erythroderma of Brocq (BIE) [3,4]. These mutations were strongly clustered in parts of the keratin molecule that are known to be critical for keratin assembly and function (see Intermediate Filament Mutation database; http://www.interfil.org). In an early genetic study of a family with a quite typical BIE mutation in K1, there were mildly and severely affected persons within one family, all of whom had inherited the same mutation [5]. Later, in a family originally diagnosed by Brocq himself as having a consistently milder BIE phenotype, a mutation was found in a region of the K1 protein, linker L12, where mutations in other keratins produced milder phenotypes [6]. Later still, larger deletion and insertion mutations have been identified in K1 that produce primarily palmoplantar keratoderma [7,8]. The latter phenotype is easily confused with the Vörner form of epidermolytic palmoplantar keratoderma (EPPK) resulting from K9 mutations [9]. Certain mutations have also been associated with mild annular [10] and polycyclic erythematous forms of BIE [11]. More recently, a frameshift mutation affecting only the V2 domain of K1 was shown to consistently produce a phenotype closely resembling ichthyosis hystrix of Curth–Macklin in an African American kindred [12]. In contrast, an almost identical frameshift in K1 produced a very much milder striate keratoderma phenotype in a British Caucasian kindred [13]. In each of the phenotypes associated with these K1 mutations, there is histological evidence of epidermolytic hyperkeratosis (EHK) and ultrastructural evidence of suprabasal tonofilament disruption; however, the tissue distribution and severity of EHK is quite variable. Similar complexity of genotype–phenotype correlation has been identified in disorders caused by mutations in desmosomal proteins and connexins.

There are a number of lessons from these studies. First, mutations affecting different parts of a gene (and thus specific protein domains) can lead to radically different phenotypes. Secondly, there can be phenotypic variation between families carrying similar mutations, and even within one family where all affected persons have the same mutation. The source of phenotypic variation is presumed to be a result of a combination of unknown genetic modifying factors and environmental influences. Thirdly, there can in some instances be ethnic variation in phenotypes resulting from similar or identical mutations. In this case, there is possibly a greater scope for variation in both genetic background and environmental factors. As time goes on and more cases are studied at the molecular level in close consultation with experienced clinicians, greater insights will be gained into the molecular basis and classification of these diseases, as well as the subtle functions not just of proteins but of individual protein domains in epithelial biology.

The biology of keratinization revealed through genetics. Over the last decade, a great deal has been learned about the basic cell biology of epidermal differentiation and keratinization through the study of genetic disorders of this biological system. The various classes of molecules shown to be involved in this system, along with their respective genetic diseases, are listed in Table 34.1. Some of the defective molecules have a mainly structural role in maintaining the mechanical integrity of the epidermis and its appendages in the face of persistent physical trauma. The keratin intermediate filament cytoskeleton has been shown to be a major player in providing mechanical strength for epithelial cells. To date, mutations in 18 keratin genes are linked to cell fragility syndromes affecting the epidermis, adnexae and other epithelia [14]. Similarly, mutations in keratin-associated proteins, such as desmosomal proteins and molecules involved in the cross-linking of keratins during cornification, such as loricrin, have been linked to other keratinizing disorders [15]. Defects in molecules involved in regulating the movement of ions and other small molecules between cells of the epidermis have also been linked to a range of keratinizing disorders, including gap junction proteins [16] and calcium pump molecules [17]. Calcium metabolism plays an important part in the control of epidermal differentiation [18], as evidenced by the phenotype of Darier's disease. Similarly, there is a range of enzymes involved in lipid metabolism, which is integral to the production of the cornified cell envelope (a highly cross-linked protein–

Table 34.1 Known gene defects in disorders of keratinization.

Disorder	Genes affected	Further information
Keratin disorders		
Annular epidermolytic ichthyosis variant of BCIE and cyclic ichthyosis	*KRT10, KRT1*	Suprabasal keratin 10 (chr 17q12–q21) for annular variant; keratin 1 for cyclic ichthyosis (chr 12q11–q13)
Bullous congenital ichthyosiform erythroderma (BCIE)	*KRT1, KRT10*	Suprabasal keratins 1 and 10 (chr 12q11–q13 and 17q12–q21)
BCIE naevus	*KRT10, KRT1*	Keratin 10 (chr 17q12–q21) and keratin 1 (chr 12q11–q13)
Diffuse non-epidermolytic palmoplantar keratoderma	*KRT1*	Keratin 1 (chr 12q11–q13)
Epidermolytic palmoplantar keratoderma	*KRT9*	Keratin 9 (type I keratin; chr 17q12–q21). Keratin specific for palm and sole skin
Focal non-epidermolytic palmoplantar keratoderma	*KRT16*	Keratin 16 (chr 17q12–q21). Constitutive expression in palm and sole epidermis and other sites
Pachyonychia congenita type 1 (PC-1; Jadassohn–Lewandowsky form)	*KRT6A, KRT16*	Dominant-negative mutations in differentiation-specific keratins K6a (chr 12q11–q13) or K16 (chr 17q12–q21)
Pachyonychia congenita type 2 (PC-2; Jackson–Lawler form)	*KRT6B, KRT17A*	Dominant-negative mutations in differentiation-specific keratins K6b (chr 12q11–q13) or K17 (chr 17q12–q21)
Steatocystoma multiplex	*KRT17A*	K17 (chr 17q12–q21). Some cases appear to be allelic variant of PC-2
Ichthyosis bullosa of Siemens (IBS)	*KRT2E*	Epidermal keratin 2 (chr 12q11–q13). Expressed in late suprabasal cells of epidermis
Ichthyosis hystrix (Curth–Macklin)	*KRT1*	Frameshift mutation in V2 domain of keratin 1 (chr 12q11–q13)
Striate palmoplantar keratoderma	*KRT1*	Frameshift mutation in V2 domain of keratin 1, almost identical to IHCM defect, above (chr 12q11–q13)
Desmosome proteins		
Dilated cardiomyopathy with woolly hair and keratoderma	*DSP*	Desmoplakin 1 (chr 6p2)
Ectodermal dysplasia with skin fragility	*PKP1*	Plakophilin 1 (chr 1q)
Naxos disease	*JUP*	Plakoglobin, component of desmosome and adherens junction (chr 17q21)
Striate palmoplantar keratoderma	*DSG1, DSP, KRT1*	Desmoglein 1, a desmosomal cadherin (chr 18q12.1) Desmoplakin 1, role in attachment of intermediate filaments to the desmosome (chr 6p2)
Cornified cell envelope proteins		
Loricrin keratoderma (Vohwinkel's syndrome: ichthyotic/Camisa variant)	*LOR*	Loricrin, component of cornified cell envelope (chr 1q21). One pedigree presented as progressive symmetric erythrokeratoderma (PSEK)
Gap junction proteins		
Clouston's syndrome (hidrotic ectodermal dysplasia 2)	*GJB6*	Connexin 30 (chr 13q12)
Erythrokeratoderma variabilis (EKV)	*GJB3*	Connexin 31 (chr 1p35.1)
EKV with erythema gyratum repens	*GJB4*	Connexin 30.3 (chr 1p35.1)
Palmoplantar keratoderma and deafness	*GJB2*	Connexin 26 (chr 13q11–q12)
Vohwinkel's syndrome (classic variant, with deafness)	*GJB2*	Connexin 26 (chr 13q11–q12)

(*continued overleaf*)

Table 34.1 (*cont'd*)

Disorder	Genes affected	Further information
Calcium pump defects		
Darier's disease	*ATP2A2*	Sarcoplasmic/endoplasmic reticulum calcium ATPase (SERCA2) (chr 12q24.1)
Hailey–Hailey disease	*ATP2C1*	Calcium transporting ATPase (chr 3q21–q24)
Metabolic and enzyme defects		
Chanarin–Dorfman syndrome	*CGI-58*	CGI-58 (chr 3), CGI protein of the esterase/lipase/thioesterase subfamily
CHILD syndrome (congenital hemidysplasia, ichthyosis and limb defects)	*NSDHL, EBP*	3β-hydroxysteroid dehydrogenase, an enzyme in cholesterol biosynthesis (chr Xq28). Mouse mutant, bare patches Mutations also reported in 3β-hydroxysteroid-δ8, δ7 isomerase
Haim–Munk syndrome	*CTSC*	Cathepsin C (see below)
Lamellar ichthyosis (LI1, LI2, LI3)	*TGM1*	LI1, keratinocyte transglutaminase I (chr 14q11.2) cross-linking enzyme in cornified envelope formation LI2 (chr 2q33–q35) LI3 (chr 19p12–q12)
Netherton's syndrome	*SPINK5*	Serine protease inhibitor LEKTI (chr 5q32)
Papillon–Léfèvre syndrome	*CTSC*	Cathepsin C, a lysosomal protease (chr 11q14.1–14.3)
Refsum's disease	*PAHX*	Phytanoyl-CoA hydroxylase (chr 10pter–p11.2), a PTS2 protein
Rhizomelic chondrodysplasia punctata type I	*PEX7*	Encoding the peroxisomal matrix protein with type 2 peroxisome targeting signal (PTS2) receptor (chr 6q22–q24)
Richner–Hanhart (tyrosine transaminase deficiency)	*TAT*	Tyrosine aminotransferase (chr 16q22)
Sjögren–Larsson syndrome	*FALDH* (also known as *ALDH10* or *ALDH3A2*)	Fatty aldehyde dehydrogenase (chr 17p11.2). Microsomal enzyme that catalyses medium and long-chain aliphatic aldehyde oxidation
X-linked icthyosis (steroid sulphatase deficiency)	*STS* (also known as *ARSC*)	Arylsulphatase C gene (chr Xp22.32)
X-linked recessive chondrodysplasia punctata	*ARSE*	Arylsulphatase E gene (chr Xp22.3) resulting in steroid sulphatase deficiency
X-linked dominant chondrodysplasia punctata (CDPX2) or Conradi–Hünermann syndrome	*EBP*	Emopamil binding protein, 3β-hydroxysteroid-δ8, δ7 isomerase. Role in cholesterol biosynthesis (chr Xp11.22–p11.23). Mouse model, tattered
Secreted protein		
Mal de Meleda	*ARSB*	Encodes SLURP-1 (chr 8q24.3)

lipid barrier structure), during the terminal differentiation of the epidermis. Proteins involved in this process include transglutaminase-1, which controls cross-linking of keratins and other structural proteins [19], SPINK5, which is a protease inhibitor of unknown specificity [20], as well as a range of enzymes important in lipid synthesis and modification. Finally, some completely unexpected molecules have been turned up by positional cloning efforts, such as SLURP-1, a novel secreted protein whose absence leads to mal de Meleda [21].

In conclusion, the field of keratinizing disorders as it stands today represents a close marriage between clinical and morphological observations and molecular and cell biology. This union of medicine and science has led to improved classification and diagnosis, including first trimester prenatal genetic testing, accurate genetic counselling and hopefully in the future, an informed mechanistic approach to the design of new therapeutic agents for this group of diseases.

Ichthyosis

Definition. Ichthyosis describes dry, rough skin with scaling over much of the body (Greek *ichthys/ikhthus*, fish + -osis). The ichthyoses are a clinically and genetically heterogeneous group of skin disorders, characterized by a diffuse, uniform, generally persistent pattern of scaling without mucosal involvement or extracutaneous disease. They are divided into congenital or genetic forms, namely primary ichthyoses, a number of rare ichthyosiform or ichthyotic syndromes, and individual cases that do not fit into either category, and acquired ichthyosis which is a complication of several systemic and malignant diseases (Table 34.2). They range in severity from mild ichthyosis vulgaris to erythrodermic forms and severe, often lethal, harlequin ichthyosis. Epidermal fragility is a feature of specific keratin mutations, while pruritus and atopy are prominent signs in Netherton's syndrome.

Ichthyosis is classified as a disorder of keratinization or cornification resulting from abnormal epidermal differentiation or metabolism. Defective epidermal desquamation is a feature of some ichthyoses while a prominent inflammatory component occurs in others, usually associated with epidermal hyperproliferation. Ultrastructural and molecular studies have informed a more accurate diagnosis and classification of the ichthyoses, shed light on pathogenetic mechanisms, and indirectly revealed a great deal about the structure and function of the normal epidermis.

History and classification. The first historic reference to ichthyosis appears in an Indian text in 250 BC, where there is mention of 'Ekakushtha, skin disease like scales of a fish' [1]. Reports of the 'porcupine men' in the 1730s highlighted the severity and familial occurrence of hystrix-type ichthyosis [2]. The first account of a harlequin (ichthyosis) fetus was written in 1750 [3]. In his treatise, *On Cutaneous Diseases*, Willan classified ichthyosis as a 'squamous disease' [4] and attempts at genetic classifications followed [5]. Brocq [6] first used the label 'congenital ichthyosiform erythroderma', and distinguished between bullous and non-bullous ichthyosiform erythroderma. The characteristic histological features of bullous ichthyosiform erythroderma were described by Lapiere [7], and

Table 34.2 Congenital and acquired ichthyoses.

Ichthyosis vulgaris (syn. autosomal dominant ichthyosis)
X-linked recessive ichthyosis (steroid sulphatase deficiency)
Non-bullous ichthyosiform erythroderma
Lamellar ichthyosis
Harlequin ichthyosis
Bullous ichthyosiform erythroderma (syn. epidermolytic hyperkeratosis)
Ichthyosis bullosa of Siemens (see erythrokeratolysis)
Ichthyosis hystrix
Ichthyosiform syndromes
Netherton's syndrome (syn. ichthyosis linearis circumflexa)
Sjögren–Larsson syndrome
Neutral lipid storage disease (syn. Chanarin –Dorfman syndrome)
Refsum's disease
Kallman's syndrome
Multiple sulphatase deficiency syndrome
X-linked dominant ichthyosis (syn. Conradi–Hünermann syndrome)
IBIDS (syn. Tay's syndrome, trichothiodystrophy, PIBIDS)
KID syndrome (keratitis, ichthyosis, deafness)
CHILD syndrome (congenital hemidysplasia, ichthyosiform erythroderma, unilateral limb defects)
Ichthyosis follicularis with alopecia and photophobia (IFAP)
Congenital ichthyosis variants
Isolated genetic syndromes with ichthyosis (case reports)
Acquired ichthyosis
Drugs (e.g. nicotinic acid, hypocholesterolaemic agents, maprotiline)
Chronic hepatic disease, renal failure, thyroid and parathyroid disease
Malabsorption states
Sarcoidosis, leprosy
Acquired immune deficiency syndrome (AIDS)
Lymphoma and other malignancies

subsequently termed epidermolytic hyperkeratosis [8]. Cockayne [5] regarded sex-linked ichthyosis as a separate entity, and lamellar ichthyosis as a recessive condition. Wells [9] differentiated X-linked and autosomal dominant ichthyosis vulgaris in an epidemiological survey. Recognition of ichthyosiform syndromes such as Refsum's disease, Netherton's and Sjögren–Larsson syndromes has come through astute clinical observation.

Early classifications depended on descriptive analogies, such as ichthyosis larvata, tarda, mitis and inversa. Wells and Kerr [9] defined groups of ichthyoses with autosomal recessive, sex-linked and autosomal dominant inheritance patterns, and clearly established X-linked recessive ichthyosis as a separate entity. Esterly [10] identified four categories of ichthyosis; major primary forms (ichthyosis vulgaris, recessive X-linked ichthyosis, bullous ichthyosis and congenital ichthyosiform erythroderma), ichthyosiform syndromes, related disorders of cornification and acquired ichthyoses.

Frost and van Scott [8] used epidermal kinetic data to characterize hyperproliferative (erythrodermic) and retention ichthyoses (ichthyosis vulgaris, X-linked ichthyosis). A numerical approach to 'disorders of cornification' lists 24 conditions (DOC 1–24), including the congenital ichthyoses and diverse diseases such as Darier's disease, peeling skin syndrome and the erythrokeratodermas [11]. Anton-Lamprecht and Schnyder [12] detailed subtle ultrastructural features of congenital ichthyosiform erythrodermas, and subdivided them into types 1–5. Traupe [13] identified four main categories: isolated vulgar ichthyoses, including ichthyosis vulgaris and X-linked recessive ichthyosis; associated ichthyoses of the vulgar type, such as Refsum's disease; isolated congenital ichthyoses, such as harlequin fetus, non-bullous ichthyosis and epidermolytic ichthyoses; and associated congenital ichthyoses, such as Sjögren–Larsson and Netherton's syndromes, IBIDS and X-linked dominant ichthyosis.

Elucidation of the underlying molecular abnormalities in ichthyoses will lead to a more logical and mechanistic classification and reveal previously unsuspected heterogeneity.

The epidermis in health and ichthyosis. Epidermal differentiation is characterized by the synthesis and post-translational modification of many structural proteins, in particular, the proteins constituting the cornified cell envelope and enclosed aggregated keratin filaments, which are the major components of the stratum corneum. Envelope precursors, such as involucrin, loricrin, small proline-rich proteins and envoplakin, are synthesized late in stratification and then cross-linked by the action of transglutaminase enzymes, which are synthesized in the granular layer. The corneocyte protein envelope is linked covalently to an outer ceramide layer, the lipid envelope, which also contains a variety of membrane-associated glycoproteins such as the integrins. Desmosomes are

modified in the stratum corneum to form an electron-dense plug, the corneosome. In normal skin, desmosome density and cohesion lessens in transit from lower to upper stratum corneum, but in hyperkeratotic states this does not occur [1]. Keratin macrofibrils are aggregated by interaction with filaggrin (filament aggregating protein), a basic histidine-rich protein stored as profilaggrin in keratohyaline granules. Keratin intermediate filaments are the major stress-bearing cytoskeletal proteins of mammalian epithelial cells, the product of two gene families encoding type I (acidic) and type II (neutral-basic) polypeptides, which are coexpressed in particular pairs in a tissue-specific and differentiation-related manner.

The intercellular spaces of the stratum corneum contain lipid-rich multilayered lamellae, which are secreted by lamellar or Odland bodies, present in large numbers in the cytoplasm of the granular layer. At the granular–corneal junction, the lamellar body gravitates to the apex of the granular cell, and secretes its disc-like contents into the intercellular spaces [2]. The lipid-rich layers are redistributed into multilayered lamellae, composed of alternating electron-dense and electron-lucent lipid bands. Evidence suggests that these structures are formed by the condensation of liposomes under the influence of ceramides (sphingolipids that contain the n6 essential fatty acid, linoleic acid), which span the layers acting as rivets. They are also rich in non-polar lipids; free sterols including cholesterol sulphate, free fatty acids and triglycerides, and contain hydrolytic enzymes [3,4]. Conversion to cholesterol by cholesterol sulphatase, present on the cell membrane surface, leads to breakdown of the intercellular lipid lamellae and resultant desquamation [5]. Stratum corneum barrier function is dependent on the intercellular lipid lamellae, and increased transepidermal water loss is a characteristic feature of ichthyosis [6].

The importance of lipid metabolism in epidermal structure and function was first noted in 1929, when an animal model deprived of dietary essential fatty acids developed hyperkeratosis, abnormal desquamation and increased transepidermal water loss [7]. In the 1950s, the lipid-lowering drugs nicotinic acid and triparanol caused a reversible ichthyosis in some patients [8]. An inherited enzyme deficiency was identified in the 1960s as the cause of Refsum's disease [9] and cholesterol sulphatase deficiency in patients with X-linked recessive ichthyosis was reported in 1976 [10]. Sjögren–Larsson syndrome, another ichthyosiform disorder with neurological disease, is associated with fatty alcohol defects [11], while peroxisomal dysfunction, specifically abnormal sterol biosynthesis, has been identified in patients with Conradi–Hünermann and CHILD syndromes [12,13].

Disordered keratinization also results from alterations in structural proteins, including individual keratins, cornified envelope proteins and keratin-associated proteins (Table 34.1). Enzyme and metabolic defects (e.g. loss of transglutaminase activity in lamellar ichthyosis) and abnormalities in gap junction proteins (connexin mutations in the keratitis–ichthyosis–deafness (KID) syndrome) have been identified in diverse ichthyoses [14]. Several ichthyoses are associated with hyperproliferative and inflammatory features. Chronic barrier damage induces keratinocyte DNA synthesis and results in epidermal hyperplasia [15], with knock-on effects on the activity of cytokines, growth factors, calcium gradients, adhesion molecules and lytic enzymes. The identification of a serine protease inhibitor mutation in Netherton's syndrome and defects in lipoxygenase activity in an erythrodermic ichthyosis provide further insights into the occurrence of inflammatory changes [16].

Congenital ichthyoses

Ichthyosis vulgaris (MIM 1467000)

SYN. AUTOSOMAL DOMINANT ICHTHYOSIS

Ichthyosis vulgaris is the most common of the inherited ichthyoses, with a reported incidence of 1 in 250 in an

English population study of 6051 healthy schoolchildren [1]. It is an autosomal dominant condition, and in the majority of affected individuals it is considered mild and may clear completely in the summer months. It appears to be more common in temperate climates and has an equal sex distribution. There is said to be a close association between ichthyosis vulgaris and atopic diseases; 37–50% of people who have ichthyosis vulgaris show features of atopic disease [1–3]. However, the difficulty in distinguishing ichthyosis vulgaris from the xerosis of atopic eczema on clinical grounds may result in an overestimate of both its frequency and its correlation with atopic eczema [4].

Histopathology. Histology of affected skin shows a mild hyperkeratosis and, usually, a diminished or absent granular layer in the epidermis. The dermis is normal. Features of keratosis pilaris may be seen. Electron microscopy reveals scanty and fragmented keratohyaline granules in granular layer cells, whereas the keratin filaments appear normal [5]. The proposed association between ichthyosis vulgaris and atopic eczema has been questioned on histological grounds, as eczematous features are found in biopsies of atopic xerosis [6]. Furthermore, ultrastructural study of xerotic lesions in 49 patients with atopic eczema and dry skin showed typical features of ichthyosis vulgaris in only two [4].

Aetiology and pathogenesis. Biochemical studies indicate that, in affected skin only, uptake of radiolabelled histidine by the granular layer is reduced [7]. Histidine is necessary for the synthesis of profilaggrin, the high-molecular-weight precursor of filaggrin, which is a major component of the keratohyaline granule and necessary for keratin filament assembly. Profilaggrin is virtually absent from the epidermis and from cultured keratinocytes (in those patients with no granular layer or keratohyaline granules) in ichthyosis vulgaris [7,8], and expression of filaggrin mRNA is reduced [9]. Cultured keratinocytes from unaffected skin formed thickened layers, with small keratohyaline bodies, and failed to react with monoclonal antibody to filaggrin [10]. Keratin expression and markers of differentiation are normal [11], and proliferative activity is reduced [12]. *In vitro* transfection studies using antisense profilaggrin RNA produced more widespread effects than occur in ichthyosis vulgaris [13], and a primary abnormality of the profilaggrin gene has not been shown by linkage analysis or mutational studies. There may be selectively impaired post-transcriptional control of profilaggrin synthesis [9], or the profilaggrin gene may be influenced by other mutated genes [8]. In addition, a mouse mutant lacking profilaggrin expression has been shown to be a good animal model for ichthyosis vulgaris, adding further circumstantial evidence of involvement of this gene and/or protein system in the human condition [14].

Fig. 34.1 Ichthyosis vulgaris.

Amino-acid breakdown products of filaggrin and some of their metabolites are able to retain water in the outer stratum corneum, and their deficiency may contribute to the scaling [15]. No consistent lipid abnormality has yet been found in ichthyosis vulgaris, although stratum corneum ceramides are reduced in atopic eczema, in lesional and xerotic skin [16]. A defect in serine proteases involved in the degradation of desmoglein 1, a transmembrane desmosomal protein, has been reported [17].

Clinical features. The skin may appear dry and scaly in the neonatal period, but more usually scaling is obvious from 2 months onwards and may be further delayed. The scale is white or grey, small, flaky or branny, and semi-adherent with turned-up edges (Fig. 34.1). It is most pronounced on the extensor surfaces of the arms and lower legs, and characteristically spares the flexural creases. The trunk, especially the abdominal wall, is often mildly affected and the nappy (diaper) area is spared. Facial scaling, generally forehead and perioral, mild dandruff and involvement of the pinnae are seen in some patients. The palms and soles are usually free of scale, but palmoplantar hyperlinearity (linear grooves crossing perpendicularly to the thenar and hypothenar eminences), a reflection of mild hyperkeratosis, is a helpful feature in many ichthyosis vulgaris patients, whether they have coexistent eczema or not [18]. It also occurs in atopic eczema without ichthyosis [4,19]. Keratosis pilaris is a common associated feature of both atopic eczema and ichthyosis vulgaris, and favours the extensor aspects of the upper arms and thighs.

Symptoms of ichthyosis vulgaris are few, mainly dryness or roughness of the skin and the cosmetic effect. In isolated ichthyosis vulgaris, pruritus is not a problem, but in patients who also have eczema, flexural lichenification and pruritus with excoriation are additional features. In these patients, a definite diagnosis of ichthyosis vulgaris as distinct from atopic xerosis can only be made on skin

histology. There is a marked seasonal variation in most patients, with improvement in warm and sunny weather, possibly as a result of ambient humidity. Many sufferers (38% of 169 patients) report a gradual improvement in adolescence [1], although a small number worsen with age. Reports of ocular manifestations and testicular cancer in ichthyosis vulgaris have not been verified, and may have arisen from inclusion of X-linked ichthyosis cases [20,21].

Diagnosis. Ichthyosis vulgaris may be mistaken for atopic xerosis, eczéma craquelé, acquired ichthyosis, Refsum's disease and a mild autosomal recessive variant reported in five of eight siblings [22].

Genetics. Ichthyosis vulgaris is an autosomal dominant disease with variable penetrance, such that disease severity can vary between generations, and affected siblings. Despite the fact that this condition is relatively common [1], an unequivocal gene locus awaits identification. The highly repetitive structure of the profilaggrin genes means that mutation analysis is difficult, a factor that has hampered attempts to link these genes to the disorder, despite compelling evidence from studies of a mouse model lacking this gene [14]. When ichthyosis vulgaris occurs with atopic eczema, gene linkage or contiguous gene defects are possible causes.

Treatment. As a general measure, avoiding low humidity environments is of benefit to all ichthyosis patients. Regular emollient application is recommended for those with ichthyosis vulgaris, and if provided with samples of a variety of suitable preparations, patients can make their own choice as to the most acceptable and appropriate for a given situation. Many do not require treatment in the summer as they spontaneously improve. In drier, colder seasons, mild and moderately affected subjects may opt to use a light emollient, such as aqueous cream, which can also be applied as a soap substitute. More severely affected individuals may prefer paraffin-based (mixtures of white soft and liquid paraffin) or cetostearyl alcohol-containing emollients, of which there are many proprietary brands. It should be borne in mind that greasy emollients such as emulsifying ointment have adverse effects on certain fabrics and washing machines.

Emollients need to be applied at regular intervals, but while morning and evening treatments are convenient for most patients, application during the day may not be possible for people with a busy work or academic routine. Assistance from carers and at school should be arranged for severely affected children. Emollient bath oils and a variety of soap substitutes are available. Cetomacrogol additives may enhance the antipruritic effect of bath oils. Bubble bath, astringent and other irritant products should be avoided.

Keratolytic agents, such as 1–5% salicylic acid, may be added to emollient cream bases, to encourage shedding of scale, but in practice they tend to be too irritant for regular usage. The risk of systemic toxicity (salicylism) precludes their widespread application, especially in young children who have a high surface area relative to body size. Alpha-hydroxy acids, such as lactate, glycollic, malic, mandelic, citric, pyruvic, gluconic and tartaric acids, 5–10% in an oil, lotion, cream or hydrophilic ointment base are said to enhance corneocyte shedding by virtue of their effect in breaking intercellular bonds [23]. They have become popular additives in many commercial skin-care products ('fruit acids') in recent years, and may be less irritant although more expensive than salicylic acid compounds. Beneficial effects from topical 12% ammonium lactate lotion have been reported [24]. Urea-containing (5–10%) emollients improve epidermal hydration, lyse keratin and are bacterostatic [25,26]. Topical retinoids are generally too irritant. The activity of keratolytic and urea treatments can be enhanced by occlusion under tubular dressings or sleep suits. In practice, they should be applied as tolerated for 2 weeks or so to produce a mild exfoliation, which can then be maintained with less frequent application. Mechanical exfoliation can be achieved with a loofah while bathing. Dandruff is not a problem for most ichthyosis vulgaris sufferers, but if present can be controlled with a tar or salicylic acid-containing shampoo.

Patients with both ichthyosis vulgaris and atopic eczema will need appropriate eczema therapy with the addition of topical anti-inflammatory or immunomodulatory preparations as required. Topical steroids and immunosuppressive agents do not benefit ichthyosis vulgaris but oral evening primrose oil, which contains essential n6 fatty acids, produced a slight improvement in some [27]. Systemic retinoid therapy is not necessary or appropriate for ichthyosis vulgaris, and in patients with associated atopic eczema would be likely to exacerbate the eczema.

X-linked recessive ichthyosis (MIM 308100)

X-linked recessive ichthyosis (XLRI) affects male offspring who inherit an X chromosome bearing a steroid sulphatase genetic mutation from their asymptomatic carrier mother. Although the ichthyosis is rarely a significant problem, XLRI is an important disease for many reasons. It may be associated with extracutaneous manifestations and obstetric complications. The underlying lipid metabolic defect and the pathogenesis of the ichthyosis have been elucidated. The gene locus for steroid sulphatase (*STS*) has been identified at the distal end of the short arm of the X chromosome.

Incidence. Wells and Kerr [1], in a large epidemiological study in 1966, differentiated XLRI from ichthyosis vulgaris and defined their clinical and genetic features. They estimated its incidence in the UK at 1 in 6190 males. A not dissimilar incidence has been reported in other countries, based on clinical diagnostic criteria. In a Danish population study of placental *STS* deficiency, a predicted incidence of XLRI of 1 in 2000 males was derived [2]. XLRI has a worldwide distribution in all ethnic groups.

Aetiology and pathogenesis. In the 1970s, *STS* deficiency was identified as the cause both of XLRI and placental sulphatase deficiency, confirming them as a single disease entity [3,4]. Fibroblasts, epidermal cells, leukocytes, nail, hair bulbs, amniocytes and testicular tissue can all be assayed to reveal a functional and immunological enzyme deficiency. The enzyme substrate, cholesterol sulphate, is elevated in many tissues, including serum, red blood cell membranes, stratum corneum and nail matrix, but serum cholesterol levels are normal, as its main synthetic enzyme is hydroxymethylglutamyl-CoA reductase. Lipid analysis of normal epidermis shows a gradual decline in cholesterol sulphate (which stabilizes lipid bilayers) from 6% in the granular layer to 3% in the stratum corneum. A concomitant rise in cholesterol, which triggers stratum corneum intercellular lipid bilayer disintegration and desquamation, reflects the increasing activity of membrane-based steroid sulphatase at the corneal–granular layer junction. In XLRI, cholesterol sulphate accounts for 12–30% of stratum corneum lipids [5–7]. Calorimetric studies have identified a failure of the normal liquid–crystalline transition phase of stratum corneum intercellular lipids in XLRI, presumably because of the polar subgroups of cholesterol sulphate [8].

Steroid or cholesterol sulphatase is one of two isomers of aryl sulphatase C, a membrane-bound microsomal enzyme, and is responsible for hydrolysing sulphate groups from cholesterol sulphate and certain other steroids. The sulphated forms of some steroid sex hormones, such as 17-hydroxyprogesterone, oestrone and dehydroepiandosterone, are also increased in patients with XLRI [9]. Testosterone sulphate is reduced, but testosterone and dihydrotestosterone levels are normal, as synthesis can be mediated by a desaturase enzyme system. Pituitary gonadotrophins, prolactin and sex steroid binding globulin are normal. The altered sex hormone profile may in part explain the abnormal testicular development in some XLRI patients.

Evidence of a direct causal link between elevated cholesterol sulphate levels and scaling is compelling. Topical application of cholesterol sulphate in the hairless mouse induced a reversible retention ichthyosis, and a threefold increase in stratum corneum thickness, after 1 week [10]. The scaling cleared within 3 days of stopping the treatment, and did not occur if other sulphated substrates of the enzyme were applied. Topical cholesterol prevented this effect, and also temporarily reduced

Fig. 34.2 X-linked recessive ichthyosis (XLRI). (a) Scaling on the arm; (b) on the legs; and (c) on the trunk.

the scaling of XLRI but not of other ichthyoses. Many cholesterol-lowering drugs have caused ichthyosis as a side effect [11].

Histopathology. Affected skin in XLRI shows an expanded stratum corneum without parakeratosis or acanthosis. The granular cell layer is usually normal, but may be mildly thickened or, rarely, diminished, making histological differentiation from ichthyosis vulgaris difficult. Ultrastructurally, the keratohyaline granules are normal or small, in contrast to ichthyosis vulgaris, but are more numerous. Desmosomes are more persistent than normal, and corneal melanosomes more prominent [12,13]. Kinetic studies have shown normal rates of cell turnover.

Clinical features. In 75% of cases, scaling is evident within the first week of life [14], but 6% develop scaling after the age of 1 year [15]. A Danish study of 76 patients revealed onset of light flaky scaling before 1 month of age, with more typical scale by 6 months in all but two children [16]. A prominent peeling episode at this stage was characteristic. The scaling tends to increase throughout childhood, often spreading up from the lower legs to the trunk. It stabilizes in the teens with little subsequent change, and in most patients scaling diminishes in the summer months. There is considerable variation in the severity of scaling between families, and even in some instances within affected kindred. Pruritus is unusual.

Scaling in XLRI is most prominent on the extensor surfaces of the upper arms (Fig. 34.2a), the outer thighs and around the lower legs (Fig. 34.2b). Typically, the scale is medium to large, polygonal, adherent, dull and light to dark brown, depending on skin type (Fig. 34.2c). The posterior and lateral neck, upper and lateral abdominal wall and pre-auricular facial skin are commonly affected with adherent, dark grey scale and, in contrast to ichthyosis vulgaris, the flexures may be involved. The face, scalp, axillae, flexor aspects of the limbs and dorsal hands and feet may show light grey scaling but the palms and soles are spared. Rarely, a fine white scaling is the predominant sign, and leads to a delay in diagnosis. In one study the average age of diagnosis was 10.3 years [14].

Extracutaneous features of XLRI. A variety of extracutaneous abnormalities have been noted in some patients with XLRI. An increased incidence of testicular maldescent,

abnormalities of sperm count or motility, and testicular cancer have been reported in patients with XLRI [16–19]. Of a group of 76 patients, nine had testicular maldescent and three developed testicular cancer in normally descended testes (one had bilateral cancer) [16,19]. Inguinal hernia appears to be more common, and unilateral renal agenesis was reported in half of those with cryptorchidism, all of whom had features of Kallmann's syndrome [14].

Corneal dot, thread-like or comma-shaped opacities, detected with the slit-lamp microscope, occur in 50–100% of adult patients, and to a lesser degree in 24% or more of female carriers, but are usually of no functional significance [15,16,20,21]. They are thought to be a result of stromal deposits on the posterior surface of Desçemet's membrane [21].

Perinatal manifestations of steroid sulphatase deficiency. It was noted in the 1970s that low urinary oestriol excretion in the third trimester of pregnancy was not invariably associated with intrauterine growth retardation. These pregnancies often ended in a prolonged labour, and the underlying defect, placental *STS* deficiency, was identified. Coincidentally, *STS* deficiency was noted in boys with XLRI [3].

Prolonged labour may occur in up to one-third of patients with XLRI. In a group of 33 patients, four had a spastic paraplegia or paraparesis, apparently as a result of perinatal complications related to prolonged labour, requiring obstetric intervention [14]. In each case, a younger male sibling with XLRI was neurologically normal.

XLRI and contiguous gene defects. Kallmann's syndrome describes the association of XLRI with hypogonadotropic hypogonadism, anosmia and a variety of neurological defects, including nystagmus and mirror movements of the hands and feet (synkinesis) [22]. It affects between 1 in 10 000 and 1 in 60 000 of the population, and may be misdiagnosed as XLRI until adult life because of delayed diagnosis of hypogonadism. Adult patients may suffer from obesity and osteoporosis. Renal anomalies and cleft palate have also been reported in Kallmann's syndrome. Developmental delay and spastic paraplegia appear to be more common in Kallmann's syndrome than in isolated XLRI. Kallmann's syndrome is caused by a large deletion of the short arm of the X chromosome proximal to and including the *STS* gene. The features of Rud's syndrome (X-linked ichthyosis, obesity, hypogonadism, mental retardation, epilepsy and endocrinopathies) can, in large part, be attributed to Kallmann's syndrome or to perinatal complications in patients with XLRI [23].

Larger X chromosome deletions distal to and including the *STS* gene may lead to XLRI associated with mild mental retardation, mild chondrodysplasia punctata or short stature [24]. Epiphyseal stippling of long bones, larynx and vertebrae may occur transiently in early childhood in the chondrodysplasia variant, while dysplastic features may be detected on X-rays later in life. Hypoplasia of cartilage and distal phalanges has been noted in affected males, and carrier females may be of short stature. Sparse, brittle hair occurred in two patients with large X chromosome deletions [14].

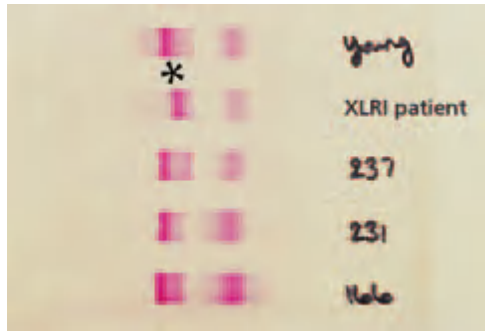

Fig. 34.3 Serum electrophoresis, showing 'fast' band in XLRI patient (compared to controls).

Diagnosis. Raised serum cholesterol sulphate in patients with XLRI can be detected on serum lipoprotein electrophoresis [25]. Cholesterol sulphate carries a stronger electronegative charge than cholesterol, resulting in increased mobility of the β low-density lipoprotein fraction (a 'fast' band 2 mm beyond that of controls) towards the anode (Fig. 34.3). This simple screening test is not widely available and equivocal results (1 mm difference) should be followed up with the definitive test, *STS* assay, which is available in regional laboratories. Enzyme activity can be measured in leukocytes or skin fibroblasts, and is much reduced or absent in XLRI [26]. Serum cholesterol levels are normal in XLRI.

Chromosomal analysis using high-resolution G-banding will detect and quantify significant Xp deletions where clinical evidence of contiguous gene defects exists. Southern blot analysis can be used to identify specific gene deletions, or mutations at and distal to the *STS* gene locus. PCR amplified testing for exons in the Kallmann's syndrome gene is the most sensitive test for this condition. Fluorescent *in situ* hybridization (FISH) analysis has been used to detect a common deletion of the *STS* gene [27].

Clinically, XLRI may resemble ichthyosis vulgaris or mild lamellar ichthyosis. A Sardinian kindred with a similar phenotype but normal *STS* activity has been reported [28].

Genetics. Linkage of XLRI and the Xg red blood cell group in the 1960s was an early example of chromosome localization identified by tracking linked traits in family studies [29]. The association of XLRI with stunted growth, hypogonadism and anosmia has enabled mapping of the

relevant genes on the short arm of the X chromosome (Xp). Gene mapping in families with X to Y translocations placed the *STS* gene at the Xp 22.3 locus [30]. The Kallmann's syndrome gene has been mapped proximal to this, while deletions distal to the *STS* gene may cause mental retardation, chondrodysplasia punctata and short stature, placing relevant genes towards the pseudoautosomal region at the tip of the X chromosome [24,31].

The virtual absence of immunoreactive *STS* in XLRI patients is matched by a complete deletion of the *STS* gene on Southern blot analysis of genomic DNA in up to 90% of cases using specific Xp complementary DNA (cDNA) probes [14,32]. Point mutations of the gene have been identified [33]. There is considerable genetic heterogeneity between XLRI and contiguous gene syndromes, with sizeable DNA loss (3.4%, up to 2 megabases) detected by flow cytometry in some [34] and in others evidence of X–Y translocations [35].

Isolated XLRI is generally a mild disease and few families are interested in prenatal diagnosis. However, placental *STS* deficiency is a risk factor in affected pregnancies, and highlights the importance of identifying carrier females. Kallmann's and other contiguous gene defects are more significant and, in these families, genetic assessment and heterozygote detection must precede genetic counselling. Prenatal diagnosis of XLRI is based on maternal urinary oestriol levels, or chorionic villus steroid sulphatase assay. Southern blot analysis and PCR can detect *STS* gene deletion or contiguous gene mutations, while high-resolution G-banding will identify large Xp deletions. FISH analysis can also rapidly identify female carriers [27].

Carrier detection. Obligate carriers show no consistent cutaneous features but corneal stromal deposits are detected on slit-lamp examination in some [20]. Lipoprotein electrophoresis is normal in obligatory female carriers. *STS* levels in leukocytes, fibroblasts or hair roots are higher in normal females than in normal males, because the Lyon effect (inactivation of one X chromosome in normal female cells) does not apply to the *STS* gene [36]. Therefore, female carriers would be expected to have 50% of the *STS* values of non-carrier females. Indeed, 30 of 31 obligate carriers had a leukocyte *STS* level below the 2.5 percentile of normal females, indicating enzyme heterozygosity [36]. However, partial X inactivation was evident in other studies, enzyme values in the range of 40–86% in known carriers were obtained. Leukocyte *STS* assay, using oestrone sulphate as substrate, proved the most reliable biochemical test for heterozygote detection [37]. Visual assessment of stained hair roots to detect *STS* has also been used. Southern blot hybridization of leukocyte DNA provides an accurate measure of the anticipated 50% *STS* gene dosage in carriers, but is applicable only to the 90% of XLRI families with complete gene deletion [38]. FISH analysis, a technically less demanding diagnostic technique, is currently the method of choice for carrier detection in XLRI families where a gene deletion is the underlying defect [27]. In the remaining 10% of cases where the gene is not deleted, PCR of the individual exons of the gene and mutation detection by direct DNA sequencing or another technique is necessary to find the mutation. Somatic and germinal mosaicism for the *STS* gene deletion in a carrier has been reported [39].

Treatment. The same principles apply to treatment of XLRI as have been outlined for ichthyosis vulgaris. Most patients achieve an acceptable level of control of their scaling and dryness with daily emollient application, and may improve sufficiently in the increased humidity of temperate summers to forgo any therapy. Keratolytic and urea-containing preparations are generally less irritating than in ichthyosis vulgaris. In severe XLRI, short or intermittent courses of oral retinoid therapy may be considered. A topical receptor-selective retinoid, tazarotene, showed promising results in a small number of patients [40]. Topical application of cholesterol reversed the effect of cholesterol sulphate in hairless mice [9], and a 10% cholesterol cream improved scaling in 18 of 20 patients after 3–5 weeks [41]. Abnormalities of genital or secondary sexual development should be investigated by an endocrinologist and appropriate treatment planned. Short stature warrants early investigation, including a radiological check of long-bone epiphyses. Neurological and developmental assessments will detect those patients with neurological damage or Kallmann's syndrome and help identify special educational needs.

Multiple sulphatase deficiency (MIM 272200)

This is an exceedingly rare autosomal recessive disorder caused by deficiency of two or more of the seven microsomal sulphatase enzymes, usually including aryl sulphatases A, B and C. This leads, in infancy, to a combination of features of mucopolysaccharidosis type 2 (aryl sulphatase B deficiency), metachromatic leukodystrophy (aryl sulphatase A deficiency) and XLRI [1].

Developmental delay and failure to thrive occur from early infancy with features of Hurler's syndrome (coarse facies, stunted growth, hepatomegaly and skeletal defects) becoming evident in the first year of life. A positive urine spot test for glycosaminoglycans (GAGs) suggests a lysosomal storage disorder. A mild ichthyosis and progressive neurological degeneration evolve in the second or third year but the phenotype varies according to the degree of reduction of each enzyme [2,3]. The neurological disease is often fatal in childhood.

Multiple sulphatase deficiency is confirmed by enzyme assays on fibroblasts, fresh leukocytes or serum, and fibroblast iduronate sulphatase activity is reduced. Urinary sulphatides and GAGs (heparan and dermatan sulphate) are elevated. Prenatal diagnosis by enzyme assay of amniocytes is possible.

Collodion baby

This accurate if outdated term is used to describe the transient appearance at birth and in the neonatal period of a baby who, in general, subsequently develops ichthyosiform erythroderma [1] (although a variety of unrelated disorders may ensue). It was reported sporadically in the 19th century [2], and familial, self-healing cases and localized forms have been noted [3,4]. There are no reliable figures on incidence and it may be overlooked or misdiagnosed in some cases.

Aetiology and pathogenesis. The collodion membrane

forms in the latter half of the third trimester, but at birth the defective stratum corneum barrier is exposed and the membrane desiccates and peels off. The association between fetal periderm, which evolves in the second month of gestation and dissolves with the onset of epidermal differentiation in the sixth month, and the neonatal collodion membrane, is unknown. Periderm does not express profilaggrin nor contain keratohyalin granules, which are present in the collodion membrane. In fetal skin biopsies of lamellar ichthyosis and harlequin ichthyosis, the periderm was normal in appearance [5].

Histopathology. Light microscopy of skin in the early neonatal phase of a collodion membrane shows a compact hyperkeratosis with a thick eosinophilic periodic acid–Schiff stain (PAS)-positive stratum corneum. However, the epidermis is attenuated because of a reduced granular layer. The mid- and lower epidermis and the dermis are usually unremarkable.

Electron microscopy features in the early neonatal phase have varied. In one case, cells of the upper two-thirds of the stratum corneum were convoluted and irregular in shape, with prominent nuclear debris and dense intracytoplasmic granules. Lamellar bodies were numerous in the intercellular spaces and desmosomes were well preserved [6]. Repeat skin biopsy at 16 months showed that, in spite of apparent 'self-healing', the ultrastructural changes persisted. Another report indicated that the ultrastructural features on the 15th day of life were predictive of the outcome, with a self-healing case showing relatively normal epidermal ultrastructure, while an infant who developed erythrodermic ichthyosis showed continuing dysplastic changes [7].

Clinical features and prognosis. Premature delivery may be slightly more common but is not a significant problem. At birth, the typical collodion baby presents a striking and characteristic clinical picture with a generalized glistening, taut, yellowish film stretched over the skin (Fig. 34.4a). It resembles a clingfilm wrap or sausage skin, although it may variously be described as a 'plastic skin', 'parchment-like' or 'as if dipped in hot wax'. Normal skin markings are obliterated, the eyelids and sometimes the lips are tethered and everted (ectropion and eclabion), the pinnae may be flattened and the nostrils obstructed (Fig. 34.4b). Sausage-shaped swelling of digits may result from acral extension of the membrane and, rarely, constricting bands encircle the limbs or digits. General examination is usually normal and movement is minimally restricted.

The collodion membrane desiccates and cracks around flexures during the first days of life (Fig. 34.5), and is usually completely shed within the first few weeks of life. It appears incomplete or localized in some infants, and may peel away only to reform, this pattern being repeated over a period of up to 12 weeks. In most cases, shedding reveals an erythrodermic ichthyosis.

(a)

(b)

Fig. 34.4 (a) Collodion baby, day 2. (b) Facial features in collodion baby.

Previously common and often lethal complications of a collodion membrane, and the associated erythroderma, were renal failure and neurological sequelae of hypernatraemic dehydration [8], hypothermia and bacterial sepsis. Affected infants require intensive nursing care in humidified incubators to control body temperature, prevent infection and combat electrolyte upset and dehydration. Increased absorption of topical agents through the skin may lead to systemic toxicity, and topical steroids should be avoided. Improved neonatal care has resulted in a reduction in neonatal mortality from 33% in the 1970s

Fig. 34.5 Early shedding of membrane.

to less than 11% in one review [9], and in uncomplicated cases mortality is now negligible [10].

Sequelae and genetics. In 60–80% of these infants, the features of non-bullous ichthyosiform erythroderma or, less often, lamellar ichthyosis become apparent [9,10]. The severity of the subsequent ichthyosis cannot be predicted from the duration or complications of the collodion membrane. The rare autosomal dominant form of lamellar ichthyosis, and a kindred with apparent autosomal dominant non-bullous ichthyosiform erythroderma, have also presented with collodion membrane [11,12]. A minority of patients with lamellar ichthyosis, or non-bullous ichthyosiform erythroderma, appear not to have a collodion membrane at birth.

Occasional cases of trichothiodystrophy (IBIDS), neutral lipid storage disease, Sjögren–Larsson syndrome, Conradi–Hünermann disease and autosomal dominant loricrin keratoderma [13] have presented as collodion babies but its occurrence in other forms of ichthyosis, such as XLRI and bullous ichthyosiform erythroderma, is doubtful. Of collodion babies, 10–20% subsequently have normal skin, so-called self-healing collodion baby or 'lamellar ichthyosis of the newborn' [14]. This autosomal recessive condition has been attributed to a compound heterozygous transglutaminase mutation where the inactive *cis* form of the enzyme converts to an active *trans* form in an extrauterine environment [15]. Collodion membrane presentation has also been reported in anhidrotic ectodermal dysplasia [16], Gaucher's disease type 2, a disorder of sphingolipid metabolism resulting from β-glucocerebrosidase deficiency [17,18] and Neu–Laxova syndrome [19]. A single case associated with palmoplantar keratoderma was observed by one of the authors and another was included in a report of 10 collodion babies in the Thai literature [20].

Differential diagnosis. A collodion baby is generally easily distinguished from the more severe harlequin fetus or harlequin ichthyosis presentation, but occasional cases with intermediate features have been recorded. These cases have been referred to as 'chrysalis babies'. Restrictive dermopathy, or the 'stiff baby syndrome', produces a generalized taut, thick, tethered and unyielding skin at birth, which does not dessicate in the neonatal period. Its persistence causes respiratory failure and early neonatal death. Infective causes of desquamation such as staphylococcal scalded skin should be included.

Management. Skin biopsy is not usually performed at this stage, but hair analysis, blood film microscopy and hearing tests should be arranged. Collodion babies should be nursed in a special care baby unit in a humidified incubator. Cleansing with warm water and sterile aqueous cream or antiseptics daily, and barrier nursing, reduces the risk of infection (associated with skin barrier dysfunction, emollient use and high humidity). An emollient, such as sterile white soft paraffin in single-dose containers, is usually applied 4-hourly to keep the membrane pliable and reduce transepidermal water loss. Analgesics may be required before handling. Intravenous lines should be avoided and regular skin swabs carried out. Signs of skin or systemic sepsis (including *Candida* and *Pseudomonas*) should be investigated and treated immediately, but prophylactic antibiotics are unnecessary. Poor sucking and weight loss may necessitate nasogastric tube feeding, and a higher than normal fluid and calorie requirement can be anticipated. Exposure keratitis resulting from ectopion can be prevented by the regular use of lubricating drops and ointments, and ophthalmological advice should be sought. Nasal obstruction can be improved by gentle probing, and constricting bands on the limbs should be divided if causing acral pressure effects. Systemic retinoids have rarely been used in severe cases. Every effort must be made to allow the parents to nurse and bond with their baby and their involvement from the beginning will enhance their confidence in managing at home.

The need for continuing neonatal care, once the membrane is shed, depends on the baby's condition, but most can be discharged within the first 4 weeks on a continuing emollient regimen. Accurate information on the condition and its prognosis should be available from regional neonatal and dermatology centres, and is necessary to allow carers and family to plan management. The details

and outcome of an individual case, including transglutaminase mutation detection, will be important for genetic counselling of the family, which should be arranged on discharge.

Non-bullous ichthyosiform erythroderma (MIM 242100)

Non-bullous ichthyosiform erythroderma (NBIE) is a rare and usually severe autosomal recessive inflammatory ichthyosis. There are few data on incidence, but an English population study estimated it to be 1 in 300 000 [1]. It occurs in all races, more so when consanguineous marriage is common. NBIE is more common than lamellar ichthyosis, but they were regarded as a single disorder until the 1980s, when clinical, histological and biochemical features that differentiated them were reported. NBIE is also referred to as erythrodermic lamellar ichthyosis. A Swedish kindred with autosomal dominant NBIE has been reported [2].

Aetiology and pathogenesis. NBIE is characterized by epidermal hyperplasia with increased mitoses, prominent PCNA staining [3] and increased expression of hyperproliferative keratins K6/K16/K17. *In vitro* studies of NBIE keratinocytes grown in organotypical culture at an air–liquid interface showed hyperkeratosis, and more marked parakeratosis, than with normal control keratinocytes [4]. There are no consistent changes in epidermal lipid content in NBIE. Although alkanes, a saturated hydrocarbon group, may be raised in certain hereditary ichthyoses, they are neither sensitive nor specific for any one type [5]. Assay of stratum corneum enzymes highlighted differences between the autosomal recessive ichthyoses. In NBIE scale, the lamellar body enzyme, β-glucosidase, was reduced while butyrase levels were maintained, and the opposite pattern pertained in lamellar ichthyosis [6].

Abnormal intracellular cytoplasmic accumulation of keratinocyte transglutaminase 1 has been reported in a subset of patients with NBIE [7]. Whereas transglutaminase activity in some patients with lamellar ichthyosis was entirely absent, intermediate levels were found in this subset of NBIE patients. Recently, mutations in two lipoxygenase enzymes, lipoxygenase-3 (ALOX3) and 12-lipoxygenase (ALOX12B), have been identified in six Mediterranean families affected by NBIE, known to be linked to chromosome 17p13.1 [8]. These two lipoxygenases are mainly expressed in epithelial cells including suprabasal keratinocytes, and are involved in the maintenance of the cutaneous permeability barrier and possibly in terminal differentiation. Lipoxygenases are involved in essential fatty acid and phospholipid metabolism, which provides the lamellar body-derived membranes responsible for the permeability barrier. Linkage to chromosome 3 has been reported, and this locus also appears to hold the gene for Chanarin–Dorfman syndrome [9].

Histopathology. Light microscopy of skin sections reveals compact hyperkeratosis and moderate increase in stratum corneum thickness. There is variable mild parakeratosis and acanthosis, a normal or prominent granular layer, increased mitoses and an accentuated broad rete ridge pattern. A mild upper dermal lymphocytic infiltrate and prominent dermal blood vessels may be present. Lipid vacuoles in the stratum corneum were noted in a family with autosomal dominant NBIE, and sweat glands were normal below the level of the stratum corneum [2].

PAS staining of frozen sections showed positivity in cell membranes of the stratum corneum and granular layer and in the basement membrane, which is absent in normal skin and in other ichthyoses, with the possible exception of Netherton's syndrome [10]. Kinetic studies, using labelled thymidine, confirmed an increased epidermal

turnover rate in NBIE, similar to that seen in psoriasis, and in contrast to the relatively normal epidermal kinetics of lamellar ichthyosis [11]. This was unaffected by retinoid therapy [12].

Electron microscopy reveals abnormal lamellar bodies, which are retained in the corneal layer. In the autosomal dominant variant, there was, in addition to increased mitotic activity, a reduced level of keratohyalin and tonofilaments, and lipid vacuolation in the stratum corneum [2]. The expanded granular layer showed normal lamellar body structure. Ultrastructural features more typical of harlequin ichthyosis have been found in several patients with severe NBIE [13]. Classification of autosomal recessive ichthyosis congenita into five subtypes, based on ultrastructural findings, highlights the clinical, ultrastructural and genetic heterogeneity of NBIE [14–19].

Clinical features. NBIE in over 90% of cases presents at birth with a collodion baby appearance (Figs 34.4 & 34.5). The few in whom this is not a recorded feature are erythrodermic from birth, and some are premature. After shedding of the collodion membrane, generalized scaly erythroderma is apparent and persistent (Figs 34.6a,b). Erythroderma may lessen while scaling increases in early childhood but there is considerable interindividual variation in severity.

Typically, scaling affects all areas including the scalp, ears, face, flexures, palms and soles. The scale of NBIE is white or grey, thin, superficial and semi-adherent. It appears feathery on the face, arms and trunk but may be lamellar or plate-like on the lower legs. Scaling may be cyclical, with build-up and shedding over periods of 2–4 weeks and, rarely, clinically normal skin may evolve in limited sites. Palmoplantar hyperkeratosis occurs in up to 70% of patients, and can cause recurrent painful fissures, digital contractures and loss of pulp volume. Scalp involvement may lead to tinea amiantacea and patchy cicatricial alopecia, especially on the temporal scalp.

Ectropion improves during infancy, but persists into adult life in 30% and, if untreated, may lead to exposure keratitis and even blindness [20]. Loss of eyebrows and lashes in severe cases accentuates the ocular problem. Hypoplasia of the nasal and aural cartilages may result from compression and scarring, increasing the cosmetic burden.

A mild nail dystrophy consisting of ridging, subungual hyperkeratosis or hypoplasia occurs in up to 50% of patients, but hair, teeth and mucosal surfaces are normal. Nail growth and skin healing are rapid. In most patients, sweating is absent or markedly reduced in childhood, and care is needed to avoid hyperpyrexia during intercurrent illness, leisure pursuits or in hot climates. Sweat gland function improves in adolescence, and in patients treated with retinoids. Hypohidrosis is therefore thought to be a result of sweat duct obstruction by the hyperkeratotic stratum corneum. Pruritus is not uncommon and NBIE often deteriorates in summer weather. Coexistent eczema causes severe pruritus. Cutaneous infections are rare, although there have been reports of widespread fungal infection in patients with congenital ichthyosiform erythroderma [21,22]. Mildly affected patients may present with an intertrigo-like pattern, mild palmar hyperkeratosis and subtle facial tightness.

Many affected children are of short stature, but may catch up with a delayed growth spurt in adolescence. NBIE may limit a child's ability to take part in sports, but swimming and less vigorous activities should be

(a)

(b)

Fig. 34.6 Non-bullous ichthyosiform erythroderma: (a) in a 4-year-old-boy; and (b) same child.

encouraged. Psychological problems often arise at school because of insensitive comments and reactions of others. However, in general, children with NBIE seem to cope well with their disability, and academically achieve on a par with their peers.

Congenital reticular ichthyosiform erythroderma. Three cases of a variant of NBIE have been described [23]. They developed enlarging areas of normal skin which accounts for the alternative names, 'ichthyosis en confetti' and 'ichthyosis variegata'. Specific ultrastructural changes were reported and one affected woman developed hyperpigmented macules on the limbs [24].

Diagnosis. Classic NBIE presents a characteristic clinical picture enabling differentiation from classical lamellar ichthyosis. Other causes of congenital erythroderma and collodion membrane presentation need to be considered in the neonatal period. Collodion presentation of loricrin keratoderma associated with ichthyosiform erythroderma was seen in two Japanese siblings and their father [25]. Congenital infections such as candidiasis, congenital psoriasis, Netherton's syndrome, immunodeficiency disorders, trichothiodystrophy (IBIDS) and neutral lipid storage disease may mimic the cutaneous signs of NBIE in the neonate. There have been sporadic cases of coexistent congenital ichthyosiform erythroderma and psoriasis [26,27].

Genetics. Classical NBIE is an autosomal recessive condition and therefore more likely to occur in societies where consanguineous marriage is common. In a personal series of 25 patients with NBIE, there were five sibling pairs and seven patients, including three Caucasians, were the offspring of consanguineous parents. The risk of further affected children for the parents of the proband is 1 in 4 for each child. Affected individuals should not have affected children, and their offspring have a 50% risk of carrier status.

A non-consanguineous Swedish kindred with typical features of NBIE in a mother and her two daughters may have a previously undescribed autosomal dominant variant, or may have occurred because of pseudodominance [1]. This theory proposes that the mother's parents and her unrelated husband were each heterozygous carriers of the recessive gene; the incidence of heterozygosity was estimated at 1.8–3.2 in 1000 population.

Prenatal diagnosis is possible by fetoscopy and fetal skin biopsy with amniocyte pelleting at 17–22 weeks to detect premature or abnormal keratinization or abnormal inclusions [28,29], but it is far from satisfactory for two reasons [14,30]. First, phenotypic heterogeneity can exist between members of the same family, so that the severity of the proband may not reflect that of the affected fetus. Secondly, normal interfollicular keratinization is established only at 24 weeks' gestation and shows a regional pattern of evolution. To avoid errors, multiple skin biopsies from different sites including the scalp are recommended. The identification of a specific genetic mutation in the proband will allow first trimester prenatal diagnosis based on chorionic villus sampling at 10–12 weeks' gestation.

Treatment. The principles of emollient and keratolytic treatments for patients with NBIE are much the same as those outlined for treatment of ichthyosis vulgaris. Because of the inflammatory nature of the condition, the potential for irritation with topical treatment is high, and keratolytics and topical retinoids are rarely used. Topical steroids are ineffective and readily absorbed but antifungals may be helpful. Hypohidrosis with the attendant risk of hyperpyrexia may be aggravated by the occlusive action of ointments. Prevention of sunburn and sunstroke in children is important.

Systemic retinoids are effective in many disorders of keratinization, and have been shown to be helpful in reducing scaling, pruritus and erythema in most patients with severe congenital ichthyosis including NBIE [31]. For many patients, this may allow a more active role in daily activities, such as schooling, sport and socializing. The recommended starting dose of acitretin is 0.5–0.75 mg/kg/day, tending to higher doses in younger children. A response is apparent within 2–3 weeks, and the maintenance dose is titrated down to the lowest effective level between 0.1 and 0.5 mg/kg/day. Effective doses tend to be lower than in the treatment of other disorders of keratinization. Because of potential toxicity and the chronicity of the disease, intermittent therapy is preferred (e.g. 3 months on, 3 months off). Patients with ectropion or corneal damage may not be able to tolerate the side effects of retinoids, and peeling of palmar skin may induce an unpleasant hypersensitivity. Rare cases of skeletal toxicity have been reported with retinoid therapy [32], but long-term use of etretinate in 42 children, 14 with NBIE, did not cause significant skeletal abnormalities [33]. Pretreatment baseline selective skeletal survey was recommended for all patients, with follow-up studies restricted to those with pretreatment lesions or who develop musculoskeletal symptoms. Older children and adults must be advised of the teratogenicity of retinoids and, where appropriate, contraceptive measures undertaken. The period of mandatory contraception is less with isotretinoin compared to acitretin but it is less effective.

A small open trial on the effect of 4 weeks' treatment with oral ciclosporin in congenital ichthyosis (three cases with NBIE and two with lamellar ichthyosis) showed no benefit [34]. Topical tacrolimus ointment 0.1% was associated with dramatic improvement in one case but increased absorption led to potentially toxic blood levels on daily application [35]. Evening primrose oil has been helpful in occasional cases.

Patients and families may benefit from contact with other affected people and patient support groups exist in several countries. Advice to carers and teachers, careers advice and ongoing support assists children and young adults in coping with the educational, occupational and social problems resulting from their chronic skin disease.

Lamellar ichthyosis (MIM 242300, 601277, 146750)

Of the two major autosomal recessive ichthyoses, lamellar ichthyosis (LI) is less common than NBIE, with an incidence of approximately 1 in 500 000. It has a worldwide distribution. In its severe form it is easily recognized, but heterogeneity exists and it may be confused with other ichthyoses. The so-called 'alligator boy' reported by Fox in 1884 probably suffered from LI [1].

The term 'lamellar ichthyosis' (Latin *lamella*, plate) was, in the early 20th century, used for any congenital ichthyosis excluding harlequin fetus and, until the 1960s, it also referred to the collodion baby phenotype. In the European literature, the prefixes erythrodermic or non-erythrodermic (lamellar ichthyosis) correspond to NBIE and LI [2]. Evidence for clinical, histological and biochemical heterogeneity in autosomal recessive ichthyosis helped distinguish between NBIE and LI [3,4] and specific genetic mutations have been found in a proportion of LI patients. An autosomal dominant pattern of inheritance of LI has been described [5].

Aetiology and pathogenesis. The main histological changes point to a disorder of cornification or terminal epidermal differentiation. Reduced skin barrier function was evident in studies of transepidermal water loss, and paralleled stratum corneum lipid defects [6]. Scale lipid analysis in severe LI showed a mild but significant rise in sphingolipids (ceramides) and free sterols, a pattern similar to that of normal palmoplantar skin [3].

Cornification involves the construction of the cornified envelope from intracellular protein precursors including loricrin and involucrin. These are cross-linked in the granular layer by the action of transglutaminase, forming γ-glutamyl-lysine isopeptide cross-links. Three cases of autosomal recessive LI examined immunohistochemically showed a high expression of abnormally distributed loricrin and involucrin in keratinocyte cytoplasm, with diminished cytoplasmic transglutaminase staining [7].

Genetics. Genetic studies of inbred and outbred families with severe LI revealed complete genetic linkage to the region on chromosome 14q11 containing the transglutaminase 1 candidate gene, *TGM-1* [8]. There was striking homozygosity at this locus, compatible with recessive inheritance, and the evidence was further strengthened by the identification of several mutations in the *TGM-1* gene [9,10]. These mutations were shown to greatly reduce or ablate transglutaminase activity [9]. Homozygous or compound heterozygote mutations of the *TGM-1* gene were found in all these families and have since been reported in mild localized LI [11]. However, there is biological heterogeneity; 13 of 23 families with a clinically similar phenotype had no evidence of linkage to the *TGM-1* gene locus [12]. Linkage to chromosome 2q33-35 [13], to chromosome 19p12–q12 [14] and to chromosome 19p13.1–p13.2 has also been reported [15]. There is close genotype–phenotype correlation in those families with linkage to these three sites.

An autosomal dominant keratoderma with ichthyosiform erythroderma in a kindred reported by Camissa [16] is a result of a loricrin mutation [17] (cf. Vohwinkel's syndrome).

Classical LI is an autosomal recessive disorder, and the same principles apply in the counselling of families as outlined for NBIE. Because of the rare occurrence of autosomal dominant LI (see below), examination of any relatives with skin disease is indicated, and in non-consanguineous families with a single affected child, the implications of dominant transmission should be borne in mind.

Histopathology. Light microscopy of the skin in LI shows striking, compact orthohyperkeratosis with variable mild focal parakeratosis, and a stratum corneum thickness at least twice that of NBIE. The granular layer appears normal or increased, the remainder of the epidermis is normal, and overall epidermal thickness is slightly increased. There may be mild papillomatosis, extension and blunting of rete ridges, and dilatation of dermal capillaries reminiscent of psoriasis.

Histochemical techniques to identify glycoconjugates and free-sterol localization showed a staining pattern similar to that of normal skin [3]. One group reported faint PAS positivity in the stratum corneum [2]. Kinetic studies surprisingly revealed a near-normal transit time, in contrast to the hyperproliferative epidermis of NBIE and psoriasis, and LI is therefore classified as a retention ichthyosis [4].

Fig. 34.7 Lamellar ichthyosis, severe.

Electron microscopy features in LI are variable. Niemi *et al*. [18] reported finding prominent cholesterol clefts or crystals in the stratum corneum, lipid droplets in corneocytes and a thin or absent cornified envelope in nine affected patients with clinical features of LI, from seven Finnish kindreds. These ultrastructural signs led to the subclassification of ichthyosis congenita type 2. Various other changes including abnormal membrane structures and vesicles within lamellar bodies have been noted in patients with a reticulated form of LI, also called ichthyosis congenita type 3 [19].

Clinical features. At birth, most affected infants present as collodion babies, and after shedding the membrane, show a less intense erythroderma than infants with NBIE—an important and persistent distinguishing feature. Scaling occurs within the first month of life and may affect the whole skin surface, or localize to the scalp, abdomen and lower legs.

The scale in LI is typically large, dark brown or grey and firmly adherent (Figs 34.7 & 34.8). In severely affected individuals, the thick, rigid scale is intermittently shed, causing deep and painful fissures, especially around

Fig. 34.8 Lamellar ichthyosis, mild (same patient as Fig. 34.4a,b).

flexures and on the digits, palms and soles. Limitation of joint movement, flexion contractures and digital sclerodactyly may result. Additional features in some patients are palmoplantar keratoderma, scarring alopecia, persistent ectropion, and congenital hypoplasia of aural and nasal cartilages. Erythroderma is absent or mild in LI. Pruritus rarely occurs, and sweating is severely impaired. The hair shaft, teeth and mucous membranes are not affected, and growth and intellectual ability are normal. Extracutaneous manifestations have not been reported. Severe forms of LI seldom improve with age, and psychological problems resulting from the cosmetic effects and limited mobility can lead to isolation, depression and poor school performance.

In mild LI (Fig. 34.9), the typical plate-like scale may only occur on the lower legs, upper arms, and possibly the forehead and trunk [11,18]. These patients may also have fine white branny scales on the flexures and neck. They have focal hypohidrosis, usually normal palms and soles, and tend to improve in summer months. Cyclical shedding or peeling may occur.

Autosomal dominant lamellar ichthyosis (MIM 146750). Traupe *et al*. outlined the clinical, ultrastructural and biochemical features of an ichthyosis that clinically resembled LI, but that showed an autosomal dominant transmission in four members, two male and two female, through three generations of a German family [20]. These patients had non-erythrodermic lamellar-type generalized scaling from birth, palmoplantar hyperkeratosis

Fig. 34.9 Lamellar ichthyosis, adult with mild disease.

and lichenification of the dorsa of the hands and feet and major flexures. They did not have a collodion membrane at birth, and pruritus was a problem in one child. The light microscopical features were similar to those of classical LI. The electron microscopy findings in two of them differed from those of autosomal recessive LI, and included normal tonofilaments and keratohyaline granules, a prominent transforming zone at the granular–corneal junction and sparse corneocyte lipid inclusions.

Since then, reports of a similar disorder in separate families (French and Swedish) have appeared, although in these cases, a collodion baby phenotype and subsequent mild erythroderma were notable features [21,22]. Of the 32 collodion babies reviewed by Larregue *et al*. [21], 10% were said to have developed autosomal dominant LI, but the disease phenotype is not clearly defined. Lipid analysis of plantar scale from two patients with autosomal dominant LI revealed a different profile compared to that of classical LI [23].

Diagnosis. Differential diagnosis includes XLRI and ichthyosiform erythrodermas with collodion presentation. DNA-based mutational analysis of the *TGM-1* gene, using PCR, requires only a blood sample.

Treatment. Mild LI can be controlled with regular emollients and keratolytics as outlined for the treatment of ichthyosis vulgaris. Topical calcipotriol has been efficacious in LI [24] and beneficial effects of a 10% urea lotion and topical *N*-acetylcysteine have been reported [25,26]. A trial of oral retinoid therapy is indicated in severe LI. Of six patients with typical severe LI, five had a marked improvement, while the sixth had a moderate response with reduction of scaling, pruritus and skin tenderness [27]. The main side effects were cheilitis, epistaxis and hair loss in one. In three of them, low-dose therapy was effective. The management of systemic retinoid therapy is detailed under the heading of treatment of NBIE. A

topical receptor-selective retinoid, tazarotene 0.05% gel, has also produced good results [28].

Harlequin ichthyosis (MIM 242500)

Harlequin ichthyosis (HI) describes a severe erythrodermic ichthyosis that causes a distinctive and alarming appearance at birth. The skin patterning and lethality prompted the label of 'harlequin fetus' but, as survival is possible, the term HI is a more appropriate name. This was one of the first genodermatoses to be recorded. An affected baby, who survived for 2 days, was described by Oliver Hart, a Charleston pastor, in his diary of 1750, published in 1896 [1]. HI is, fortunately, a very rare occurrence (approximately five cases in the UK annually) and was invariably associated with stillbirth or early neonatal death until Lawlor's report of a survivor in 1985 [2,3]. Other survivors have been reported since, with most eventuating in a severe erythrodermic ichthyosis, although one was mildly affected [4–9]. Most cases are sporadic with autosomal recessive inheritance, but some kindred have had several affected children [2,8–10].

Aetiology and pathogenesis. Defects in keratin expression and epidermal lipid deposition were reported in the 1970s [11,12]. HI cultured keratinocytes show excessive cornification and failure of desquamation. A study of 10 clinically similar cases from eight separate families revealed defective lamellar bodies (replaced by small vesicles) and intercellular lipid lamellae in all of them. There was abnormal, although variable keratin and filaggrin expression, suggestive of genetic heterogeneity [13,14]. Three subtypes were evident: type 1 cases had a normal keratin profile and positive profilaggrin staining but absent filaggrin expression; type 2 displayed a hyperproliferative keratin pattern in suprabasal cells (prominent K6/16 and reduced K1/10); type 3 had suprabasal K6 and 16 expression and absence of profilaggrin staining and keratohyaline granules, except in intraepidermal sweat ducts. Filaggrin was not expressed in any form of HI; in types 2 and 3, profilaggrin cannot be converted to filaggrin because of a block in post-translational processing [14]. A primary epidermal defect was suspected, specifically defective dephosphorylation secondary to abnormal protein phosphatase activity. In type 2 HI, abnormal expression of protein phosphatase 2Ac, a widely distributed serine–threonine protein phosphatase whose gene is located on chromosome 11 was found [15]. Low reactivity was also seen in type 1 cases [15]. However, in neither type 1 nor type 2 HI have these observations been backed up by molecular genetic evidence.

The expression of a calcium-dependent neutral protease, calpain 1, is reduced in HI epidermis but not in other epidermal disorders [16]. Calpain 1 plays an important part in epidermal differentiation via its role as a regulator of signal transduction and cytoplasmic protease activity. It plays a part in profilaggrin processing and in the activation of transglutaminase and phospholipase

(a) (b)

Fig. 34.10 Harlequin ichthyosis: (a) neonate; (b) aged 18 months.

C. Again no defects in this or related genes have been reported to date.

Histopathology. Skin biopsy shows marked, compact orthohyperkeratosis extending down into dilated hair follicles and pilosebaceous units. Parakeratosis is marked in type 3 HI (see above) and may occur in types 1 and 2. Usually, no other specific changes are noted on light microscopy, and the basal and spinous layers appear relatively normal. In some cases, vacuoles are seen in the stratum corneum and the granular layer is reduced in thickness. Rarely, papillomatosis and a dermal inflammatory infiltrate are present. Pilosebaceous and sweat glands are preserved and non-keratinizing mucous membranes are normal.

Electron microscopy of 10 cases, including one fetal skin biopsy, revealed multiple vacuoles, lipid droplets and cellular remnants in corneocytes in all cases [13]. Keratohyaline granules were abnormal in types 2 and 3. Lamellar bodies in spinous and granular cells were either absent or abnormal in all, and the intercellular lipid lamellae at the granular–corneal junction were not formed. Immunohistochemical staining of the cytoplasmic vesicles seen in granular layer cells suggested that they were abnormal lamellar granules. In fetal biopsies, large abnormal mitochondria in keratinocytes have been noted at 16 weeks' gestation, prior to keratinization [17]. Adnexal keratin plugging at 18–20 weeks preceded interfollicular changes, and a thickened cornified envelope was also evident.

A skin biopsy from a 2-year-old survivor showed histological and ultrastructural features similar to those of severe NBIE with more pronounced lamellar body defects [10]. However, there was a persisting defect in filaggrin synthesis.

Clinical features. The affected infant, usually premature, sometimes stillborn, is encased in a rigid, taut, yellow-brown, adherent skin, a hyperkeratotic 'coat of armour', covering the whole body surface. Deep fissures occur prenatally over the scalp and soon after birth, the inflexible 'cast' splits, producing further red fissures and a skin pattern resembling a harlequin's costume. The head may appear microcephalic, and facial features are distorted because of severe ectropion, conjunctival oedema, which obscures the eyes, and eclabium (everted lips) (Fig. 34.10a). The scalp feels boggy, and the nose and external ears are tethered and appear rudimentary. Oedematous hands and feet may either be encased in hard mitten-like casts, or covered with a mucoid membrane, but the digits are well formed underneath. Additional congenital defects have been found in some cases.

Movement is restricted, and respiratory insufficiency results from limited chest expansion and sometimes coexistent skeletal deformity. Absence of effective sucking causes feeding difficulties leading to hypoglycaemia, dehydration and renal failure. Temperature instability and infection commonly supervene, and may lead to rapid demise. However, several survivors have been reported in recent years [2–10]. In these cases, intensive nursing and medical care prolonged survival until the plate-like scale was shed over a period of weeks. Early retinoid therapy was instituted in some cases and in all but one

a severe ichthyosis resembling NBIE was the eventual outcome. One survivor, at 9 years of age, was reported to be of normal intelligence and had discontinued retinoid therapy [4]. Another, at age 9 years, had severe ichthyosiform erythroderma, a nutritional osteomalacia, short stature and limb contractures but was bright and attending mainstream school (Fig. 34.10b) (F. Lawlor, personal communication, 2002) [2,3].

Genetics and prenatal diagnosis. HI is an autosomal recessive disorder. However, it has been suggested that some cases may result from a sporadic new dominant mutation with parental mosaicism in families with recurrent cases [2,10,13]. The uniform HI phenotype contrasts with its genetic heterogeneity. Each family may possess a different genetic defect, but within families disease expression is consistent.

Detailed genetic counselling is required for affected families, and prenatal diagnostic testing in future pregnancies is available in selected centres. In the past, this depended on the identification on light microscopy of premature keratinization by the 20th to the 22nd week of gestation [18]. Earlier diagnosis is possible with electron microscopy, which shows atypical intraepidermal vesicles at 18 weeks' gestation, during the periderm phase and before the onset of cornification [19]. Amniocentesis at 17 weeks' gestation has also shown intracellular lipid vesicles in clumped shed keratinocytes, presumably derived from follicular epidermis [20]. Ultrasound detection of amniotic fluid debris in HI has been noted [21]. It is hoped that identification of specific genetic mutations will allow first trimester diagnosis and accurate prognosis in individual families.

Despite the disproportionately high incidence of affected offspring in some families, HI is regarded as autosomal recessive and the extended family should be advised of the genetic risk of intermarriage. HI has been reported in one non-identical twin [22] and in two twin pairs [10,23].

Differential diagnosis. The distinctive clinical features of HI are unlikely to be confused with the less severe presentation of the collodion baby, but a small proportion of affected neonates fall between the two presentations. These may in the past have been referred to as 'chrysalis babies'. The early neonatal appearance of HI may resemble that of restrictive dermopathy, but in the latter the tight thick skin persists and skeletal and facial abnormalities are evident. A variant of infantile systemic hyalinosis and the 'stiff skin syndrome' (congenital fascial dystrophy) also present with tight skin.

Treatment. Up to the 1980s, the outcome was uniformly bleak with death resulting in the first days or weeks of life. The potential for survival of HI babies presents families and carers with the dilemma of providing intensive neonatal care while accepting the outcome of severe lifelong ichthyosis. The family should be informed of the implications of the condition, encouraged to consider all options and supported in the part they wish to play. Staff unfamiliar with the startling and distressing deformity also need to be enlightened about the evolution and practical problems associated with HI. If survival seems possible and intensive care is available, a care plan should be drawn up within the first day of life and support provided for staff in their difficult role. The facilities of a neonatal intensive care unit are required to cope with the predictable problems of hypothermia, feeding and respiratory difficulties, dehydration, electrolyte and renal complications and sepsis. Regular paraffin-based emollient and oil baths are required from day 1 onwards. The apparent benefit of early retinoid therapy is difficult to assess and not all survivors have received it [8]. Early introduction of acitretin accelerates shedding of hyperkeratotic plates. Later, staged plastic surgery may improve the cosmetic result, and intermittent retinoid therapy may reduce the degree of disability.

Bullous ichthyosiform erythroderma (MIM 113800)

Bullous ichthyosiform erythroderma (BIE) is a rare autosomal dominant disorder of keratinization that, in its early phase, is associated with blistering. It was first described by Brocq in 1902 [1]. The incidence is thought to be less than 1 in 100 000, although it is likely that some mild cases go unrecognized. A characteristic histological picture of hyperkeratosis with lysis and tonofilament clumping in granular layer keratinocytes characterizes this condition, and BIE may also be known as 'epidermolytic hyperkeratosis'. To date, all investigated cases of BIE have been shown to result from mutations in particular keratin genes, with good correlation of phenotype and genotype as skin lesions occur in sites where the affected keratin is expressed.

Aetiology and pathogenesis. The aggregation of tonofilaments in suprabasal keratinocytes in BIE is suggestive of an underlying genetic defect of keratin synthesis or degradation, involving keratins K1 and/or K10, as they are distributed only in the suprabasal compartment in normal epidermis [2]. Immunoelectron microscopy, using highly specific keratin monoclonal antibodies, showed selective involvement of K1/K10 in the aggregated tonofilaments suprabasally, while the non-aggregated filaments seen in basal cells consisted of K5 and K14 [3]. These data pointed to a primary genetic defect in K1 or K10 [3]. Increased filaggrin reactivity was also evident on immunohistochemistry and protein blotting, but was preceded by keratin filament aggregation, suggesting that the aggregation was independent of the action of profilaggrin. In some cases, there appeared to be defective keratin–filaggrin interaction because of premature cell death, abnormal filaggrin processing and structural alteration in keratin interaction points. Affected fetuses have been shown to develop suprabasal tonofilament clumps at a stage of skin development where keratohyalin granules are not yet expressed, implying that filaggrin changes are secondary [4]. There are also alterations in the staining pattern and electron density of cornified envelope proteins, thought to be secondary to the keratin defects [5]. Loricrin staining was prematurely expressed and associated with keratin aggregates. Trichohyalin reactivity, not normally found in epidermis, was found in granular cells.

Genetic linkage studies confirmed autosomal dominant inheritance, and revealed linkage to either of the keratin gene clusters on chromosomes 12q and 17q [6–8]. Transgenic mice carrying mutant K10 developed skin abnormalities similar to BIE [9], and transgenic mice expressing a severely truncated K10 protein displayed a BIE-like phenotype in heterozygotes and a more severe phenotype in homozygotes [10]. Several groups have described mutations in the highly conserved regions of K1/K10, predominantly involving point mutations resulting in amino acid substitutions within the specialized sequences of the ends of the rod domains [11–18; see also Intermediate Filament Mutation Database, http://www.interfil.org]. These conserved regions are critical for filament integrity and assembly, and the mutations disrupt higher filament assembly in a dominant-negative fashion, leading to collapse of the network and filament aggregation around the nucleus. Most mutations occur within the conserved sequence motif at the beginning of the helical rod domain, with a particular arginine codon in K10 being most vulnerable, the 'hotspot arginine' [13,15]. Specific mutations involving different amino acid substitution within the 2B rod domain of K1 have been associated with the rare annular migratory variant of BIE [19].

Identification of the gene abnormality in a parent can permit prenatal diagnosis by direct gene sequencing from a chorionic villus sample earlier than by prenatal skin biopsy. In a genetic study of 21 American families, the presence or absence of palmoplantar keratoderma (PPK) was used to subset the patients [20]. Of the six families with PPK, four had K1 mutations whereas eight of the 15 families without PPK had K10 mutations.

Histopathology. Skin biopsy shows marked epidermal acanthosis and hyperkeratosis. In the cells of the prominent and degenerate granular layer, and in the upper spinous layers, there are multiple perinuclear vacuoles and large clumped keratohyaline granules. Inter- and intracellular spaces form as a result of suprabasal cytolysis or cell rupture, and a split with oedema in the granular layer marks the site of a blister (Fig. 34.11). These features together are described by the term 'epidermolytic hyperkeratosis'. In mild forms of the disease, these changes may be subtle. The basal keratinoyctes are normal and there is a mild upper dermal lymphocytic infiltrate. The epidermis is hyperproliferative and the number of basal keratinocyte mitoses approaches that of psoriatic erythroderma [21].

Electron microscopy reveals clumped keratin tonofilaments dispersed around the keratinocyte nucleus. Desmosomes are disrupted to a variable degree, and clefts between keratinocytes are associated with oedema and acantholysis. The ultrastructural tonofilament changes precede the vacuolation in spinous and granular cell layers [2,22]. EHK is not unique to BIE but is seen in ichthyosis bullosa of Siemens, some cases of ichthyosis hystrix,

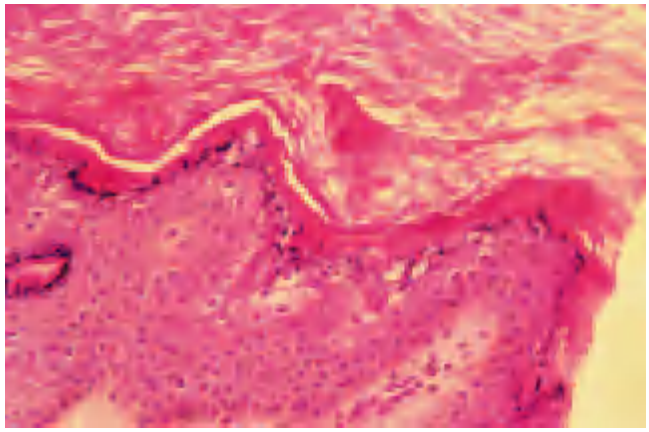

Fig. 34.11 Bullous ichthyosiform erythroderma: histological features of epidermolytic hyperkeratosis.

Fig. 34.12 Bullous ichthyosiform erythroderma, neonate.

Vorner's palmoplantar keratoderma, a subgroup of epidermal naevi, and as an incidental finding in a variety of unrelated lesions such as solitary acanthoma, dermatofibroma, melanocytic, actinic and inflammatory lesions, in the walls of epidermal cysts and even occasionally in normal oral mucosa [23,24].

Clinical features. BIE typically presents with epidermolysis (fragile skin), which gives way to gradual evolution of hyperkeratosis. A mild generalized erythroderma is present at birth. Flaccid blisters, peeling and superficial erosions at sites of minor trauma or friction are apparent within the first few hours of life (Fig. 34.12). Frequent misdiagnoses at this stage include staphylococcal scalded skin syndrome and epidermolysis bullosa. However, the baby is generally apyrexic and well, and focal hyperkeratosis may hint at the diagnosis. In the past, many of these infants developed severe infection, dehydration and malnutrition leading to a considerable mortality, but with intensive neonatal care their prognosis has greatly improved. The superficial erosions heal rapidly without scarring, and easy blistering ceases in the first few months

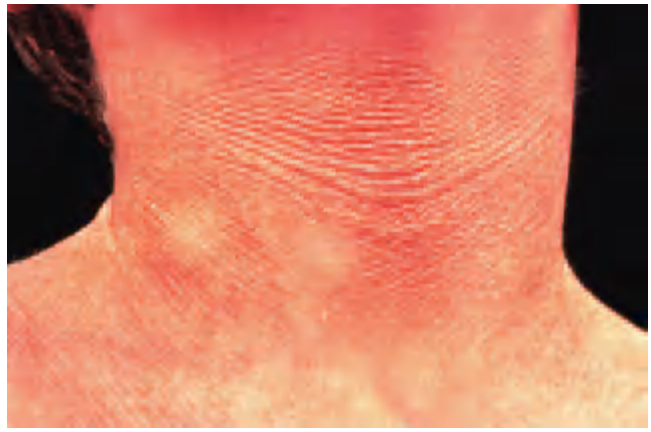

Fig. 34.13 Bullous ichthyosiform erythroderma, neck.

of life. Localized blistering at sites of trauma (the nappy/diaper area, thighs, knees) or infection continues through childhood. Erythroderma fades while the characteristic grey waxy scale progress.

Increasing hyperkeratosis is obvious from early childhood and is most prominent around the anterior neck, flexures, abdominal wall, infragluteal folds and scalp (Figs 34.13 & 34.14). Yellow–brown, waxy, ridged or corrugated scale builds up in skin creases, sometimes forming spiny (hystrix) outgrowths. Cobblestone-like keratoses occur at other sites such as the dorsal hands and feet, and over the trunk. Verrucous plaques may coat bony prominences, scalp and areolae, and chunks are easily dislodged, leaving tender erosions where scale slowly accumulates again. Skin colonization by *Staphylococcus*, brevibacterium and possibly fungi produces a distinctive and embarrassing body odour. Repeated skin infections, causing blisters, pustules or cellulitis, especially in macerated flexural areas, are a troublesome complication in some children. The central face is mildly affected but scalp involvement can be severe and cause patchy alopecia. Spontaneous blistering virtually disappears by adolescence and only a mild erythema persists. Some mildly affected individuals have transient blistering in infancy with focal hyperkeratosis thereafter.

Palmoplantar hyperkeratosis develops in approximately 60% of patients with BIE and may result in recurrent painful fissures, contractures, sclerodactyly and foot deformity with impaired function. It does not relate to disease severity. Nail dystrophy is rare, although curvature may result. Severely affected children may be of short stature, although many catch up in adolescence.

An unusual variant of BIE, characterized by recurring, migrating, truncal annular and polycyclic plaques in association with more typical flexural lesions has been reported [25]. Histological features of EHK and keratin K10 or K1 mutations, similar to those of BIE, have been identified and it has been termed annular epidermolytic hyperkeratosis [19,25,26].

(a)

(c)

(b)

Fig. 34.14 Bullous ichthyosiform erythroderma: (a) arms; (b) palms; and (c) legs.

Evolution of BIE is variable, but in common with other autosomal dominant skin disorders it tends to improve with age. BIE sufferers may have significant physical and psychological morbidity. Visible scaling, skin fragility, keratoderma and odour can lead to social and occupational problems. Mild learning difficulties in some patients may be related to perinatal complications.

Naevoid BIE. There have been several reports of individuals with an asymmetrical linear, focal or naevoid lesion (including comedo and systematized naevi) showing histological features of EHK, who have had a child with generalized BIE [27–29]. The limited or naevoid disease expression in the parent, which is distributed in Blaschko's lines, is suggestive of a genetic somatic mutation of keratins K1 or K10 at an early stage in embryonic life, producing phenotypic and gonadal cell mosaicism [27]. K1/K10 mutations have been found in keratinocytes from affected but not unaffected sites in the parent [30]. The parental lesions may be overlooked or misdiagnosed.

Differential diagnosis. In the neonatal period, other blistering disorders such as epidermolysis bullosa, staphylococcal scalded skin syndrome, herpetic infection and incontinentia pigmenti must be excluded by clinical, histopathological and microbiological assessment. In older patients, ichthyosis hystrix, ichthyosis bullosa of Siemens and non-epidermolytic epidermal naevi may resemble BIE.

Genetics. At least half of cases of BIE have no family history of the disease and are presumed to have suffered a new keratin gene mutation. However, both parents of an affected child should be carefully examined for focal keratotic lesions suggestive of somatic and gonadal mosaicism. In the absence of suspicious parental lesions, further siblings should not be at risk, but an affected parent will transmit the condition in an autosomal dominant fashion to their offspring, who will have generalized disease. The occurrence of inter- and intrafamilial variation in disease severity further complicates genetic assessment. A mildly affected parent may have a severely affected child, either because they have improved with age or because they have a mosaic expression. The reverse can also happen with an attenuated form of familial BIE appearing in the next generation, or variation in severity among affected offspring. It is postulated that a benign simultaneous polymorphism in keratin or keratin-associated protein genes has a modifying effect on the phenotypic expression of the disease in these families [14].

Prenatal diagnosis, based on identification of the characteristic ultrastructural changes on fetal skin biopsy, can be carried out at around 20 weeks' gestation, using ultrasound-guided fetoscopy [31]. Tonofilament clumping is the earliest morphological abnormality, occurring during the second trimester, and precedes the formation of keratohyalin granules and stratum corneum [32]. It is now possible to apply DNA screening techniques to identify specific K1 and K10 gene mutations in chorionic villus samples, following direct gene sequencing of the index case [15].

Treatment. Emollients are of limited value in BIE as the scale is often waxy and macerated. Keratolytic preparations (salicylic acid, α-hydroxy acid or propylene glycol compounds) reduce hyperkeratosis on exposed sites but their irritancy limits patient tolerance. Patients are best placed to decide which, if any, they wish to use and their needs will change over time. Regular use of antiseptic washes and appropriate systemic antibiotics may be required to control repeated cutaneous bacterial and fungal infection and associated body odour. Sensitivity testing of *Staphylococcus aureus* isolates, and cyclical rotation of long-term antibiotics, are indicated for those requiring long-term antibiotic treatment. Topical calcipotriol produces a slight reduction in scaling at the cost of skin irritation [33]. Retinoid therapy is beneficial in some patients, but significant reduction in scaling is often associated with unacceptable skin fragility, blistering and tenderness [34] (for details of acitretin dosage and surveillance, see treatment of NBIE, p. 34.19).

Fig. 34.15 Ichthyosis bullosa of Siemens.

Ichthyosis bullosa of Siemens (MIM 146800)

A mild variant of BIE was described by a Dutch dermatologist, Siemens, in 1937 in a large Dutch kindred [1]. The concept was revived by Traupe who confirmed autosomal dominant inheritance [2] and the phenotype was described in detail in additional Dutch kindreds [3]. Ichthyosis bullosa of Siemens (IBS) is probably less common than BIE, but some milder cases may escape detection.

Aetiology and pathogenesis. In addition to keratins K1 and K10, the high suprabasal keratinocytes express a further type II keratin K2e, a protein of molecular weight 65.8 kDa encoded by a 2.6-kb RNA species [4,5]. As the site of EHK in IBS correlates with its expression sites, K2e was recognized as a likely target gene [6]. Linkage analysis of two affected Dutch families showed linkage with the type II gene cluster on chromosome 12 [7]. Direct sequencing of PCR products of keratin K2e showed point mutations in the highly conserved helix termination motif in a five-generation kindred and a sporadic UK case [8]. Three different K2e mutations were found in four Dutch families, including the descendents of Siemens' original kindred [9]. Several K2e rod domain mutations have been reported in other patients [10–13]. The identical substitution of a glutamic acid with a lysine in helix 2B rod domain of K2e has been found in the majority of IBS cases, including a number of sporadic cases (Intermediate Filament Mutation Database, http://www.interfil.org), indicating that this is a mutation hotspot.

Histopathology and pathogenesis. On histological examination, features of EHK are confined to the prominent granular layer and the upper spinous layer. Basal and suprabasal keratinocytes appear normal. Sites of 'mauserung' (moulting) reveal intracorneal blistering with orthohyperkeratosis above and below the split. Electron microscopy shows granular cell oedema with thick bundles and some clumps of tonofilaments [2].

Clinical features. The characteristic features are mild neonatal disease, or delayed onset, with episodes of superficial blistering persisting through childhood and sometimes into adult life. These occur predominantly on the flexures, shins and abdomen, and quickly rupture to produce annular peeling. There is variable, grey, rippled hyperkeratosis on the limbs and lower trunk, with flexural accentuation and mild hypertrichosis in some. IBS is less severe than BIE, and may resemble the flexural lichenification of atopic eczema. Circumscribed patchy scaling occurs elsewhere, and focal desquamation or moulting of scale, which Siemens called 'mauserung', is seen at the flexures and acral sites, especially the dorsal hands and feet (Fig. 34.15). Palmoplantar blistering is associated with hyperhidrosis and is more severe in summer, but PPK and skin odour are absent. Erythroderma does not occur in IBS, but sudden deterioration with diffuse erythema and peeling resulting from staphylococcal infection has been observed.

A similar ichthyosis, also caused by K2e mutations, has been reported under the title of ichthyosis exfoliativa [14,15]. This and IBS are now regarded as a single entity [7]. An autosomal recessive form of exfoliative ichthyosis (without epidermolytic hyperkeratosis) in an inbred Bedouin family has been documented [16].

Diagnosis. This condition may be mistaken for other autosomal dominant ichthyoses, ichthyosis vulgaris, the dominant variant of lamellar ichthyosis and mild BIE. In certain phases, epidermolysis bullosa simplex, peeling skin syndrome, infected atopic eczema or staphylococcal scalded skin syndrome may be suspected. Prenatal diagnosis, although possible, is rarely an issue. Molecular diagnosis can be performed using whole blood.

Treatment. Emollients and mild keratolytic preparations suffice in most, and often appear to induce an impressive remission. A beneficial effect from 12% lotion of ammo-

nium lactate has been reported in IBS [17]. Avoidance of friction and measures to reduce hyperhidrosis are indicated. Antibiotics should be used to treat skin infection and may prevent episodic widespread blistering. Some cases responded well to low-dose retinoid therapy [18].

Ichthyosis hystrix (MIM 146590)

The subgroup of ichthyosis hystrix (IH) encompasses a number of rare conditions, characterized by spiny hyperkeratotic scale similar to that of BIE. They differ from BIE in that blistering is not a feature, erythroderma is mild or absent, limited or naevoid forms are more common and few show the histological features of BIE. They are autosomal dominant disorders.

History and nomenclature. The first documented kindred with familial IH was the Lambert family of Suffolk, who between 1731 and 1851 had 11 affected members in four generations [1]. The first, Edward Lambert, attended the Royal Society of Medicine in 1731 and some of his affected descendents, known as the 'porcupine men', appeared in circuses, billed as 'a new species of man'. A review in the 1950s showed that, contrary to reports, females were also affected and the ichthyosis was autosomal dominant [2]. Their skin, normal at birth, developed dark warty scaling after 7 weeks of age. There was no blistering, and the face, palms and soles were spared. The severity of the ichthyosis varied among family members and lessened in later generations.

Similar cases of ichthyosis were reported during the 19th century, and in 1954 Ollendorff-Curth and Macklin described two teenage brothers who had congenital verrucous scale on the scalp, neck and limbs, PPK and keratoses on the lips, ears, nipples and buttocks [3,4]. Histological examination of their skin showed acanthosis, hyperkeratosis and swollen hydropic granular layer keratinocytes. Affected relatives spanning five generations had a variable phenotype and it was regarded as an autosomal dominant condition.

Other variants include an isolated case reported by Bafverstedt [5] with striking hystrix scaling on the face, IH gravior of Rheydt (two patients with ichthyosiform erythroderma, PPK and deafness) now known as HID syndrome [6,7]. HID syndrome is allelic with KID syndrome and caused by the same connexin 26 mutation [8]. Zeligman proposed that, on histological grounds, many cases of IH were variant BIE [9]. A single case of a biphasic ichthyosis (typical IH followed by centrifugal scaly lesions in middle age) was described [10]. IH shows considerable phenotypic heterogeneity [11].

Aetiology and pathogenesis. Features suggestive of abnormal keratin expression in middle and upper spinous keratinocytes, from both affected and unaffected skin, were noted [12] but other groups reported normal epidermal keratin labelling [13] and absence of linkage to the keratin gene clusters on chromosome 12q and 17q in a mildly affected family [14]. The electron microscopy features of thick, continuous, perinuclear shells of haphazardly arranged intermediate filaments, flanked by a region rich in ribosomes, are suggestive of a disorganized keratin intermediate filament network [15]. Binucleate cells and perinuclear vacuolation are common, although epidermal proliferation rates are normal. Recently, a novel keratin mutation affecting the variable tail domain (V2 domain) of keratin 1 has been described in an African American family with severe mutilating PPK diagnosed

as IH of Curth–Macklin [16]. This led to a distinctive cytoskeletal abnormality (unlike that of EHK), with failure of intermediate filament bundling, retraction of the cytoskeleton from the nucleus and failure to translocate loricrin to the desmosomal plaques at the cell periphery. Interestingly, a British Caucasian family with an almost identical frame-shift mutation in K1 presented clinically with striate keratoderma of the palms and focal keratoderma of the soles, a phenotype much milder than and quite distinct from that seen in the African American kindred [17]. Interracial differences in genetic modifiers may explain this phenotypic disparity. IH is both clinically and genetically heterogeneous.

Histopathology. Early reports identified the histological features of EHK [9] but the phenotype of these cases is not clearly defined and epidermolysis is typically absent. Light microscopy shows orthohyperkeratosis, patchy parakeratosis, acanthosis and papillomatosis. Scattered vacuolated and binucleate keratinocytes in the upper epidermis are characteristic. The granular layer is reduced and contains rounded and some vacuolated cells. Electron microscopic studies of Curth–Macklin type IH highlighted a characteristic continuous perinuclear tonofilament shell (in contrast to the clumped filaments in EHK) in the upper spinous and granular layers, resulting in three distinct cytoplasmic compartments [12,15,18,19]. That inside the tonofilament shell contained ribosomes, mitochondria and deformed lamellar bodies, while the band outside had normal tonofilament structure terminating on desmosomes. Conspicuous vacuoles (some of which contained lipid material) were present in 30%, and double nuclei in 10% of spinous and granular keratinocytes. Similar changes were seen in clinically uninvolved skin, and persisted with retinoid therapy [19]. An unusual histological finding in a family of eight with IH was the presence of cornoid lamellae [20].

Clinical features. Affected cases may present at birth with a generalized or naevoid scaly erythema without blistering or skin fragility. However, delayed onset in infancy or childhood has been noted. Hystrix ('porcupine spine') scaling, often a muddy brown or grey colour, accumulates during childhood and affects extensor aspects of the limbs (Fig. 34.16a), truncal areas to variable degrees and flexures to a lesser extent than in BIE. Mild scaling may occur at other sites including the scalp, and PPK, diffuse or striate, affects most patients. This may lead to functional impairment, contractures and nail dystrophy. Scaling stabilizes or improves slightly in adulthood. Naevoid lesions follow the lines of Blaschko, and are accentuated by summer tanning of unaffected skin (Fig. 34.16b). There is little seasonal variation, and disturbances of sweating are rare.

IH of Rheydt was reported in two unrelated sporadic cases [6,7]. Generalized scaling, more pronounced on the face and limbs, developed from birth and was associated with profound deafness and PPK. This is now known as HID syndrome.

(a)

(b)

Fig. 34.16 Ichthyosis hystrix: (a) adult male; and (b) naevoid acral lesions in Blaschko's lines in a child.

The development of multiple keratoses and squamous cell cutaneous carcinoma in two patients may have been linked to prior carcinogenic treatments (poorly documented), but a cancer proneness related to IH or EHK cannot be excluded [21,22].

Genetics. Where a positive family history is available, all types of IH have been inherited as an autosomal dominant trait [2,4,12]. There is considerable inter- and intrafamilial variation, and the occurrence of naevoid forms also complicates genetic counselling.

Treatment. Non-greasy emollients are used by some patients, while others prefer keratolytic preparations such as salicylic acid or propylene glycol compounds to reduce hystrix scaling. Their use is not influenced by the fragility or malodour that occurs in patients with BIE. Topical calcipotriol or retinoid may be helpful. Systemic retinoid therapy, intermittent or continuous, is beneficial in some [19] but not in others [20] (for details of acitretin dosage and surveillance, see therapy section of NBIE, p. 34.19).

Netherton's syndrome (MIM 256500)

Netherton's syndrome (NS) is the most common of the multisystem ichthyosiform syndromes, and comprises an ichthyosiform dermatosis (primarily episodic peeling) with a variable erythroderma, hair shaft defects and atopic features. It is an autosomal recessive condition with a worldwide distribution, and an incidence similar to or greater than NBIE, perhaps more than 1 in 100 000. In the absence of a family history, diagnosis may be delayed because of the gradual evolution and heterogeneity of the clinical features. Misdiagnosis and a high neonatal mortality rate in the past have contributed to an underestimate of its incidence.

Netherton's original patient, reported in 1958, was a young girl with a generalized, scaly, erythematous 'dermatitis', paroxysmal pruritus and a hair shaft defect subsequently identified as trichorrhexis invaginata (TI) [1]. Later reports noted the association of TI with migratory double-edged scaly lesions termed ichthyosis linearis circumflexa (ILC) [2]. ILC had been described by Comel in 1949, but there was no comment on that patient's hair [3]. TI is a pathognomonic finding in NS, while the skin manifestations are variable.

Aetiology and pathogenesis. Although genetic mutations of the serine protease inhibitor Kazal type 5 (*SPINK5*) gene have been identified in several NS patients [4–6], the pathogenetic mechanisms of NS are poorly understood. Clinical and histopathological features point to an intermittent disruption of epidermal and hair shaft maturation and keratinization. Electron microscopy shows premature lamellar body secretion and abnormal lipid processing in the intercellular space, which accounts for the severe impairment of the stratum corneum permeability barrier in NS [7]. This leads to an increase in epidermal DNA synthesis and turnover, further disrupting lipid metabolism. In the hair follicle, the TI lesion coincides with a bulge of external root sheath cells, which invaginate the hair shaft at the level of the keratogenous zone [8]. Failure to convert sulphydryl groups to disulphide bonds in the cortical cells of the hair at this level may contribute to the focal softening [9]. The intermittent nature of the hair shaft defect and the migratory pattern of lesions of ILC is, as yet, unexplained. Retinoid therapy induces deterioration in most patients with NS, and a parallel exists in a transgenic mouse model with negative retinoic acid receptors, which also develops erythroderma and poor barrier function. Impaired transcription of differentiation-relevant retinoic acid receptor genes in NS has been suggested [10].

Some features of atopic eczema are seen in NS and the skin permeability barrier is disrupted in both. Histological changes in NS include spongiosis and exocytosis as seen in atopic eczema, but immunohistochemical markers differed [11]. Raised total and specific IgE levels are characteristic [12,13]. Other immune function tests have usually shown only minor and inconsistent abnormalities. The *SPINK5* gene is located adjacent to a cytokine gene cluster

and research efforts are now focusing on the genetic mechanisms of atopy and IgE responses.

The *SPINK5* gene is composed of 33 exons spanning over 61 kb on the distal long arm of chromosome 5q32. It encodes a serine protease inhibitor proprotein, also called LEKTI, which is thought to be necessary for epidermal cell growth and differentiation. *SPINK5* transcripts are expressed in the upper stratum spinosum, the stratum granulosum and in hair follicle and sebaceous gland epithelium. The substrates and mode of activation of the *SPINK5* gene product are unknown. The resultant peptides appear to exert an inhibitory effect on epidermal serine proteases that mediate corneocyte desquamation (perhaps by targetting desmoglein 1) and indirectly help to maintain the epidermal permeability barrier [14]. Elevated trypsin-like proteolytic activity in the stratum corneum in NS provides support for this hypothesis and helps to explain the prominent inflammatory nature of the cutaneous lesions. In NS patients with severe erythroderma, the trypsin levels were higher than in those with a mild phenotype. Homozygous frameshift and splicing *SPINK5* mutations were associated with more severe disease than downstream nonsense mutations, which caused milder ILC-type lesions [5].

Histopathology. The histological features vary with the type and phase of the lesion sampled. Hyperkeratosis is mild, in contrast to other ichthyoses, but parakeratosis and a reduced or absent granular layer occur at the spreading border of a lesion. Eosinophilic material may collect within the corneal and granular layers in ILC lesions. An intracorneal split at the site of degenerative parakeratotic corneocytes was noted by Comel [3] and others. Psoriasiform epidermal hyperplasia, papillomatosis and a mixed perivascular inflammatory infiltrate occur in older ILC lesions and in the more diffuse, scaly erythroderma. Acute erythroderma in NS is accompanied by pronounced inflammatory changes with spongiosis, exocytosis, intraepidermal microabscesses and upper epidermal eosinophilic necrolysis, which may lead to a subcorneal split. Features of a non-specific dermatitis may be reported.

Ultrastructural studies in NS have identified inclusion bodies (possibly lysosomes) containing finely granular material in suprabasal keratinocytes, reduced numbers of tonofilament–keratohyalin structures and desmosomes and abnormal lamellar bodies [7,10]. Intercellular lipid lamellae in the stratum corneum were, as a result, disorganized and even absent in places. Lesions of ILC and erythroderma may show similar epidermal changes of retarded keratinization and eosinophilic granular material between and within cells [10].

Microscopy of the scalp and eyebrow hair in NS shows, in a variable proportion of intact hairs, the 'bamboo' nodal dilatation consisting of a bulbous distal hair end invaginating a concave dilated proximal hair terminal (Fig. 34.17). The proportion of scalp hair affected varies from 5 to 50%, and the only clue to its presence may be ragged cupped proximal hair ends, where the fragile node has fractured, 'golf tee hairs' [15]. Hair sampling may have to be repeated several times, and clipped hairs, especially eyebrows, may be the most informative. Pili torti and trichorrhexis nodosa also occur. Scalp biopsies have shown early nodal deformity occurring at the keratogenous zone within the hair follicle and variable perifollicular inflammatory changes [8–10].

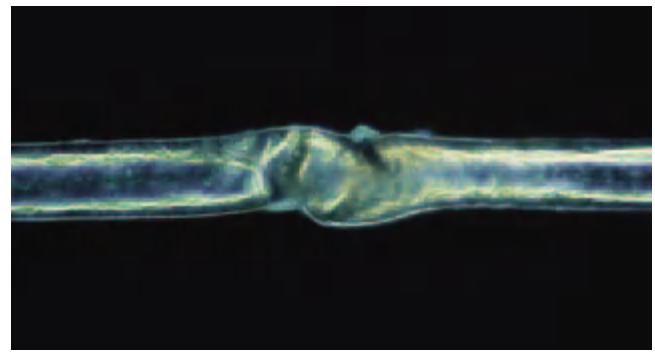

Fig. 34.17 Trichorrhexis invaginata.

Clinical features. Generalized erythroderma of variable intensity is usually evident at or shortly after birth, and desquamation and scaling quickly develop (Fig. 34.18). A minority is mildly affected. Collodion membrane is not a feature, and the infant is usually born at term with average birth weight. Common complications in the neonatal period and infancy, resulting from epidermal barrier disruption, are temperature instability, skin and systemic infection including fungal sepsis and hypernatraemic dehydration. Hypernatraemia in infancy is more common in NS than in other congenital erythrodermas [16,17]. Severely affected infants often suffer from marked failure to thrive in the first year or so, and may have mild diarrhoea. This occurs even with dietary supplementation and, although malabsorption is a recognized though rare complication of erythrodermas ('dermopathic enteropathy'), it is more pronounced in NS. Jejunal villous atrophy was found in one of three NS infants who had biopsies (non-gluten sensitive and resolving spontaneously at 10 months of age) [13] and in three of five patients in another report [18]. In fact, most of these infants begin to put on weight in their second year, although they may remain below the 25th centiles for height and weight. The erythroderma tends to improve also, but can recur unpredictably. Infant mortality in NS was, in the past, significant and often attributed to 'Leiner's syndrome' or other congenital erythrodermas. A rare late complication is dilated cardiomyopathy [19].

During childhood, approximately half of NS patients

Fig. 34.18 Netherton's syndrome, erythrodermic neonate.

develop lesions of ILC on the trunk and limbs, but they may still be at risk of acute erythroderma. A typical ILC lesion is an erythematous, exfoliating or scaly, annular or polycyclic, flat patch with an incomplete advancing double edge of peeling scale (Fig. 34.19). ILC is episodic, with migrating lesions, often in a cephalocaudal pattern, each lasting a few days. Lesions without the double-edged scaly margin are commonly seen. While many patients have recurrent ILC every few months, some have infrequent lesions. In severe NS, a fluctuating erythroderma persists, which may be triggered by intercurrent illness, and rarely pustular lesions are superimposed. Between acute attacks, the skin may look surprisingly normal. In a literature review of 43 cases, ILC was recorded in 30, while ichthyosiform erythroderma was the predominant skin lesion in 13 [12]. Many patients are distressed by prominent facial, particularly perioral erythema and peeling. Pruritus or burning irritation may be troublesome, and another feature reminiscent of atopic eczema is flexural lichenification. Impaired sweating can lead to hyperpyrexia. Bacterial and yeast colonization of the skin and human papilloma virus (HPV) viral warts are common in NS. Chronic blepharitis and ectropion may lead to a keratitis. Mild mental impairment in a minority of NS patients may be related to neonatal complications.

There is gradual improvement with age in most patients, but those with chronic erythroderma may develop painful and disabling flexural oedema and papillomatosis of the axillae, groin, vulva and lower legs [12,13]. This is

Fig. 34.19 Ichthyosis linearis circumflexa.

a premalignant lesion with pseudoepitheliomatous histology; carcinoma of the vulva has been reported in a 63-year-old woman [20]. There are two reports of squamous skin cancer in adult males with NS [21,22]. A progress report 21 years on in the first of these reveals that he developed multiple skin cancers, including a single basal cell carcinoma, on photoexposed sites [23]. He had a history of widespread chronic viral warts and oncogenic HPV types were isolated from skin lesions. The other patient developed eight skin cancers, the first on the scalp at age 27. There is no mention of warts in this report but he was an outdoor worker.

Hair defects. The major diagnostic clue in NS is the hair shaft defect known as trichorrhexis invaginata (Fig. 34.17), but it is often missed in infancy, because scalp hair growth is poor, and attributed to erythroderma. In childhood, scalp, eyebrow, eyelash and even body hair remains sparse, slow growing, lustreless and brittle, and patchy traumatic alopecia results from normal wear and tear. Hair growth improves with age, but in many it is unruly or short and spiky, and some patients may opt to wear a wig. A few older patients have clinically normal, although microscopically defective hair. Broken hair shafts at follicular orifices produces a peppered appearance, especially on the limbs. A small proportion of patients have a nail dystrophy, ranging from thickening to pterygium formation in individual nails.

Atopic features. Many patients with NS have a personal or family history of atopy, especially hay fever or asthma. The question as to whether they may have atopic eczema is controversial. The pruritus, flexural accentuation, periods of remission and raised IgE are suggestive; however, the skin lesions are not clinically eczematous, histological features are not consistent and they do not respond to appropriate eczema therapy. Recurrent urticaria and facial angio-oedema, triggered by certain foodstuffs, are

common complications, although the incidence varies [12,13]. The most common food allergens are nuts and fish, and it can manifest in childhood or even in infancy.

Diagnosis. The diagnosis of NS was suspected prenatally in one case because of ultrasound detection of amniotic fluid debris [24]. The triad of congenital erythroderma, poor hair growth and failure to thrive in infancy, or the detection of ILC suggests the diagnosis. In milder cases without a family history, diagnosis is delayed until the specific hair shaft defect of TI is detected. Atopic features in childhood are associated with positive skin prick tests, and high specific serum IgE tests to common airborne and food allergens. Total IgE levels peak, often at very high values, in early childhood and then may fall towards the normal range [5,12,13]. Minor IgG subclass deficiencies have been noted. Lymphocyte subpopulations are normal, though evidence of T- or B-cell activation and reduced natural killer cell numbers have been found in a few [13]. Impaired lymphocyte mitogen responses were noted in one case [21]. Transient aminoaciduria and neutrophil function defects were identified in one patient [12]. C1 esterase inhibitor levels were normal in eight patients studied, and complement C3 or C4 were raised in three of them [13].

In infancy, the differential diagnoses include erythrodermic atopic or seborrhoeic eczema, staphylococcal or candidal infection, non-bullous ichthyosiform erythroderma (NBIE), psoriasis, hyper-IgE syndrome, immunodeficiency states, zinc or biotin deficiency, cystic fibrosis and protein metabolic disorders. In older children and adults, NBIE is the usual diagnosis, but others have included atopic eczema, familial peeling skin syndrome, pemphigus foliaceus and erythrokeratoderma.

Genetics. NS is an autosomal recessive disorder with several reports of affected siblings and a proportion of patients coming from consanguineous families. The clinical manifestations may vary between siblings, and may be less severe in female sufferers. Several *SPINK5* mutations have been identified in NS, but in up to 34% mutations have not yet been found. Close genotype–phenotype correlation has been reported by three groups [5,14,25] but not by another [6]. Prenatal diagnosis may be requested by parents of severely affected offspring, but, prior to molecular diagnosis, was unreliable. Mutational analysis of *SPINK5* gene on a chorionic villus sample in one case and amniotic fluid in another successfully predicted an unaffected fetus in both [5,25].

Treatment. In the neonatal period, intensive medical, nursing and nutritional care must be available to manage erythroderma and its complications and, specifically, to prevent hypernatraemic dehydration and failure to thrive. Frequent occlusive emollients, such as paraffin mixture, provide a partial skin barrier, which reduces insensible loss that contributes to hypernatraemia. Regular skin and eye swabs and stool culture will guide decisions on the need for antimicrobial therapy; staphylococcal, Gram-negative and candidal isolates are common. Nasogastric tube feeding is often required for several months and a gastrostomy is occasionally necessary. Topical steroids are ineffective, and should be avoided as the erythroderma and high surface area at this age contribute to rapid systemic steroid toxicity.

The day-to-day treatment of older patients with NS is similar to that of other ichthyosiform erythrodermas. Regular emollients are helpful, and patients tend towards greasy paraffin-based products. Excessive use in one patient led to a granulomatous lymphadenopathy [26]. Ammonium lactate lotion 12% has been recommended [27]. Keratolytics are poorly tolerated, but intermittent mild topical steroid therapy may help to lessen facial erythema and antifungal creams improve intertrigo. Topical or systemic antibiotics are often required in childhood for skin and respiratory infections. Antipruritics are only partially effective. Significant improvement in the cutaneous features was reported with topical tacrolimus 0.1% application [28] but there may be significant percutaneous absorption [29].

A peculiar feature of NS is the deterioration induced by systemic retinoid therapy, which is usually beneficial in other erythrodermic ichthyoses [9,12,13,23]. Retinoids are known to aggravate atopic eczema. Some patients with ILC do benefit from low-dose therapy [30]. Psoralen with ultraviolet A (PUVA) therapy has produced variable results [22,31]. Methotrexate and ciclosporin A were ineffective [23,32]. Dermabrasion and subsequent excision of papillomatosis lesions on the lower leg, with split-skin grafting, was performed in an adult patient [13]. Grenz ray therapy has been used in the past, and recently laser ablation of hypertrophic areas has been suggested. A trial of topical protease inhibitors in a group of NS patients is underway [14].

Sjögren–Larsson syndrome (MIM 270200)

Sjögren–Larsson syndrome (SLS) is a rare autosomal recessive condition comprising congenital ichthyosis, spastic diplegia and mild to moderate mental retardation. In addition, a characteristic retinopathy has been noted. Although this syndrome may have been described some years before, credit goes to Sjögren and Larsson, Swedish psychiatrists, for their detailed monograph in 1957. They reported a clinical and epidemiological study of 28 institutionalized patients from 13 families, many of them consanguineous, in an area of north-west Sweden where the condition is common [1]. Common ancestry for most of these was traced back to the 17th century, and a founder mutation introduced to the area in the 13th century has been proposed [2]. Over 200 cases worldwide have been reported, and it occurs in all races. The incidence in Sweden has been estimated at 1 in 100 000 rising to 1 in 10 000 in the north-west region of Vasterbotten [2]. In the UK, the estimated incidence of 1 in 300 000 may be an underestimate [3].

Aetiology and pathogenesis. A defect in essential fatty acid metabolism in plasma phospholipids, involving δ6-desaturase deficiency, was reported in the 1980s [4,5]. Rizzo *et al*. [6,7] demonstrated elevated plasma hexadecanol (C16) and octadecanol (C18) long-chain fatty alcohols, because of a deficiency of fatty alcohol : NAD oxidoreductase (FAO). FAO was assayed in leukocytes and cultured skin fibroblasts and the fatty aldehyde dehydrogenase component (FALDH) of this two-part enzyme is predominantly affected. Reduced enzyme levels in the absence of clinical signs were found in obligate carriers [7,8]. FAO activity combines an alcohol dehydrogenase converting fatty alcohols to fatty aldehydes, and microsomal FALDH oxidizing medium- and long-chain fatty aldehydes to fatty acids. The histochemical demonstration of absent alcohol–hexanol dehydrogenase in the epidermis (Fig. 34.20) and jejunal mucosa in SLS, but not in other ichthyoses, provided further evidence of the importance of abnormal fatty alcohol metabolism in SLS [8]. The neurological defects result from abnormal lipid development in myelin, specifically in the glycerol ether pathway, a side arm of the fatty alcohol cycle, and plasmalogen deposition.

The 31-kb FALDH gene (*FALDH3A2*) is located on chromosome 17p11.2, close to the neurofibromatosis-1 gene [9]. Several different mutations, including deletions, insertions and point missense mutations have been reported [10–12]. FALDH is a 485 amino acid membrane-bound protein with a hydrophobic carboxy-terminus, which is necessary for microsomal membrane anchoring.

Histopathology. Skin sections show orthohyperkeratosis, acanthosis and papillomatosis. The granular cell layer is normal or increased, and there may be mild upper dermal inflammatory change. Kinetic studies in one patient indicated a hyperproliferative epidermis [13]. Ultrastructurally, atypical membranous structures have been reported in spinous and granular layer cells, associated with numerous, large lamellar bodies some of which were irregular or disc-shaped. A proportion contained granular

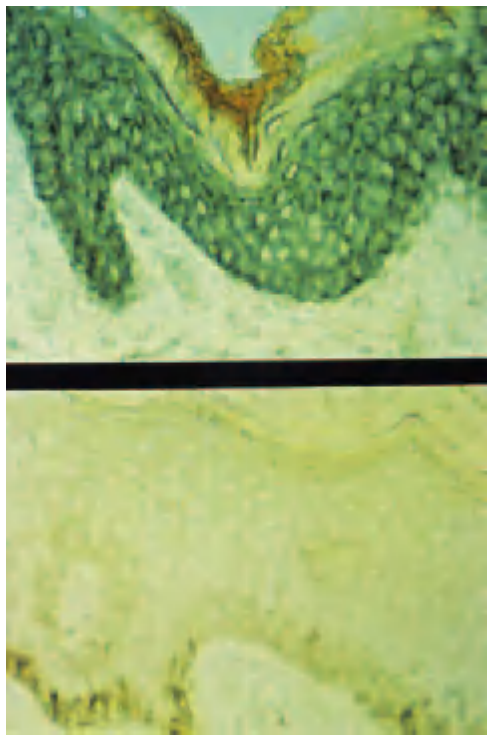

Fig. 34.20 Sjögren–Larsson syndrome, negative staining for alcohol dehydrogenase in the skin, lower panel.

material in addition to lipid lamellae [14]. Membranous inclusions persisted into the corneal layer and increased numbers of mitochondria were present in the basal epidermal cells.

Clinical features. Collodion baby presentation has been reported [15,16], but usually the skin is dry and mildly erythrodermic at birth, and scaling develops within the first 3 months of life. Thereafter, a mild erythema persists and a variable degree of scaling develops, consisting of diffuse peeling on the trunk and more pigmented, lamellar-type ichthyosis on the lower limbs. Scaling tends to follow a cyclical pattern of accumulation and shedding, and predominantly affects the limbs and face (Fig. 34.21). A velvety orange or brown lichenification, sometimes topped with verrucous hyperkeratosis, is most obvious in and around the flexures, neck and periumbilical folds. This characteristic feature may even be noted during the first year of life, and is helpful in diagnosis. Lichenification becomes prominent and is embarrassing to older children, in whom it may also restrict the mobility of already hypertonic limbs. Skin infections are rare, but scratch marks on the trunk reflect the persistent pruritus that SLS patients suffer.

Neuro-ocular features. Variable neurological dysfunction is obvious in early infancy, with delayed motor milestones and evolution of upper motor neurone signs (a non-progressive spastic paraparesis) in the legs and rarely the arms also. Most patients learn to walk unaided or with crutches in early childhood. Altered posture and movement predispose to kyphoscoliosis, dislocated hips and short stature. Development of speech is delayed and seizures are a rare complication. Mild to moderate learning disability is the rule and, although many SLS patients were institutionalized in the past, most can achieve limited independence. They are notable for their cheerful, friendly disposition. Patchy leukodystrophy and myelination defects have been reported on CT and MR scanning and in post-mortem studies in SLS [12,17].

Ocular signs were reported in 1980, and consist of glistening dots on the fovea and parafovea of the retina, which develop during childhood and which do not seem to interfere with vision [18]. They are detected in up to 80% of patients and may fade with advancing age. They may be caused by deposition of lipofuscin pigment granules in the specialized retinal epithelium [19].

Diagnosis. The cutaneous and retinal features are characteristic and quite unlike those of other ichthyosiform syndromes. Biochemical assay of cultured fibroblasts from a skin biopsy or of leukocytes to identify reduced FAO activity, in particular FALDH, confirm the diagnosis. Histochemical analysis of hexanol dehydrogenase in skin is also diagnostic. Assay of plasma C16 and C18 fatty alcohols can be used to assess the effect of dietary interventions. The main differential diagnoses are congenital ichthyosiform erythrodermas with neurological signs, neurocutaneous disorders such as neutral lipid storage

disease, hystrix-like ichthyosis and deafness (HID) syndrome and a neuroichthyotic condition with absent laboratory markers of SLS described in one patient [20].

Genetics. Although rare outside northern Sweden, SLS is a severe autosomal recessive disorder and fully penetrant [2]. Many families seek prenatal diagnosis in subsequent pregnancies, and relations of affected consanguineous families may also request an assessment of their risk. Although FAO is reduced in most obligate carriers, this assay does not allow accurate identification of carrier status. In contrast, the fibroblast FALDH component of FAO was significantly reduced in 10 of 11 heterozygotes [21], and combination of the two enzyme assays was deemed useful in carrier detection. Prenatal diagnosis by fetal skin biopsy was successful in detecting premature keratinization at 20–22 weeks [22]. Accurate first and early second trimester diagnosis based on FALDH and FAO deficiency in cultured chorionic villus cells and amniocytes has been reported [23]. Mutational analysis of the FALDH gene on a chorionic villus sample will be the ideal test, provided the index case mutation is known.

Treatment. The abnormal fatty acid profile in plasma phospholipids in three SLS patients prompted treatment with a 6-month course of essential fatty acid supplements, but there was minimal improvement in the skin or neurological features [5]. An early report of the beneficial effects of a diet rich in medium-chain triglycerides on the skin manifestations in SLS [24] has been followed by further small trials with mixed results. Reduction of total fatty intake (to 30% of total calorie intake) with essential fatty acid supplements resulted in significant improvement in the skin and neurological features (and in plasma fatty alcohol levels) in two infants after some months but was less effective in older children [16,25]. This approach failed in another study [26].

Regular emollient and keratolytic therapy may help. Retinoid (etretinate) therapy proved effective in relieving scaling and disabling lichenification in several patients [16,27]. Three children and two adults assessed by one of the authors (MRJ) also responded well, but tolerance developed after approximately 3 months, and intermittent therapy may be a better option. Intensive physiotherapy and extra tuition in early childhood clearly improve motor and social development in SLS, and orthopaedic treatment of skeletal deformities of the legs is beneficial in some cases. The discovery of a role for leukotrienes in SLS led to a trial of a 5-lipoxygenase inhibitor in one patient with a partial response [28].

Refsum's disease (MIM 266500)

Refsum's disease (RD) is a very rare autosomal recessive neurocutaneous disorder, caused by defective fatty acid

metabolism. Refsum, a Norwegian neurologist, first defined it as a clinical entity in 1946, and called it 'heredopathia atactica polyneuritiformis' [1].

Aetiology and pathogenesis. In the early 1960s, accumulation of a storage product identified as a branched-chain 20-carbon fatty acid was reported [2]. Impaired oxidation of phytanic acid, a long-chain 20-carbon branched fatty acid (3,7,11,15-tetramethylhexadecanoic acid), in cultured skin fibroblasts, was demonstrated in 11 patients with RD [3]. Asymptomatic heterozygote carriers possessed 50% phytanic acid oxidase levels, pointing to autosomal recessive inheritance.

Phytanic acid is derived from plant chlorophyll and, to a lesser extent, animal sources (phytol) in the diet, and cannot be synthesized by human tissues. In health, it is barely detected in serum (1 mg/100 mL) but in RD it accounts for 5–30% of serum lipids, and levels rise to over 60 mg/100 mL. In lipid-rich tissues, it replaces other fatty acids and binds to sterols, resulting in lipid vacuoles in the basal epidermis. It interferes with membrane structure and function. The genes for two enzymes involved in α-oxidation of phytanic acid to pristanic acid have been cloned and their protein products localized to peroxisomes [4]. Mutations in the first of these genes, phytanoyl-CoA 2-hydroxylase (*PAHX*), are responsible for most, but not all, cases of adult RD. The *PAHX* gene is located on chromosome 10p13.

Histopathology. Skin biopsy changes are similar to those of ichthyosis vulgaris but without the typical ultrastructural findings. An important feature is the presence of lipid droplets in the basal and suprabasal layers of the epidermis (also seen in neutral lipid storage disease). Their significance may only be appreciated after special lipid stains are used. Kinetic studies in one patient with advanced disease showed a hyperproliferative pattern [5]. Electron microscopy reveals enlarged distorted mitochondria [6].

Clinical features. Diagnosis is often delayed until early adult life. Neurological features develop in adolescence or the early twenties, and progress slowly over a period of some months or years. Failing vision and night blindness result from progressive retinitis pigmentosa, and cataracts may also develop. Sensorineural deafness, tinnitus and, in some, anosmia occur in the early stages. Progressive weakness, foot drop and loss of balance are caused by cerebellar ataxia. A mixed sensorimotor polyneuropathy (type IV) with hypertrophied peripheral nerves and an elevated cerebrospinal fluid (CSF) protein are characteristic findings. In the early stages of evolution, the neurological symptoms and signs of RD may fluctuate, and patients may be labelled as clumsy and neurotic. Consequent delayed diagnosis may result in severe neurological impairment, wasting and depression, and a high mortality has occurred in the past. Some patients develop a cardiomyopathy with serious conduction defects [7], and skeletal defects have been noted in others.

The ichthyosis, which either coincides with or postdates the onset of neurological signs, resembles ichthyosis vulgaris with a fine white scaling, most noticeable over the lower trunk but also affecting the limbs. In late untreated cases, lamellar scaling develops.

Infantile Refsum's disease. This is an autosomal recessive peroxisomal disorder with several enzyme abnormalities including phytanic acid oxidase deficiency. It manifests in early infancy with neurodegenerative disease and signs similar to those seen in adult RD, but ichthyosis is an unusual feature.

Genetics. Diagnosis of a new case of RD should prompt intensive family screening for other presymptomatic cases [8]. Carrier heterozygotes may have marginally elevated phytanic acid levels and show intermediate values for phytanic acid oxidase [3]. Prenatal testing by amniocentesis and culture of amniocytes to assay phytanic acid oxidase and, more recently, by a molecular genetics approach in the first trimester using chorionic villus biopsy are theoretically possible, but the availability of effective dietary therapy may reduce the demand for this approach [9]. It has been suggested that all families with retinitis pigmentosa should be screened for RD [8].

Treatment. Exclusion of sources of chlorophyll in the diet is mandatory in the treatment of RD. The major dietary exclusions are green vegetables (phytanic acid) and animal fat (phytol), and the aim of dietary treatment is to reduce daily intake from the usual level of 50 mg/day to less than 5 mg/day. Rapid weight loss should be avoided, as it mobilizes tissue phytanic acid, which can lead to acute clinical manifestations [10]. A high carbohydrate intake ensures adequate calories and, when instituted in the early stages of the disease, blood levels of phytanic acid fall rapidly, followed by clearance of the ichthyosis and, to a variable extent, reversal of recent neurological signs. Retention of vision and hearing is less certain but has been reported [11]. Lifelong strict adherence to the diet is necessary, and recurrence of scaling is an obvious marker of rising phytanic acid levels. Plasmapheresis has been used to reduce phytanic acid levels rapidly in acutely ill patients at diagnosis [10,12].

IBIDS syndrome (MIM 601675)

SYN. TAY'S SYNDROME;
TRICHOTHIODYSTROPHY E, F

This rare and heterogeneous genodermatosis belongs to a group of disorders that has in common a hair defect termed trichothiodystrophy. The trichothiodystrophies have been classified into subtypes A–H, two of which (IBIDS and PIBIDS) feature skin lesions. The acronym IBIDS describes *i*chthyosis, *b*rittle hair, *i*mpaired intelligence, *d*ecreased fertility and short *s*tature [1]. In 1968, a sibling pair with brittle hair, intellectual impairment, short stature and trichorrhexis nodosa was reported [2]. Reduction of sulphur-containing amino acids in the hair (Greek *thio*, sulphur) was a central feature of the disorder [2,3]. In 1971, Tay reported three Chinese siblings (of cosanguineous parents) who also had a generalized ichthyosiform erythroderma and progeric facies [4]. Decreased fertility, in an affected Amish kindred, was added to the list of features of the syndrome [5]. Other rare genetic disorders such as the Marinesco–Sjögren syndrome are variants (BIDS), and misreporting of IBIDS cases has occurred [6]. This is an autosomal recessive syndrome and occurs worldwide. UV-induced DNA repair defects have been demonstrated in some patients and recent genetic and molecular advances help to explain the phenotype of this and other DNA repair defect syndromes [7].

Aetiology and pathogenesis. Reduced levels (approximately 50% of normal) of hair sulphur and sulphur-containing amino acids, cysteine, methionine and proline are the hallmark of trichothiodystrophy, but circulating amino acid levels are normal. The cornified envelope of stratum corneum cells is cysteine-rich, and sulphur-rich amino acids form hair-specific matrix proteins that cross-link keratin fibres in the hair shaft.

DNA repair studies on skin fibroblasts and lymphocytes from patients with IBIDS with (PIBIDS) and without photosensitivity have shown markedly reduced levels of duplicative and unscheduled DNA synthesis on UV exposure [8–10]. The response pattern of nucleotide excision repair defects was similar to that seen in xeroderma pigmentosum (XP) complementation group D. In contrast to classical XP, PIBIDS and XP group D patients do not develop skin malignancies. The DNA repair gene *ERCC2/XPD* can correct the photosensitivity of both IBIDS and XP group D and different mutations within this helicase gene, specific to each disorder, have been identified [11]. IBIDS is caused by mutations that alter the transcriptional role of *ERCC2*, while XP is caused by mutations that mainly affect the repair role of the gene. *XPD* mutations account for 95% of PIBIDS. Defects in two other genes, *TTDA* and *ERCC3/XPB*, underlie the photosensitivity in a small number of IBIDS cases [11,12].

Further DNA studies in patients with typical IBIDS revealed three subgroups: one with a normal UV response (for which no gene mutation has been identified); one showing an XP group D response pattern; and a third with reduced clearance of 6–4 photoproducts, reduced DNA repair synthesis and normal cell survival [13]. The patient reported by Jorizzo *et al*. [1] subsequently developed photosensitivity and was found to have a DNA repair defect, which complemented all XP types [14]. There is no correlation between the severity of the DNA repair defect and the clinical features. DNA repair-deficient transgenic and knock-out mouse models have been produced, including one that mimics IBIDS with photosensitivity [15]. The growth defects, brittle hair and nails and neurological abnormalities are not features of nucleotide excision repair defects, and may be caused by impairment of the transcription function of *XPD* and *XPB* gene products leading to reduced RNA synthesis [16].

Histopathology. In most cases, skin biopsy has shown changes similar to those of NBIE with hyperkeratosis, focal parakeratosis, acanthosis and a normal or reduced granular layer. Ultrastructural features include perinuclear vacuoles and abnormal tonofilaments. Hair microscopy shows wavy hair shafts with pili torti, trichorrhexis nodosa and trichoschisis (transverse fractures). Polarizing light reveals characteristic alternating zig-zag light and dark bands, which give rise to the term 'tiger tail' hair. This defect may also occur in inherited amino acid and zinc deficiencies. Scanning electron microscopy highlights flattening and irregular ridging of the shaft.

Clinical features. IBIDS typically presents in a low-birthweight premature infant with a collodion membrane or

Fig. 34.22 IBIDS/trichothiodystrophy, 18-year-old male. (Courtesy of Professor J.I. Harper, Great Ormond Street Hospital for Children, London, UK.)

congenital erythroderma, which evolves during infancy into an ichthyosis. Skin manifestations vary widely from generalized fine scaling, which may have a delayed onset, to an erythrodermic hypohidrotic ichthyosis resembling congenital ichthyosiform erythroderma. Additional features in some patients are eczema, palmoplantar hyperkeratosis, pulp atrophy and flexion contractures, hypoplastic aural cartilage and nail dystrophy [1]. An elfin-like and aged face resulting from fat atrophy, prominent ears and chin recession is typical (Fig. 34.22).

Scalp and eyebrow hair is sparse, short and unruly, but its growth may improve with age. Mild to moderate intellectual impairment is the rule, and hypogonadism leads to delayed puberty and infertility in most adult patients. Severe growth failure is usual and cataracts, skeletal defects, otosclerosis, dental anomalies and neurological signs (microcephaly, cerebellar dysfunction, seizures, nerve deafness, autism) have been described [17,18]. Abnormal myelination may account for the wide range of neurodevelopmental problems. An increased incidence of asthma has been noted and bronchiectasis developed in one patient, although no immune defect was found [1]. Early death from sepsis may occur. A friendly disposition is characteristic.

Marked photosensitivity and photophobia were reported in a review of 15 patients with features of IBIDS [10]. In this group, neurological disease and cataracts were more common and hypogonadism less common than expected. Photosensitivity occurs in 50% of IBIDS patients [1].

Diagnosis. Amino acid analysis and microscopy of hair, DNA repair studies and phototesting are essential for diagnosis. Immune studies and growth hormone assay are generally normal and skin histology is non-specific. The main differential diagnoses are NS, SLS, NBIE, Cockayne and other progeric syndromes.

Genetics. The clinical heterogeneity of this syndrome appears to result from the variety of DNA repair gene mutations and diverse mutations within the critical functional area of the *ERCC2*/*XPD* DNA repair gene [11,12]. The *XPD* gene maps to chromosome 19q13.2–13.3 while the *XPB* gene is located on chromosome 2q21. IBIDS and its variants are autosomal recessive disorders. Successful prenatal diagnosis has been reported in two families by identifying defective DNA repair in amniocytes taken at 21 weeks' gestation and trophoblasts at 9 weeks' gestation, as well as on fetal hair analysis [19]. Prenatal DNA studies are relevant only to the 70% of families with DNA repair defects.

Treatment. Emollients are helpful in improving skin comfort and suppleness. The influence of retinoid therapy and keratolytics on the ichthyosis has been disappointing. Sun avoidance and sunscreens should be used in photosensitive patients. Growth hormone treatment failed in one patient, and the effect of sex hormone therapy is unknown. Physiotherapy and splinting may reduce the severity of digital contractures.

X-linked dominant ichthyosis (MIM 302960)

SYN. HAPPLE'S SYNDROME; CONRADI–HÜNERMANN–HAPPLE SYNDROME; X-LINKED DOMINANT CHONDRODYSPLASIA PUNCTATA TYPE II/ICHTHYOSIS/CATARACT SYNDROME

X-linked dominant ichthyosis (XLDI) is a distinctive skin disorder occurring in a mosaic pattern in females, often associated with skeletal and ocular defects. It is usually lethal *in utero* in affected males. The characteristic features were described by Happle in 1979, and it is now referred to as Happle's syndrome or Conradi–Hünermann–Happle syndrome [1]. It is one of the variants of chondrodysplasia punctata (CP), a group of genetic disorders that have in common a congenital punctate epiphyseal and skeletal calcification which affects growth. CP was first described by Conradi in 1914. There are three other subgroups of CP: an autosomal recessive rhizomelic type; an autosomal dominant form without cutaneous disease, now referred to as Conradi–Hünermann syndrome [2]; and an X-linked recessive variant.

Aetiology and pathogenesis. A deficiency of a peroxisomal enzyme, dihydroxyacetone phosphate acyltransferase (DHAPAT), was identified in cultured fibroblasts from patients with both rhizomelic chondrodysplasia punctata and XLDI [3,4]. DHAPAT is responsible for synthesis of plasmalagen phospholipids and glycolipids. An animal model, the 'bare patches mouse', has an X-linked dominant disorder with a phenotype and peroxisomal defect similar to that of Happle's syndrome [5]. Accumulation of 8(9)-cholesterol and 8-dehydrocholesterol in tissue samples from seven XLDI patients suggested a defect in C8-C7 isomerization, which is catalysed by sterol-Δ8-isomerase, an emopamil-binding protein [6]. Functional mutations of the candidate gene, located at Xp11.22–p11.23, have been confirmed in these patients. There was no obvious genotype–phenotype correlation and lyonization of X-linked genes at this site may influence the severity of the clinical phenotype as well as causing mosaicism. Similar mutations have been found in the X-linked dominant 'tattered mouse' [7], whereas the 'bare patches mouse' phenotype is caused by a mutation of the gene coding 3β-hydroxysteroid dehydrogenase, which maps to Xq28 [8]. Abnormalities of sterol metabolism have been implicated in other genetic skeletal dysplasias, possibly by interfering with hedgehog (HH) signalling pathways. The Indian HH protein is necessary for vertebrate skeletal development and mutations cause chondrocyte degeneration, affecting epiphyseal growth plates, and ectopic calcification. Ectopic epiphyseal and sometimes epidermal calcification are recognized features of X-linked dominant ichthyosis. Rhizomelic CP is caused by three different peroxisomal enzyme mutations, including two involved in phospholipid biosynthesis [9].

Histopathology. Biopsy of ichthyotic skin shows changes similar to those of ichthyosis vulgaris, but without the typical ultrastructural features. There is orthohyperkeratosis with a reduced granular layer, mild acanthosis and a light perivascular inflammatory infiltrate in the upper dermis in childhood. Older lesions show prominent perifollicular atrophy. Epidermal calcification, needle-like inclusions in granular keratinocytes and reduced numbers of Langerhans' cells, some of which are degenerate, have been reported [10]. Electron microscopy reveals persistent desmosomal structures in the stratum corneum layer. Abnormal degenerate mitochondria and vacuolated lamellar bodies were seen, and the dilated intercellular spaces contained disordered lipid lamellae and debris [3].

Clinical features. Affected babies are typically female, premature and born with either a collodion membrane or generalized ichthyosiform erythroderma. Within the first year, generalized linear and swirling patterns of erythroderma and scaling, following the lines of Blaschko, are established (Fig. 34.23). Intervening areas of skin are unaffected. Palmoplantar hyperkeratosis and nail dystrophy may occur. Recurrent infections, especially in the flexures, can be troublesome, and scalp and eyebrow hair growth is sparse and lustreless. The ichthyosis improves with age and the residual signs are often so subtle in adult life that an affected mother may be missed. Signs to be sought in adults include swirls of fine scale, linear pigmentary change, follicular atrophoderma mainly on the limbs and cicatricial alopecia, all in a Blaschkoid distribution. An adult patient had persistent ichthyosis and also developed psoriasis in Blaschko's lines [11].

Other variable features include rounded or asymmetrical facies with frontal bossing, a broad flat nasal bridge, congenital asymmetric cataracts in 60% of patients

Fig. 34.23 X-linked dominant ichthyosis in a 2-year-old girl. (Courtesy of Dr D.J. Atherton, Great Ormond Street Hospital for Children, London, UK.)

(mosaic lens involvement), short stature, asymmetrical or, rarely, symmetrical shortening of limbs [12], kyphoscoliosis, supernumerary digits and other skeletal defects. Stippled calcification of long-bone epiphyses is a characteristic but not universal radiological finding in the neonatal period, and usually resolves by adulthood. Patients have normal or mildly impaired intellectual development and neural hearing loss has been reported [11,12].

Genetics. The mosaic pattern of X-linked dominant ichthyosis reflects the effects of the two populations of keratinocytes that result from the X chromosome alleles: one normal, the other mutated (functional mosaicism). This X chromosome mutation is compatible with survival in female embryos, because of the Lyon effect of X inactivation allowing expression of either allele in a given somatic cell. It shows variable penetrance in females and is generally lethal in male embryos. However, male patients with cutaneous and skeletal features have been reported, and at least one had the Kleinfelter karyotype [13,14]. The spontaneous improvement with age may reflect progressive elimination of mutant cells by adjacent normal cells, which have a growth advantage. However, clinical severity may worsen in successive generations [13,15].

Autosomal recessive rhizomelic CP can cause cataracts but rarely affects skin. An X-linked recessive variant may represent XLRI with contiguous gene defects. Genetic counselling must include assessment of all members of the extended family, looking for dysmorphism, residual skin signs, subclinical cataracts and a history of radiological abnormalities. Fetal warfarin or hydantoin toxicity and congenital rubella can mimic CP syndromes.

Prenatal testing, assaying DHAPAT, has been successfully used in one family. Ultrasound scans in the second trimester may detect skeletal and other defects. The variability of disease expression and improvement with age make decisions on prenatal diagnosis difficult but mutational analysis of chorionic villus biopsy should simplify the process.

Treatment. Emollients are helpful and antimicrobial therapy may be needed for skin infections. Some patients may opt to use a wig. Clofibrate, a peroxisome inducer, did not help one patient [15]. The effect of retinoids is unknown and the need for treatment diminishes with age. Appropriate orthopaedic procedures may be indicated for skeletal anomalies.

Neutral lipid storage disease (MIM 275630)

SYN. CHANARIN–DORFMAN SYNDROME

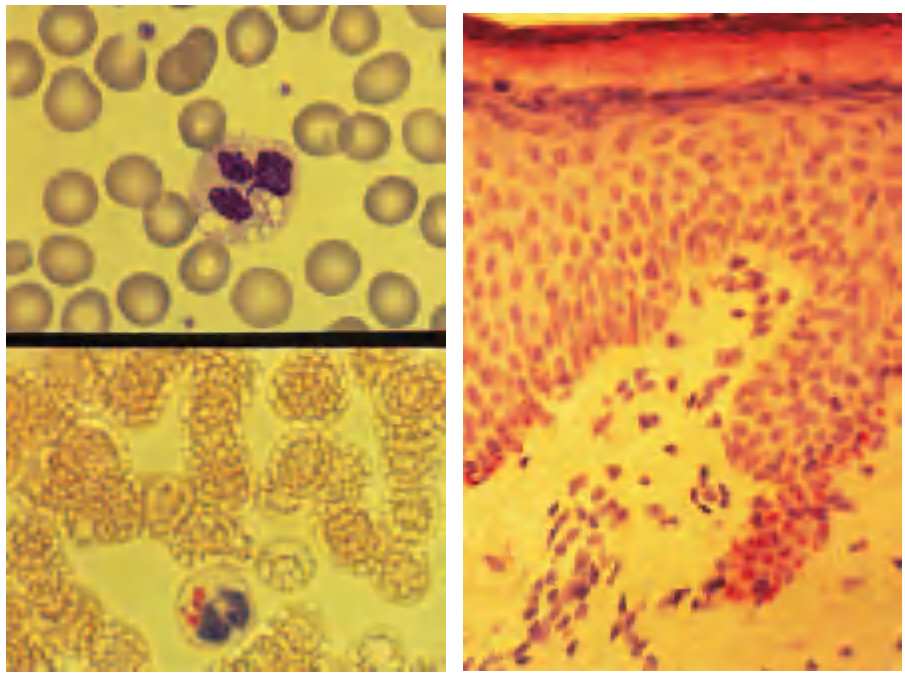
The association of an autosomal recessive congenital ichthyosis and leukocyte lipid vacuolation affecting two sisters was first described in 1966 [1]. Dorfman reported four cases including a follow-up of the two sisters and recognized that this was a specific multisystem lipoidosis [2]. Chanarin, describing a similar case, referred to it as neutral lipid (triglyceride) storage disease (NLSD) [3]. The triglyceride deposition in white blood cells and several organs results in a combination of skin, hepatic, muscle and ocular abnormalities. There are more than 30 reported cases of NLSD, mainly in people of Mediterranean or Arabic descent, many from consanguineous families [4,5].

Aetiology and pathogenesis. Serum lipid analysis is normal in NLSD and scale lipids show a raised triglyceride content [6]. Histochemical studies on cultured fibroblasts and keratinocytes confirmed that the stored lipid was neutral lipid triacylglycerol or triglyceride [3]. Increased fibroblast triglyceride synthesis with a complete failure of endogenous triglyceride breakdown was demonstrated [6,7]. Exogenous triglyceride metabolism was normal and dietary lipid restriction was unhelpful. A defect in recycling of mono- or diacylglycerols from triglycerides to phospholipids or in long-chain fatty acid oxidation was suspected [8].

Linkage in several families with NLSD to a locus (the *NCIE2* locus) at chromosome 3p21 led to the identification of mutations in the *CGI-58* gene in 13 patients [9]. CGI-58 is one of a large family of proteins, many of them enzymes, with a characteristic α/β-hydrolase fold. Its function is unknown but it is widely expressed in tissues such as skin, muscle, liver and brain.

Histopathology. A notable feature of NLSD (seen to a lesser extent in heterozygote carriers) is the presence of lipid droplets, visible on light microscopy, in circulating polymorphs (neutrophils, eosinophils and basophils) and monocytes but not in lymphocytes, red cells or platelets (Fig. 34.24a). The vacuoles are oil red O and Sudan black positive and this feature is termed 'Jordan's anomaly'. Electron microscopy shows non-membrane-bound cytoplasmic lipid droplets.

Biopsies of muscle, liver and skin and cultured fibroblasts also reveal numerous cellular lipid droplets. Skin biopsy shows acanthosis and hyperkeratosis, and closely packed lipid droplets of varying size are seen in basal (Fig. 34.24b), granular and adnexal (sweat gland and duct) keratinocytes and in dermal fibroblasts, smooth muscle cells and endothelium. Lipid vacuoles are seen in the epidermis, but not in other tissues, in RD. Ultrastructurally, vacuoles may be seen in upper epidermal layers and arrector pili muscles [6]. Epidermal lamellar bodies and intercellular lipid lamellae are disrupted by globular electron lucent inclusions [10]. Lipid vacuoles are present in muscle fibres and marrow. Liver biopsy reveals hepatocyte fatty vacuolation, lobular fibrosis in late-stage disease and normal Kupffer cells.



(a) (b)

Fig. 34.24 Neutral lipid storage disease: (a) lipid vacuoles (lower panel, oil red-O positive) in neutrophils; and (b) in basal keratinocytes. (Courtesy of Dr B. Lake, Institute of Child Health, London, UK.)

Clinical features. Clinical features are variable [4–6,9]. Affected newborns are either collodion babies or erythrodermic. The pattern of skin disease thereafter resembles mild to moderate NBIE with fine white scale on an erythematous background and lamellar scaling on the legs. Scaling may diminish in warm weather and with advancing age. Pruritus is often troublesome and hypohidrosis may occur. Mild ectropion and flexural lichenification are common, and palmoplantar hyperkeratosis (with nail dystrophy) and scalp alopecia have been reported.

Muscle involvement ranges from an asymptomatic or subclinical myopathy with elevated muscle enzymes in most patients, to marked proximal myopathy in a few late cases. Hepatomegaly, abnormal liver enzymes and fatty infiltration of the liver are common, even in childhood. Liver biopsy is more sensitive than biochemical markers in detecting the degree of involvement. Splenomegaly and malabsorption, resulting from intestinal mucosal lipid deposition, are occasional features. Cataracts of the nuclear type may be detected from infancy in over 50% of cases but rarely affect vision. Retinal disease, nerve deafness, ataxia, microcephaly, neuropathy, short stature and mental retardation have been reported, but most patients are intellectually normal. Prognosis depends on the pattern and degree of organ involvement.

Diagnosis. The diagnosis is confirmed by microscopy of a peripheral blood smear, which shows lipid droplets in granulocytes (Jordan's anomaly) [1]. Careful inspection of a fresh blood film may also be used to detect carriers and should be a routine investigation in all patients with congenital ichthyosis [11]. Moderate elevation of muscle and hepatic enzymes is usual but raised urinary creatine with normal serum muscle enzymes has been noted [5]. Liver biopsy changes are noted above. Muscle biopsy reveals lipid droplets in muscle fibres and EMG signs of myopathy are detected.

Gaucher's disease type 2, muscle carnitine deficiency and Wolman's disease should be excluded, as they share some of the features of NLSD. Lipid vacuoles are seen in the epidermis, but not in the blood smear, in RD.

Genetics. Most NLSD families have come from Mediterranean regions and the majority are of Arab descent. The majority of patients have consanguineous parentage. The disease is clearly autosomal recessive and the asymptomatic heterozygote carriers may be identified by detection of lipid vacuoles in myeloid leukocytes, especially eosinophils on a fresh blood film [12]. This screening test should be offered to members of the extended family. Prenatal diagnosis using fetal blood microscopy, or skin biopsy at 20 weeks' gestation, is possible and identification of the *CGI-58* mutation in an affected family should allow first trimester diagnosis by chorionic villus sampling and molecular genetic analysis.

Treatment. Emollients are helpful and retinoid therapy, either low-dose continuous or intermittent courses, improves the cutaneous features. Dietary manipulation to reduce intake of long-chain fatty acids and increase medium-chain fatty acids has been reported to benefit two patients, but one was also receiving retinoid therapy [5,13]. In another case, dietary treatment was ineffective [6].

KID syndrome (MIM 148210) and HID syndrome (MIM 602540)

The combination of *k*eratitis, *i*chthyosis and *d*eafness was first reported in 1915 as a generalized congenital keratoderma with ocular and mucosal involvement [1]. The acronym KID was coined in 1981 to highlight the main features of the syndrome [2]. However, the skin disease combines features of a hystrix-like ichthyosis and an erythrokeratoderma, and keratitis is not present in all cases. The pattern of inheritance is uncertain, as most cases have been sporadic. It has a worldwide distribution and at least 70 cases have been recorded in the literature, some under different terms. A change in terminology has been suggested but not yet accepted.

HID syndrome describes *h*ystrix-like *i*chthyosis and *d*eafness. It was originally reported in two patients from Rhedyt in Germany [3] but is now regarded as an allelic variant of KID.

Aetiology. Mutations in gap junction proteins called connexins have been reported in various epidermal diseases including hidrotic ectodermal dysplasia (connexin 30), erythrokeratoderma variabilis with and without deafness (connexin 31 and 30), Vohwinkel's syndrome (connexin 26) and non-syndromic hearing loss (connexin 26 and 31). Connexins are universal membrane proteins that form inter- and intracellular channels for ion and molecule transfer, which is the basis of all cellular communications. Similar defects were considered likely in KID and to date three different missense mutations of connexin 26 (GJB2) have been reported in 10 patients [4,5]. KID and HID share the same connexin 26 mutation [6].

Histopathology. Skin biopsy shows marked orthohyperkeratosis and acanthosis, focal parakeratosis and papillomatosis. Fungal and bacterial elements are frequently present within the keratin, and perinuclear vacuolation with keratohyaline clumping are a minor feature. Proliferating keratoses should be examined for signs of pseudoepitheliomatous hyperplasia and malignancy. There is a mild upper dermal inflammatory infiltrate with plasma cells, and atrophic or plugged hair follicles reflect the widespread alopecia.

Ultrastructural study has shown irregular clumped tonofilaments in lower epidermal layers with perinuclear distribution in the granular layer (similar to changes noted in IH) and indented keratinocyte nuclei [7]. Intercellular membrane-bound granules have been noted.

Clinical features. Many affected neonates have generalized erythema and some also have diffuse scaling and a leathery skin. The typical skin changes gradually develop during infancy with linear and spiny hyperkeratosis around the flexures, elbows and knees, and hystrix-like scaling on the limbs [7]. Scattered follicular hyperkeratoses appear on the trunk. Typical feature are the evolution of symmetrical well-demarcated hyperkeratotic plaques on the scalp, ears, face (Fig. 34.25) and occasionally the trunk and limbs, and, in some patients, thick perioral rugae, and an aged or leonine facies [8,9]. Keratotic, hyperplastic nodules may develop on the scalp, face, trunk and lower legs, and *in situ* and invasive squamous cell carcinoma arising within these dysplastic lesions have been reported in several KID patients in adult life [4,10–12]. Squamous cell carcinoma of the tongue has occurred in two children [13,14] and a 28-year-old had a fatal malignant fibrous histiocytoma [15]. Multiple hair follicle tumours occurred in an adult with KID syndrome [16].

Most patients have extensive scarring alopecia of the scalp and loss of eyebrows, lashes and body hair resulting from follicular hyperkeratosis. A reticulated PPK resembling grained leather is a characteristic feature, and progressive nail dystrophy and shedding may occur. Acneiform eruptions on the upper trunk are common, and

Fig. 34.25 KID syndrome in an 8-year-old boy. (Courtesy of Dr D.J. Atherton, Great Ormond Street Hospital for Children, London, UK.)

chronic deep abscesses and discharging sinuses are a distressing late complication in some. Chronic cutaneous granulomatous fungal and candidal infections may develop and contribute to the alopecia, nail dystrophy and body odour. Death in infancy from overwhelming infection has been reported in several patients with KID syndrome [17]. No specific immune defect has been identified. Premature caries, oral leukoplakia, short stature, breast hypoplasia and cryptorchidism are occasional complications.

Congenital sensorineural deafness is evident during infancy in most patients. In typical KID syndrome, progressive corneal vascularization occurs in childhood, often after a febrile illness, and leads to blindness by adolescence. Delayed onset of the keratitis has been reported [18]. A progressive peripheral neuropathy has occurred in several adults with KID [8]. Intellect is unaffected and it is no surprise that the combined disabilities of deafness, blindness and disfigurement impose severe limitations and hardship on the individual.

The cutaneous features of the HID syndrome vary from a diffuse hyperkeratosis with pruritus to a generalized hystrix hyperkeratosis with mild PPK. Multiple squamous cell skin cancers occurred in an adult patient [6]. The deafness runs a similar course to that of KID syndrome and mild punctate keratitis has been noted in some patients (evidence that HID and KID are a single disorder).

Diagnosis. KID/HID syndrome is a clinical diagnosis, supported by audiological and ophthalmological evidence

of neurosensory deafness and keratitis. In spite of the occurrence of chronic skin infections, consistent immune defects are not found. The differential diagnosis includes congenital erythrokeratoderma with deafness, IH and unusual ectodermal dysplasias. Typical HID syndrome must be differentiated from SLS.

Genetics. Most reported cases of KID/HID syndrome have been sporadic, but autosomal dominant inheritance was evident in two families with KID [11,19] and one with HID syndrome [6]. A report of two sisters of consanguineous ancestors affected with KID syndrome pointed to autosomal recessive transmission [20] but this sibship and half-sibs affected with KID could also be explained by gonadal mosaicism [21]. First trimester prenatal molecular diagnosis on chorionic villus sampling is possible where the connexin mutation in the index case in a family has been defined.

Treatment. Early and frequent audiology and eye assessment should be performed to enable treatment such as hearing aids, cochlear implants and speech therapy. Corneal transplant for advanced keratitis has usually failed [19]. Keratolytics and emollients have a limited role. Antiseptic baths and cleansers, intermittent antibiotic therapy and systemic antifungal agents all play an important part in controlling skin infections and odour, and regular bacteriology screening of the skin should guide the choice of antimicrobial treatment. Cleansing, débridement and grafting of hyperplastic lesions may be needed and may reduce the potential for malignant transformation. Mohs microsurgery is appropriate for invasive malignancies. Systemic retinoids have been tried in several patients with variable success. The potential of acitretin to reduce the skin cancer risk provides further justification for its use. Isotretinoin aggravated the keratitis in one patient [22]. PUVA phototherapy was unhelpful in a few adult patients [7].

CHILD syndrome (MIM 308050)

The acronym CHILD describes a very rare disorder comprising *c*ongenital *h*emidysplasia with *i*chthyosiform erythroderma and unilateral *l*imb *d*efects, mainly skeletal hypoplasia [1]. The skin lesion more often resembles a unilateral inflammatory epidermal naevus, rather than an ichthyosis. Happle suggested that it is a unique inherited naevus determined by an X-linked dominant mutation, as the female : male ratio is 28 : 1 and skin involvement may occur in Blaschko's lines [2]. Over 30 cases have been reported since the 1960s [3].

Aetiology. Keratin expression studies indicate a hyperproliferative epidermis [4]. Abnormal fibroblast activity, increased prostaglandin E_2 synthesis and defective peroxisomal structure and function in lesional skin were reported and similarities with XLDI (Happle's syndrome) noted [5,6]. Indeed, abnormal 3β-hydroxysteroid-Δ8,Δ7-isomerase activity has been found in one case while reduced NAD steroid dehydrogenase (NSDHL) has also been reported [7,8].

Histopathology. The epidermis is acanthotic with areas of hyper- and parakeratosis. Neutrophilic collections in the stratum corneum and a dermal lymphocytic inflam-

matory reaction are suggestive of psoriasis. Hair follicles are plugged, and foamy macrophages may be seen in distended dermal papillae. Ultrastructural features include lipid vacuoles in granular layer keratinocytes, keratin filament defects, disrupted mitochondria, patchy disruption of lamellar bodies, vacuolated intercellular lamellae and lamellated structures in fibroblasts [4,6,9].

Clinical features. The skin lesions are usually noted in the first days of life as an inflamed, hyperkeratotic, crusted or thickened plaque covering a large area or most of one side of the body, with sharp demarcation at the midline. Linear bands of normal skin on the affected side and of ichthyotic scaly red skin on the 'normal' side may occur, and suggest a mosaic somatic mutation [1,4]. The flexures on the affected side are preferentially involved, and the head is usually spared. The skin lesions may progress in the first year of life and then improve with time. Unilateral alopecia and nail dystrophy may occur. Various other defects, some of which may prove lethal, include congenital heart disease, spina bifida and renal defects [9]. The most common skeletal defect is ipsilateral limb hypoplasia, and calcific stippling of epiphyses in infancy has been reported. A sibling of an affected patient had bilateral limited skin disease in the absence of extracutaneous features [10]. Bilateral symmetrical lesions were reported in one patient with a novel NSDHL mutation [11]. The lesions may be mistaken for an epidermal naevus, lichen striatus or linear psoriasis. Cataracts do not occur.

Genetics. The theory of X-linked dominant inheritance is convincing and explains the apparent lethality in male embryos [2]. The predominantly unilateral and mosaic distribution is attributed to the Lyon effect of random X chromosome inactivation. An early teratogenic insult and syndromes associated with limb reduction defects must be included in the differential diagnosis.

Treatment. Emollients and keratolytics are helpful. Urea-containing emollient, retinoid therapy and methotrexate have improved the skin lesions in individual patients [2,9].

Ichthyosis follicularis with alopecia and photophobia (MIM 308205)

Isolated follicular ichthyosis is an ill-defined and controversial entity and may overlap with keratosis pilaris and coexistent ichthyosis vulgaris. On the other hand, the syndrome of ichthyosis follicularis with alopecia and photophobia (IFAP) is a well-recognized but very rare ectodermal disorder, which was first reported by MacLeod in 1909 [1]. Fewer than 20 cases have been recorded.

Histopathology. Skin biopsy shows follicular plugging and orthohyperkeratosis with a normal granular layer (which is thickened at the infundibulum), effaced rete ridges and thin dermis. Absence of sebaceous glands, atrophy of hair follicles with perifollicular lymphocytic infiltrates and reduced numbers of sweat glands are characteristic findings [1,2]. No specific ultrastructural features have been noted, although a psoriasiform lesion showed reduction in desmosomes, and electron microscopy of the cornea in an adult revealed a thickened basement membrane and absent Bowman's capsule [3].

Clinical features. The phenotype is variable, but patients have a striking facial similarity. One presented at birth with a collodion membrane [2]. All have generalized non-inflammatory follicular keratoses, persistent non-cicatricial scalp and body alopecia, and severe photophobia from birth. The keratotic papules are most pronounced on the knees, elbows and fingers, and follicular spiny projections develop over extensor surfaces. Generalized xerosis and cheilitis, lamellar scaling, skin infections and pruritus are common, and the keratoses may improve with age. Pregnancy-related vulvitis occurred in one patient and her affected daughter developed psoriasiform plaques in early childhood [3]. Teeth, nails and sweating are generally normal, although one infant had natal teeth [4], and nail dystrophy does occur [2,3]. Palmoplantar erythema was present in one case [2]. Severe photophobia, reduced visual acuity, nystagmus and head tilt are caused by

punctate keratitis, which leads to corneal erosions and vascularization. Occasional features include atopy [1,2,4], recurrent chest infections, growth and psychomotor retardation, hypotonia and seizures. Hearing is normal.

Diagnosis. IFAP must be distinguished from the keratosis pilaris variants, keratosis follicularis spinulosa decalvens (KFSD) and keratosis pilaris rubra atrophicans facei, which are associated with inflammatory scarring alopecia of the scalp and eyebrows. Ocular disease is prominent in KFSD, the KID syndrome and IFAP, but palmoplantar hyperkeratosis is not a feature of IFAP. Skin histology helps to exclude other congenital ichthyoses, such as ichthyosis vulgaris. An autosomal recessive congenital atrichia with papular lesions has been reported [5]. Hereditary mucoepithelial dystrophy/dysplasia shares certain clinical traits with IFAP, but the striking mucosal changes do not occur in IFAP [6].

Genetics. X-linked recessive inheritance was proposed in a family with three affected male siblings [1]. However, two girls with typical lesions were reported, and, as one had an affected father, autosomal dominant transmission was suggested [7]. This pattern was evident in an affected Japanese mother and daughter [3].

Treatment. Keratolytics, urea preparations and emollients are used. Topical calcipotriol may improve psoriasiform lesions. Oral retinoid (vitamin A) therapy produced a partial response in one case, while topical retinoid proved too irritant [2]. Early and regular ophthalmological assessment is necessary.

Isolated genetic syndromes with ichthyosis

There are several reports of individuals or small groups of cases with congenital ichthyosis occurring in association with extracutaneous defects that do not fit within the classification of inherited ichthyoses discussed above. These are discussed under headings indicating the main systemic features.

Ichthyosis associated with neurological and ocular disorders

In 1983, Zunich and Kaye [1] reported a child with migratory ichthyosiform erythroderma, retinal colobomas, neurological disease, fine sparse hair and dental abnormalities—the acronym CHIME derives from *c*oloboma, *h*eart disease, *i*chthyosis, *m*ental retardation and *e*ar defects. A further four cases have been described [2,3] and occurrence in a sibling pair suggests autosomal recessive inheritance. Generalized pruritus, erythema and scaling occurred within the first month, and figurate red scaly patches developed on the head and body in early childhood [3]. Characteristic facial dysmorphism and other skeletal defects were noted, and neurological features included seizures and developmental delay. Degenerative changes in the myelin sheaths of cutaneous nerves have been detected ultrastructurally. Impaired epidermal maturation is associated with a distinctive perinuclear oedema and nuclear pyknosis in upper granular keratinocytes. A similar syndrome of generalized ichthyosis, mental retardation, hypotonia and craniofacial anomalies occurred in a Turkish boy of consanguineous parents [4]. Abnormal nerve myelination also occurred in a patient with ichthyosis associated with congenital sensory neuropathy [5].

Generalized ichthyosis with mental retardation and spasticity was noted in a single patient in whom SLS was excluded [6], and a similar syndrome in identical twins was also associated with cortical atrophy, epilepsy and a hearing defect [7]. An inbred Swedish family was reported where two siblings and an aunt and uncle had an ichthyotic syndrome with mental retardation, alopecia, eclabion and ectropion [8]. Ichthyosis was noted in a patient with Dubowitz syndrome, which causes microcephaly and growth retardation [9], and in a boy with microcephaly and lentigines, diagnosed as LEOPARD syndrome [10].

Retinitis pigmentosa associated with congenital ichthyosis and other defects was reported in two women [11], and an adult female patient had ocular albinism, Noonan's syndrome and ichthyosiform erythroderma (with collodion baby presentation) [12].

An infant with ichthyosis and deafness may have had KID syndrome but he died of malnutrition brought about by Hirschsprung's disease [13]. A patient with ichthyosis, deafness and mental retardation had, in addition, dental and skeletal defects and developed thyroid cancer [14]. A family with a variable syndrome of unspecified deafness, microphthalmos and ichthyosis is recorded [15].

Ichthyosis associated with renal disease

Passwell reported three siblings of a consanguineous family whose skin was red with fine scaling, atrophic changes and small blisters over the dorsal hands and feet. Skin biopsy revealed vacuolation in basal keratinocytes, reminiscent of neutral lipid storage disease, and collagen disruption. They had a generalized aminoaciduria, dwarfism and mental retardation [16].

Congenital ichthyosis has also occurred with renal parenchymal disease, growth retardation and hypogonadism in three siblings of another family [17]. A possibly autosomal dominant syndrome of renal disease, prolinuria, nerve deafness and a poorly defined ichthyosis affected a third family [18]. Fanconi's syndrome with jaundice occurred with congenital ichthyosis [19].

Ichthyosis and skeletal defects

The ICE syndrome, reported in five subjects in four generations of one family, consisted of *i*chthyosis vulgaris, fullness of the *c*heeks and thinning of the *e*yebrows [20]. Other dysmorphic features occurred, and skeletal abnormalities included kyphoscoliosis. Accessory ribs, cortical thickening, arthrogryposis and osteopetrosis have been recorded in individual patients with ichthyosis [14,20–23].

Ichthyosis with immune defects

Patients with ichthyosiform erythroderma associated with defective chemotaxis have been described [24]. Abnormal T cells, hypogammaglobulinaemia, neurological defects, eczema and fungal infection were reported in an infant boy who died at 9 months (cf. Ommen's syndrome) [25]. Three patients with congenital ichthyosiform erythroderma and IgM or IgG deficiencies had recurrent respiratory infections [26].

Ichthyosis and cancer

Apart from the increased incidence of skin cancer in KID and Netherton's syndromes, the occurrence of both in the same patient is rare. A youth with an ill-defined ichthyosis, micropinnae, universal alopecia and ectropion developed a scalp squamous cell carcinoma [27, case 2]. The predisposition to testicular cancer in XLRI is likely to be related to the endocrine dysfunction in that disorder. Other non-cutaneous malignancies (e.g. thyroid cancer and medulloblastoma) have been associated with inherited ichthyosis, but may be coincidental [14,28].

Miscellaneous

Ichthyosiform erythroderma from early infancy has been reported in 50% or more of patients with Shwachman's syndrome. Its main manifestations are exocrine pancreatic insufficiency, growth retardation and bone marrow hypoplasia with neutropenia [29,30]. Granular droplets in keratinocytes and defective lamellar bodies were seen ultrastructurally [29]. Migratory ichthyosis and pruritus associated with type 2 diabetes mellitus occurred in a large consanguineous family [31]. A sibship with an autosomal recessive ichthyosis, developmental delay and cirrhosis [32], a single case of ichthyosis, hepatomegaly and cerebellar degeneration [33] and a syndrome of erythrodermic ichthyosis associated with PPK, hypogonadism and hepatosplenomegaly have been reported [34]. Two related inbred Moroccan families with diffuse nonerythrodermic ichthyosis, scarring alopecia, sclerosing cholangitis and eosinophil vacuolation have shown linkage to chromosome 3q27–q28 [35]. An autosomal dominant syndrome in four generations of a family included ichthyosis, abnormal platelet function, asplenism, migraine, fatigue and dyslexia [36]. Ichthyosis has been present in some patients with ectodermal dysplasias [37,38] and two reports of ichthyosis vulgaris-like scaling associated with follicular atrophoderma, hypotrichosis and woolly hair have been published [39,40].

Acquired ichthyoses

Acquired or late-onset ichthyosis is a rare and significant occurrence, as it is generally associated with underlying pathology such as malignancy. It presents with features similar to ichthyosis vulgaris and must be distinguished from both it and RD in which scaling starts in early adult life.

Ichthyosis associated with malignancy

The most commonly reported malignancy that produces ichthyosis is Hodgkin's disease, and the skin lesions as a rule occur simultaneously or after the lymphoma is diagnosed [1,2]. The fine scaling affects the trunk and limbs, spares the flexures and histologically resembles ichthyosis vulgaris with orthohyperkeratosis and reduced or absent granular layer. It clears with effective anticancer treatment and may be an early marker of subsequent recurrence. It may be associated with pruritus. Reduced skin lipogenesis, as measured by radiolabelled carbon uptake in lipid groups except sterols, paralleled the severity of the ichthyosis and contrasted with results in ichthyosis vulgaris in one study [3]. Production of transforming growth factor (TGF-α) by the tumour has been proposed [2].

Ichthyosis has also been reported in association with non-Hodgkin's lymphoma [4], mycosis fungoides [5–7], multiple myeloma [8], carcinoma of breast, lung, cervix [9] and liver [10], leiomyosarcoma [11] and Kaposi's sarcoma [12]. It preceded by 2 years the development of lymphomatoid papulosis in one case [13], and occurs in patients with acquired immune deficiency syndrome (AIDS), with or without demonstrable malignancy [14,15].

Ichthyosis and non-malignant disease

Ichthyosis may occur with chronic metabolic derangement such as malnutrition [6], malabsorption [3,5], essential fatty deficiency, which is extremely rare [16], and Shwachman's syndrome (pancreatic insufficiency) [17]. In these conditions, there is a disturbance of lipid and possibly vitamin absorption; because epidermal structure and integrity are dependent on complex lipid interactions, disordered epidermal maturation and desquamation, and permeability barrier dysfunction ensue. It occurs in renal failure with or without secondary hyperparathyroidism [6,18] and is an occasional feature of hypopituitarism [4], hypothyroidism [5] and diabetes [19,20]. Ichthyosis may rarely occur in connective tissue diseases such as systemic lupus erythematosus [21] and dermatomyositis without associated malignancy [22]. It has been noted in patients with the granulomatous diseases, sarcoidosis [23] and leprosy [24], following bone marrow transplant [25], and in association with Haber's syndrome [26] and eosinophilic fasciitis [27]. A single case of ichthyosiform erythroderma

with lichenoid features, starting at 10 years old and proving fatal at 28 years old, was reported [28]. No underlying cause was identified.

Drug-induced ichthyosis

The cholesterol-lowering drugs triparanol and nicotinic acid induced ichthyosis in a few patients [29,30]. Normal desquamation depends on the conversion of cholesterol sulphate (which maintains the structure of intercellular lipid lamellae in the subcorneal layers) to cholesterol, by cholesterol sulphatase, located on keratinocyte cell membranes. This enzyme is unaffected by hypocholesterolaemic agents but cholesterol constitutes 25% of stratum corneum lipid. Keratinocytes lack low-density lipoprotein receptors, which may explain why so few treated patients show this complication. HMG CoA (hydroxymethylglutaryl coenzyme A) reductase inhibitors are also a rare cause of ichthyosis. Ichthyosis and variable effects on hair have been attributed to certain butyrophenones, the phenothiazine dixyrazine, maprotiline, cimetidine (an antiandrogen), allopurinol, hydroxyurea and clofazamine [31–34].

Pityriasis rotunda

Definition. Pityriasis rotunda describes a rare, persistent, large, sharply defined, circular patch of ichthyosiform scaling with no inflammatory changes. This name is preferred to pityriasis circinata, under which Toyama described the condition in 1906, and to acquired pseudoichthyosis [1].

Aetiology. Pityriasis rotunda is relatively common in the Far East, where it accounts for some 0.2% of dermatological cases [1]. It has been reported also in South African Bantus [2], in an Egyptian [3] and in West Indians living in London [4]. It typically occurs in black patients, but has been described in caucasians [5]. Its true incidence and geographical distribution are unknown. It is possible that a genetic factor is involved, but systemic illness (including tuberculosis) and pregnancy favour the development of lesions, which may have been latent [2]. It may also be a cutaneous marker of malignancy, including hepatocelluar carcinoma [6,7].

Pathology. The histological changes are unimpressive and resemble those of ichthyosis vulgaris.

Clinical features. The lesions of pityriasis rotunda are often almost perfectly circular, sharply defined patches

Fig. 34.26 Pityriasis rotunda.

Fig. 34.27 Erythrokeratolysis exfoliativa of palms.

of dry skin with ichthyosiform scaling, usually 2–3 cm in diameter but sometimes much larger (Fig. 34.26). They are commonly situated on the buttocks, thighs, abdomen, back or upper arms, and may be solitary or multiple. They develop between the ages of 25 and 45 years (7 and 76 years are the reported extremes) and remain unchanged throughout life.

The age of onset, distribution, strikingly circular outline and absence of inflammatory change should suggest the diagnosis. In prereticulotic eruptions, the lesions show atrophy and telangiectasia. Dermatophytosis can be excluded when necessary by the microscopy of scrapings.

Treatment. Emollients and topical keratolytics may help, but topical steroid and antifungals do not. Where an underlying cause is found, appropriate therapy should clear the lesions.

Peeling skin syndromes (MIM 270300)

Periodic peeling of the superficial layers of the skin resulting from damage to the stratum corneum has widely differing aetiologies. Histologically, there is cleavage within the stratum corneum and some alteration in the staining properties of defined layers. Involvement of the most superficial layer of the stratum spinosum is suggestive of pemphigus foliaceus. A few cases and families have been reported with either generalized skin peeling (deciduous skin, familial continual skin peeling or shedding) or acral peeling. In Oudsthoorn disease (erythrokeratolysis hiemalis), the peeling is more pronounced and is associated with erythema.

Acquired peeling of the palms

The most common condition encountered is *keratolysis exfoliativa*. This affects the palms of young adults, usually in the summer months. This suggests that it may be related to sweating. Lesions appear as tiny white rings or 'air bubbles', which soon rupture and peel off ('ringed keratolysis') (Fig. 34.27). Attempts to identify a specific fungal or bacterial agent proved negative [1]. Emollients are usually prescribed but are not very effective.

Cases are seen where the peeling is not seasonal. In these patients, the peeling episode may be preceded by a few days by intense itching of the palms. Histologically, there is minimal spongiosis and it may represent a *forme fruste* of hand eczema. The use of degreasing chemicals may produce similar damage to the stratum corneum, by affecting intercorneocyte adhesion.

Familial peeling skin syndrome

Variously known as keratolysis exfoliativa congenita [1] or deciduous skin [2], the label 'familial continual skin peeling' was suggested in 1969 in a case report of four affected siblings [3]. Two further kindreds and a number

of individual cases have since been described and some authors prefer the title peeling skin syndrome [4–8]. The peeling was generalized and variations in the salient features among reported cases led to the identification of type A [2–4,6] and type B [5,7] inflammatory peeling skin syndrome [9]. Two affected families were consanguineous [3,4] and the occurrence of affected siblings also points to autosomal recessive inheritance. A familial, predominantly acral peeling has been reported [10]. The paucity of reported cases makes estimation of the frequency difficult but it occurs worldwide.

Aetiology. A defect in profilaggrin or a site-specific keratin with resultant abnormal keratin filament aggregation has been suggested [10]. Evidence for a desmosomal abnormality and altered vitamin A metabolism has been put forward [11]. Reduced trytophan with aminoaciduria was reported in one case [5].

Histopathology. Mild hyperkeratosis with loose irregular stratification at follicular orifices and a normal granular layer thickness are common findings [4], although psoriasiform acanthosis was noted in one case [5]. Kinetic studies suggested a hyperproliferative disorder [3], but this has been disputed [6]. The split exists at the corneal–granular interface and ultrastructurally intercellular disruption occurs above the lower two layers of stratum corneum, within the stratum lucidum. At this site, intercellular lamellae are irregular and fragmented, keratohyalin granules are abnormal and desmosomes may be normal [10] or reduced [4]. Lamellar bodies are aggregated in the upper granular layer, but other cytoplasmic structures are normal. A patient with adult-onset disease was found to have intracellular keratinocyte cleavage with globular lipid deposits between corneal cells at all levels [6]. Immunofluorescence studies were normal in two cases [5,12].

Clinical features. Generalized superficial peeling starts at birth or in early childhood and is then persistent or periodic in most affected people. Collodion membrane and blisters do not occur in this condition, although vesicles were noted in one case [8]. Peeling is not preceded by fever or erythema, and can be produced by rubbing intact skin, especially if pre-soaked in water. Exfoliating flakes and peeling sheets of stratum corneum spread across the trunk, limbs and occasionally face, leaving mildly erythematous intact skin. Mild pruritus is a problem for some patients and patchy hyperpigmentation has been noted. The palms and soles are either spared or mildly thickened without peeling, and hair, nails and teeth are usually normal. However, one patient did have severe palmoplantar subcorneal blistering, ichthyosis and keratotic cheilitis [11]. The acral variant occurred in an adult male with lifelong episodic peeling of the dorsal and volar aspects of the hands and feet, and to a lesser extent in a niece and nephew [10]. Two patients had easily plucked hair [5,12], another shed nails as well [13] and a woman of 26 was stunted with hypogonadism and anosmia [5]. Developmental delay was noted in one case [14]. Some cases are more severely affected in the summer [2,8,10,12], but generally there is only slight seasonal variation. Shedding occurred in a cephalocaudal pattern for a week once a year in an Indian boy [13].

Diagnosis. Several unrelated skin disorders eventuate in skin shedding, but differentiation from peeling skin syndrome is generally not a problem. IBS (ichthyosis exfoliativa) produces transient blisters and erosions on a background of flexural hyperkeratosis and typical histopathology. An autosomal recessive form of exfoliative ichthyosis (without epidermolytic hyperkeratosis) in an inbred Bedouin family has been documented [15]. It shares some of the clinical features of familial peeling skin syndrome type A. In epidermolysis bullosa simplex superficialis and Weber–Cockayne variant, subcorneal or basal layer blisters occur with friction but there is no continual peeling, the histology is characteristic and they are autosomal dominant [16]. Peeling lesions without double-edged scale do occur in NS, but inflammatory lesions, atopy and hair defects should enable accurate diagnosis. Acquired keratolysis may complicate tinea (the original definition of keratolysis exfoliativa, an id reaction mainly affecting the palms), staphylococcal or streptococcal infection, atopic eczema or retinoid therapy.

Treatment. Minimizing immersion in water is recommended. Absorbing powders or aluminium antiperspirants may help, especially in the acral variant, by reducing sweating and friction. Keratolytic and urea creams speed up shedding. Topical and oral steroids, emollients and tar, oral retinoids [14], methotrexate and UVB phototherapy are among those agents tried without success.

Oudtshoorn disease (MIM 148370)

SYN. KERATOLYTIC WINTER ERYTHEMA; ERYTHROKERATOLYSIS HIEMALIS

This rare epidermal disorder, characterized by recurrent skin peeling, palmoplantar erythema and seasonal variation, was originally described as erythrokeratolysis hiemalis in 1977. It has been observed in at least 35 white or mixed-race related South African families of European descent originating from the Oudtshoorn district of Cape Provence [1,2]. The incidence in this population is 1 in 7000. Cases have since been identified in several other countries, and a familial link to the Oudtshoorn cluster is evident in most. It is an autosomal dominant disorder with variable penetrance and linkage to chromosome 8p22-p23 has been reported in five South African and one German kindred [3]. The genetic mutation may have arisen in a French immigrant in the late 1700s. Over 400 descendants are affected.

Histopathology. Biopsy of the advancing edge of a lesion shows focal cellular oedema, necrobiosis of the Malpighian layer and absence of the overlying granular layer, through which the Malpighian layer is ejected. It forms a parakeratotic wedge, which becomes sandwiched within the hyperkeratotic stratum corneum and is shed. Hyperproliferative features are evident in the basal layer—so-called basaliosis [2].

Clinical features. Symmetrical keratolysis of the hands and feet may begin at any age from infancy to early adult life but it is not usually present at birth (Fig. 34.28a). Cyclical centrifugal peeling (sometimes preceded by erythema multiforme-like papules) at several sites on the palms and soles is a constant feature, and may spread to the dorsal hands and feet, and the interdigital spaces. Episodes may be preceded by itch and hyperhidrosis and are associated with pustulation. Palmoplantar erythema develops, and is followed by the evolution of superficial opaque dry blebs, which peel or can be pulled away, leaving a red base with intact markings. A second wave may begin at the centre of a lesion, resulting in gyrate and polycyclic annular erythema, which eventually resolves. Cycles repeat every few weeks and the palms and soles appear normal between attacks. Similar rosette lesions may arise on the lower legs, knees and rarely thighs (Fig. 34.28b), upper arms and shoulders. Truncal lesions were reported in one patient [2]. The father of a typical case apparently had involvement of one interdigital space only [4].

(a)

(b)

Fig. 34.28 Oudtshoorn disease: (a) palmar lesions; and (b) truncal lesions.

A frequent precipitant is cold dry weather and, although in South Africa it is most active in wintertime, it may be perennial in temperate climates. Other triggers include febrile illness, stress and menstruation, and it improves in pregnancy and with age.

Diagnosis. The differential diagnosis includes familial peeling skin syndrome (keratolysis exfoliativa congenita), pustular bacterids, erythrokeratoderma en cocardes and variabilis, and Weber–Cockayne epidermolysis bullosa simplex.

Treatment. There is no effective treatment, and topical keratolytics, retinoids and steroids may aggravate the condition. Urea, tar, antiperspirants and oral retinoids have been tried.

Erythrokeratoderma

Erythrokeratoderma (or erythrokeratodermia) is the association of localized hyperkeratotic plaques with circumscribed areas of persistent but variable erythema. Many associations and possible syndromes have been reported. There is clinical overlap with KID and transgredient keratoderma syndromes. Identification of underlying genetic defects in gap junction proteins in some erythrokeratodermas (Table 34.1) has led to re-evaluation of their classification [1], but reliable classification on clinical grounds remains challenging.

Erythrokeratoderma variabilis (MIM 133200)

SYN. MENDES DA COSTA'S SYNDROME

Mendes da Costa described a mother and daughter with relatively fixed hyperkeratotic plaques and erythematous areas with geographical margins that changed by the hour [2]. The inheritance is usually autosomal dominant, but recessive inheritance is reported [3,4].

Aetiology. There is a disease locus near the rhesus cluster on chromosome 1 [5], at which several genes encode members of the connexin family. Connexins are the constituents of gap junctions, intercellular channels that allow traffic of ions and small molecules between adjacent cells [6]. Mutations have been identified in gap junction beta-3 (*GJB3*), encoding connexin 31, in several pedigrees of erythrokeratoderma variabilis (EKV) [7–9]. Homozygous missense mutations in connexin 31 causing recessive EKV have also been reported [4]. The mechanisms by which impaired protein trafficking [10] or gap junction function give rise to the cutaneous abnormalities remain unknown. Connexin 31 mutations are not found in all pedigrees of EKV [9,11]. Other mutations in *GJB3* cause autosomal dominant or recessive deafness, in isolation or with peripheral neuropathy [12–14]. In a family with EKV associated with unusual rapidly evolving erythematous lesions resembling erythema gyratum repens, a mutation of *GJB4* (encoding connexin 30.3) was found [15]. This phenotype appears to be specific to mutations in *GJB4*, but other mutations in this gene present as more typical EKV [16].

Pathology. Histology is non-specific: orthohyperkeratosis or parakeratosis, with acanthosis and papillomatosis. Immunohistochemistry shows aberrant staining for basal cytokeratins in the stratum corneum, improved by etretinate [17]. There is an increase of suprabasal staining for involucrin [18]. Connexin 31 is expressed in an abnormal perinuclear distribution, rather than at the cell membrane [10]. Reduced numbers of keratinosomes within the stratum granulosum, restored by isotretinoin, and clumped tonofilaments have been reported [19]; the latter were not confirmed in other cases [20,21].

Fig. 34.29 Erythrokeratoderma variabilis: migrating polycyclic erythematous lesions.

Clinical features [21–25]. Onset is usually in infancy. The manifestations vary within a family and within the individual. There are two types of lesions. Relatively fixed well-demarcated keratotic and erythematous plaques show a predilection for extensor surfaces. These extend and regress in area, thickness and degree of erythema. Secondly, transient erythematous polycyclic or comma-shaped macular lesions occur at any site (Fig. 34.29). These may be triggered by trauma, irritation or temperature change, and evolve in shape over hours. They last days or weeks, fading *in situ* or migrating slowly, leaving a residual fine scale. Improvement may be seen after extended sun exposure. In some cases the erythema is annular or 'en cocarde' (Degos' syndrome) [26,27]; in others, it may resemble erythema gyratum repens [15,16,28]. Palmoplantar involvement in EKV may take the form of mild scaling or peeling [23], but transgredient keratoderma resembling Greither's syndrome is recorded [29]. The condition persists throughout life, but may improve at

puberty or worsen during pregnancy or with oral contraceptives [30]. Migratory polycyclic erythematous plaques suggestive of EKV have also been reported in two families with the same heterozygous point mutation in the keratin 1 gene [31].

Treatment. Acitretin is now the treatment of choice [32]. Isotretinoin may also be helpful [19]. Successful use of bath PUVA has been reported [33]. Non-sedating antihistamines have been reported to benefit pruritic erythematous lesions [34].

Progressive symmetrical erythrokeratoderma (MIM 602036)

SYN. GOTTRON'S SYNDROME

In progressive symmetrical erythrokeratoderma (PSEK) [1,2], fixed plaques of hyperkeratotic erythema, which gradually extend during childhood, resemble those of EKV, but migratory erythema is not seen. PSEK is more common than EKV, and probably also heterogeneous. Approximately half the cases are familial with autosomal dominant inheritance [3], while the remainder are sporadic.

Aetiology. In a Japanese pedigree, lesions suggestive of PSEK were associated with honeycomb keratoderma, and an insertional mutation in loricrin was found, of the same type as those found in honeycomb keratoderma with ichthyosis [4]. This is probably an exceptional finding, as histological findings were more consistent with loricrin keratoderma, of which PSEK is not otherwise a feature.

Pathology [5,6]. The epidermis is acanthotic with a preserved granular layer. The stratum corneum is hyperkeratotic with a basket-weave pattern and foci of parakeratosis. The variable presence of perinuclear vacuolation of keratinocytes further suggests heterogeneity. Ultrastructurally, the granular cells contain swollen mitochon-

Fig. 34.30 Symmetrical progressive erythrokeratoderma: sharply demarcated 'geographical' orange–red plaques. (Courtesy of Dr A.G. Smith, North Staffordshire Hospital, Stoke-on-Trent, UK.)

dria, and corneocytes show lipid-like vacuoles, both of which are reduced by etretinate therapy. Labelling studies show increased epidermopoiesis with shortening of the interphase [7,8].

Clinical features [3,9,10]. The skin is usually normal at birth. Large, geographical but symmetrical fine scaly plaques with an orange–red erythema appear in infancy (Fig. 34.30). There is little pruritus. The shoulder girdle, cheeks and buttocks are most often affected with limited plaques on the ankles and wrists. Keratoderma may be present. Hair and nails are usually normal, but one case showed thickened nails [11]. The plaques extend during childhood but become fixed or occasionally remit. Erythroderma present at birth [12], and onset delayed to 17 years [13], have been recorded. A family with mal de Meleda keratoderma first presenting with inguinal lesions was originally diagnosed as PSEK [14].

Treatment. Limited data suggest that etretinate and acitretin are effective [13,15] although etretinate was reported in one patient to cause generalization of the erythema [12]. PUVA treatment has been reported [16].

Other erythrokeratoderma syndromes

Erythrokeratoderma with sensorineural deafness [1] may be a form of the KID syndrome (see above), now known to be caused by mutations in connexin 26 [2,3]. Schnyder's syndrome (asymmetrical erythrokeratoderma with deafness, peripheral neuropathy, muscle atrophy and mental retardation, and occasionally keratitis) [4–6] and overlapping syndromes may be pathogenetically related. In a five-generation Canadian pedigree, erythrokeratoderma appearing in infancy and clearing in later life was associated with late-onset ataxia and neuropathy (Giroux–Barbeau syndrome, MIM 133190) [7,8]. The defective gene maps to the connexin gene cluster at 1p34–p35 [8]. A sporadic case of a boy with atypical erythrokeratoderma mainly localized to periorificial regions also had acral involvement and pachyonychia [9]. Vakilzadeh and Rose [10] described a boy with slowly migrating orange–brown plaques over the buttocks and legs from the age of 1 year, without large zones of erythema and without fixed plaques, leading the authors to separate this disorder from both EKV and PSEK. Faninger [11] reported a case of localized hyperkeratosis

resembling symmetrical interdigital keratoderma, but with marked underlying erythema.

Folliculocentric keratotic disorders

Keratosis pilaris (MIM 604093)

Keratosis pilaris [1,2] is characterized by keratinous plugs in follicular orifices with varying degrees of perifollicular erythema. Mild forms, appearing in childhood and reaching a peak incidence in adolescence, can be regarded as physiological. Mevorah *et al*. [3] recorded its presence in 44% of 155 normal people, but few were markedly affected. Prevalences of 2.7–4% are recorded in schoolchildren from various countries [4–6]. Nutritional deficiency may have caused a higher prevalence in postwar Germany [7]. It is often seen in ichthyosis vulgaris [3]. It was present in 72% of 54 atopic black children with eczema [8], but in a group of white children only 37% of patients with keratosis pilaris had a personal history of atopy [9], and it is a poor discriminator of atopic eczema [10].

Aetiology. Follicular hyperkeratosis is a feature of several syndromes (see below) but keratosis pilaris in isolation may be inherited as an autosomal dominant trait with variable penetrance. One locus is suggested by the occurrence of more severe forms with translocations and deletions of chromosome 18p [11–13]. An X-linked dominant form in women has been suggested [14].

Pathology. The follicular orifice is distended by a horny plug which may contain one or more twisted hairs. There may be mild inflammatory changes in the dermis. Lectin staining did not demonstrate abnormal keratinization [15].

Fig. 34.31 Keratosis pilaris on the extensor aspect of the upper arm.

Clinical features [9] (Fig. 34.31). Small grey–white plugs of keratin obstruct the mouths of the follicles, entrapping the body hair. Extensor surfaces of the upper arms (92%), thighs (59%) and buttocks (30%) are most commonly involved. Occasional cases are generalized. Uneven involvement of a given area is usual, with some follicles completely spared, while adjacent ones are grossly plugged. Individual follicles show a long strand of keratin glinting when examined in side light (antenna sign). Perifollicular erythema is often present, and may be psychologically distressing for the patient [16]. The age at onset was in the first decade in 51%, the second decade in 35% and the third decade in 12%. Improvement in the summer months was noticed in 49% [9]. Improvement with age is common, occurring at a mean age of 16 years [9]. The term keratosis rubra pilaris is sometimes used when redness is marked. The erythematous component without plugging is also seen. Severely affected follicles may show a tiny pustule.

Associations. Keratosis pilaris is seen in association with ichthyosis vulgaris and in atopic xeroderma rather than atopic eczema *per se* [3]. Keratosis pilaris (or 'follicular ichthyosis') also occurs with Noonan/cardio-facial-cutaneous syndromes [17–20], renal insufficiency [21], prolidase deficiency [22], Down's syndrome [23] and various mental deficiencies, in which it overlaps with trichostasis spinulosa [24,25], and in Fairbanks' [26] and Olmsted's [27] syndromes. A syndrome of hypotrichosis

and leukonychia is recognized [28,29]. Follicular hyperkeratoses occur in monilethrix, pachyonychia congenita and ectodermal dysplasias [30–36]. Follicular hyperkeratosis may be seen during systemic steroid [37] or lithium therapy [38].

Keratosis pilaris with atrophy [39–43]. Keratosis pilaris is sometimes succeeded by atrophy. The nosology is debated [39,40] as only keratosis follicularis spinulosa decalvans can be distinguished genetically at present. *Ulerythema ophryogenes* or *keratosis rubra pilaris faciei atrophicans* shows prominent facial erythema with involvement of the eyebrows and scalp and prominent atrophy, with simple keratosis pilaris on extensor surfaces, and may occur in Noonan's syndrome [20,40,44,45]. The late stage of a previously active case shows fine follicular atrophy. The condition is thought to be inherited as an autosomal dominant [40]. *Atrophoderma vermiculatum* is rare, and affects the cheeks and preauricular regions with a combination of keratotic papules giving way to an atrophic worm-eaten appearance, and may be recessively inherited [40,46].

Erythromelanosis follicularis faciei et colli. This comprises the triad of well-demarcated erythema, hyperpigmentation and follicular plugging on the cheeks and neck [37,47]. Patches of red-brown skin with follicular plugging and a granular feel are found on the cheeks and pre-auricular region, spreading onto the neck anterior to the angle of the mandible. The majority of cases are in Asian men [48], but cases have been reported from the Middle East [49], and women are also affected [50]. Associated keratosis pilaris on the arms suggest that it is a pigmented variant of keratosis pilaris, and overlap with ulerythema ophryogenes is also reported [51]. Juhlin and Alkemade [52] report a woman with centrifacial erythrosis pigmentosa peribuccalis which moved onto the cheeks, and argued that these entities are also the same. Unilateral cases occur [53,54]. Reported dermal calcium deposition [55] has not been confirmed as a specific histological feature [48]. A report of possible autosomal recessive inheritance in a consanguineous family [56] is inconclusive.

Follicular ichthyosis. The capacity of this term to describe an entity distinct from keratosis pilaris is doubtful. IFAP is discussed above. A report of follicular hyperkeratosis distinguished from keratosis pilaris may be Noonan's syndrome [57].

Treatment. Simple emollients are rarely effective in keratosis pilaris. One recommended routine is based on initial control of the inflammatory component with a topical steroid, followed by 2% salicylic acid in 20% urea cream and an abrasive sponge [16]. Systemic retinoids are ineffective, and calcipotriol was not effective in nine patients [58], but benefit from topical tazarotene has been claimed [59].

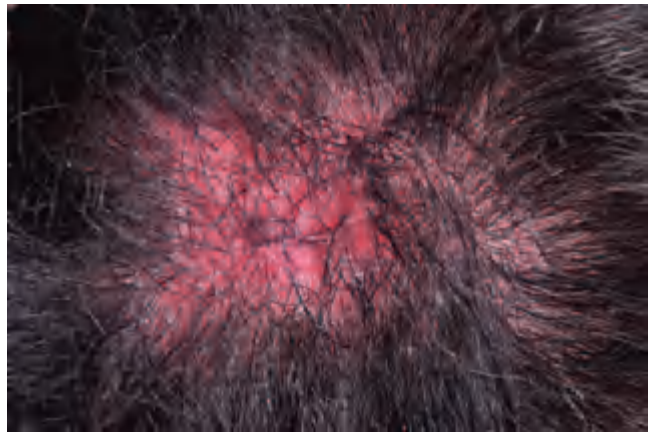

Fig. 34.32 Keratosis follicularis spinulosa decalvans showing atrophy and loss of scalp hair.

Keratosis follicularis spinulosa decalvans (MIM 308800)

KFSD [1,2] is an X-linked recessive disorder mapped to a locus at Xp21.13–p22.2 [3,4]; there may also be an autosomal form [3] and sporadic cases are reported. Keratotic follicular papules develop on the scalp in the first few years of life [5–9]. Progressive scarring alopecia follows with variable degrees of inflammatory change (Fig. 34.32), resembling folliculitis decalvans (see Chapter 63). Erythema and plugging of eyebrow follicles, follicular hyperkeratosis and prominent cuticles are seen. Ocular signs include blepharitis, ectropion and corneal dystrophy. Variable focal plantar keratoderma may be present [10]. Female heterozygotes may exhibit a phenotype that is usually mild [7,9]. The cutaneous and ocular features overlap with ichthyosis follicularis and photophobia (see above) in which palmoplantar involvement is absent [11,12]. Other associations reported include Noonan's syndrome [13], and with deafness [14], cutis laxa, big pinnae and clinodactyly [15], and aminoaciduria high in aspartic acid [16]. Treatment is generally unsatisfactory. *Staphylococcus aureus* is occasionally found in the inflamed lesions but improvement does not follow extensive appropriate antibiotic therapy. Retinoids, either topically or systemically, produce little improvement [17] but were helpful in one report [8].

Other folliculocentric disorders

Lichen spinulosus (syn. keratosis spinulosa). This appears to have become uncommon in Western practice. Typical grouped lesions appear predominantly in childhood as crops of minute follicular papules, each with a projecting keratinous spine [1,2], and without erythema, chiefly about the neck, buttocks, trochanteric regions, abdomen, thighs, popliteal spaces and extensor aspects of the arms (Fig. 34.33). The face, hands and feet are usually spared.

Fig. 34.33 Lichen spinulosus: even flesh-coloured grouped keratotic papules.

Similar appearance may arise in lichen planus, seborrhoeic dermatitis and reactions to dermatophytes, syphilis and tuberculosis. Friedman [2] studied 35 cases and concluded that it was probably a reaction pattern to several pathogenic processes. Many cases previously described as lichen spinulosus show follicular atrophy and loss of scalp hair, and would currently be termed ulerythema ophryogenes. One case was associated with Crohn's disease [3] and one case was considered to be a reaction to omeprazole [4]. In patients with human immunodeficiency virus (HIV), follicular lesions termed 'PRP-like' or 'lichen spinulosus-like' appear to be more filiform and florid than the disorder described here [5].

Phrynoderma. This condition, also now rare, is a distinctive form of follicular keratosis associated with nutritional deficiency first reported among prisoners in Beijing province [6]. Horny plugs with perifollicular papules are seen on the elbows, knees, neck and posterior axillary fold. The lesions are 2–3 mm in diameter and easily distinguished from keratosis pilaris. Adjacent skin may be pigmented and scaly. Hypovitaminosis A was the most likely cause, but deficiencies of other factors, such as calories and vitamins B and E, have also been incriminated.

Keratosis follicularis squamosa (Dohi). This is an acquired disorder of follicular hyperkeratosis with a surrounding scale 'like lotus leaves on the water', well-recognized in Japan, but apparently unusual elsewhere [7]. The condition responds to antibiotics.

Disseminate and recurrent infundibulofolliculitis. This striking eruption of unknown cause has been reported almost exclusively in young black male adults [8,9]. Recent reports are few. Profuse, monomorphic, tiny follicular papules with a variable degree of follicular plugging occur mainly over the trunk and back. There is no erythema. The epithelium of the upper follicle is oedematous and in parts spongiotic, and is surrounded by a predominantly lymphocytic infiltrate. Immunofluorescence was negative [9]. Both recurrent and chronic cases have been described. It has been suggested that it is a reaction pattern of atopic eczema in black people. The condition is resistant to therapy, but five of six cases responded to oral vitamin A [9], and a young Indian woman responded to photochemotherapy [10].

Familial dyskeratotic comedones [11–14]. This is an autosomal dominant condition characterized by scattered comedo-like lesions. The lesions appear around puberty, showing a predilection for the trunk, arms, legs, face and the shaft of the penis. The glans, and palms and soles are spared. The comedones can be picked out without producing bleeding. The lesions reform over a few weeks, and the condition gradually worsens with time. The lesions usually

lack any inflammatory signs, but around puberty approximately 50% may show concomitant acne. Histologically, there is a lamellar keratin plug with patchy parakeratosis; there may be acantholysis and scattered but not universal evidence of dyskeratosis. A naevus comedonicus is usually unilateral and the lesions are more closely packed [15]. Retinoid therapy has proved unrewarding.

Pityriasis rubra pilaris

Pityriasis rubra pilaris (PRP) is a heterogeneous group of disorders that have in common circumscribed follicular keratoses, branny scale and an orange-red erythema, and PPK [1–5]. Classification is debated [6–8] but that of Griffiths [6] has been most widely used. There is a bimodal age of onset [9,10], but juvenile and adult forms of PRP, and indeed their variant forms, may be unrelated disorders. Incidence was approximately 1 in 5000 among patients presenting to a specialist dermatology centre.

Aetiology. The causes are unknown. Familial cases (MIM 173200) are rare [11,12]. Epidermal thymidine labelling is increased [13–15] from an average normal 3% to 27%, and the rate of growth of nails is faster than normal (although not so fast as in psoriasis). An infective aetiology is suggested, especially in the juvenile form [16–19]. Human leukocyte antigen (HLA) phenotype frequencies in 31 Finnish PRP patients did not differ significantly from those in a control population [19]. A PRP-like eruption is seen in patients with HIV [20].

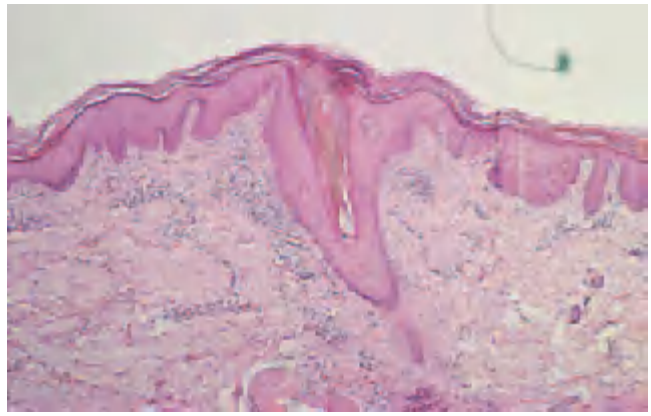

Fig. 34.34 Histopathology of pityriasis rubra pilaris: follicular plugging, acanthosis with exaggerated follicular shoulders, spotty parakeratosis and mild upper dermal inflammatory infiltrate.

Pathology [13,21,22]. The histology of classical adult PRP is distinctive, but varies with the stage of the process, and may differ from site to site. Affected follicles are filled with dense horny plugs and there are foci of parakeratosis in the perifollicular shoulder and interfollicular epidermis (Fig. 34.34). At other sites, basket-weave hyperkeratosis overlies a prominent granular layer and there is little parakeratosis, but there may also be attenuation of granular and horny layers. Dermal capillaries are dilated, but not tortuous, and there is a lymphohistiocytic dermal infiltrate. Unlike psoriasis, the acanthotic epidermis is not thinned above the dermal papillae, and there is no neutrophil infiltration. In discriminating PRP from psoriasis, follicular plugging and an increased granular layer in PRP may be valuable signs [22], but focal acantholysis also occurs. In one study there was increased staining of keratinocytes for β-D-galactose [23]. Expression of keratins K6/K16, a marker of epidermal proliferation, was present in affected epidermis in familial cases [12]. Circumscribed juvenile PRP shows dense lamellated hyperkeratosis with a normal or increased granular layer and little acanthosis. There is little capillary dilatation, and a sparse histiocytic dermal infiltrate. The pattern of keratin components seen by protein gel electrophoresis indicated a rapid epidermal turnover, as in normal skin, following adhesive-tape stripping of the stratum corneum, which contrasts markedly with that found in psoriasis [24]. Ultrastructural changes of uncertain significance have been reported [13,25].

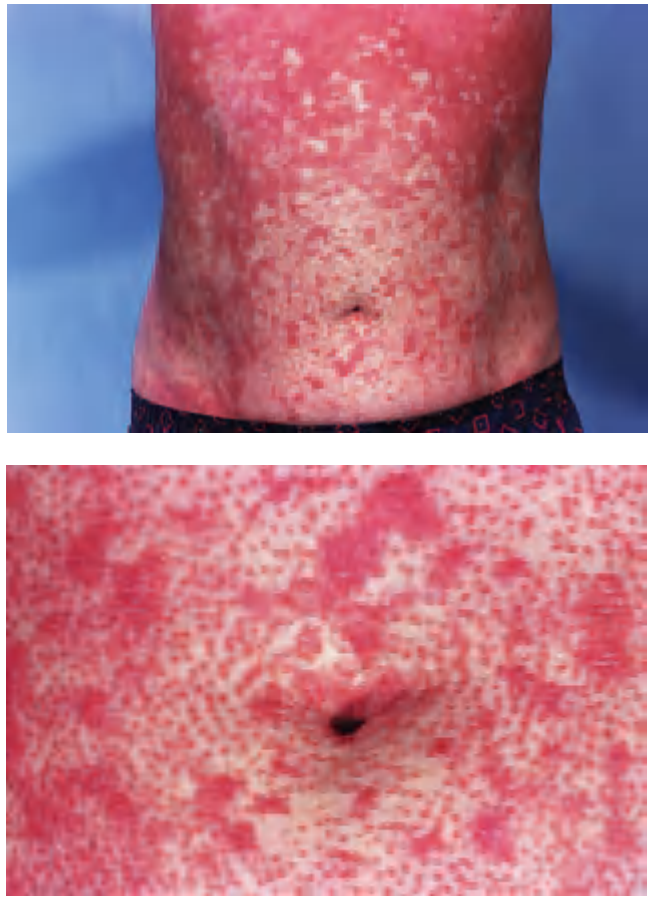
Clinical features. In view of the clinical and histological heterogeneity, confident diagnosis of PRP necessitates

Table 34.3 Some differences between pityriasis rubra pilaris and psoriasis.

	Pityriasis rubra pilaris	Psoriasis
Age at onset	Bimodal	Second decade
Scalp scaling	Furfuraceous	Adherent
Keratoderma	Constant	Less common
'Islands' of pale skin	Constant	Less common
Nail changes	No salmon patches	Present
Nail growth rate	Moderate increase	Marked increase
Epidermal kinetics	Moderate increase	Marked increase
Munro microabscesses	Absent	Common
Response to UVB	Poor	Good
Response to corticosteroids	Poor	Positive
Response to methotrexate	Variable	Good
Seronegative arthropathy	Rare	Common

strict criteria, and in the early or late stages of disease distinctive findings may be lacking. Repeated observation and multiple biopsies may be necessary. Psoriasis, notably follicular psoriasis in children [26], may present difficulties, but these are resolved by the clinical course or histology of psoriasis. Some differences between psoriasis and PRP are indicated in Table 34.3. Atypical forms of PRP must be regarded as provisional diagnostic categories.

Type I: Adult onset, classical. The most common and recognizable form, classical adult PRP affects the sexes equally with highest incidence between 40 and 60 years of age. The eruption usually starts without obvious precipitating factors as an erythematous, slightly scaly macule on the head, neck or upper trunk. Further macules appear within a few weeks, showing profusion of erythematous perifollicular papules with a central keratotic acuminate plug. Follicular lesions appear singly at first, and then coalesce to form groups of two, three or more (Fig. 34.35a,b). Irritation is initially absent, but may be pronounced as the disease spreads. Interfollicular erythema appears, and the follicular lesions are gradually submerged in sheets of erythema with a slight orange colour, which typically spreads from head to feet [6]. The face becomes uniformly erythematous and mild ectropion may follow. Prolonged erythema may give rise to peripheral oedema, and in the elderly precipitate high-output cardiac failure. The scalp shows diffuse bran-like scaling. The palms and soles become hyperkeratotic and yellow (PRP 'sandal'; Fig. 34.36). Erythroderma frequently develops within 2–3 months. In most cases, sharply demarcated islands of unaffected skin 1 cm in diameter remain as a helpful diagnostic sign [27]. Islands of deeper erythema are sometimes seen. The nails are thickened and discoloured distally, showing splinter haemorrhages, but unlike psoriasis there is no dystrophy of the nail plate and pitting is minimal [28] (Fig. 34.37). Spontaneous resolution occurs in 60–80% of patients in 1–3 years, but the condition may persist indefinitely [9,10]. The eruption resembles seborrhoeic dermatitis as it resolves. Relapses are rare [29].



(a)

(b)

Fig. 34.35 Pityriasis rubra pilaris type I: (a) cephalocaudal spread of follicular papules; and (b) follicular papules beginning to coalesce.

Type II: Adult-onset, atypical. This uncommon variety affects some 5% of patients. Follicular hyperkeratosis is prominent in some areas, while more lamellar scaling may be seen elsewhere, especially on the legs. Many patients show areas of eczematous change. The orderly caudal progression seen in type I does not occur and there is less tendency for the disease to become erythrodermic.

Fig. 34.36 Pityriasis rubra pilaris (PRP) type I: the PRP 'sandal'.

Fig. 34.37 Pityriasis rubra pilaris type I: thickening of the nails, subungual hyperkeratosis and splinter haemorrhages.

Type III: Juvenile-onset, classical (Fig. 34.38). The onset is between the age of 5 and 10 years. It resembles type I PRP, but may rapidly follow acute infection [16–18], and spontaneous clearing is usual within 1–2 years [7,30,31]. One case appeared to show a change from type III to type IV [32]. The atypical varieties described below are less exanthematic and have a poorer prognosis.

Type IV: Juvenile-onset, circumscribed. Several years after birth, well-demarcated plaques of follicular plugging with variable degrees of erythema appear on the knees and elbows (Fig. 34.39). A few scattered scaly erythematous macules are often found on the trunk or in the scalp. Some cases also show marked PPK. The histological changes are more reminiscent of psoriasis, but lack neutrophil microabscesses, and evolution to psoriasis is not reported. Circumscribed juvenile PRP must also be differentiated from the erythrokeratodermas. The prognosis is uncertain but some cases clear in the late teens. *Keratosis circumscripta*—prominent follicular papules on the knees, elbows, nape of the neck, and posterior axillary folds—reported in

Fig. 34.38 Pityriasis rubra pilaris type III: orange-red erythema with cephalocaudal spread.

Fig. 34.39 Pityriasis rubra pilaris type IV (circumscribed juvenile PRP) showing well-demarcated plaques of follicular plugging.

African patients is probably identical to localized juvenile pityriasis rubra pilaris [33–35].

Type V: Juvenile-onset, atypical. Patients in this group show erythema and hyperkeratosis at birth or in the first few years of life. Keratoderma is common, and follicular plugging and erythema suggest a diagnosis of PRP. The group overlaps with poorly defined ichthyotic disorders and erythrokeratoderma. Several patients have shown a scleroderma-like change of the digits. There is little tendency for the disorder to clear spontaneously. Some cases within this group are clearly familial [12].

PRP and immunodeficiency. A PRP-like eruption associated with HIV infection and responding to antiretroviral therapy is recognized [36–39]. The term *type VI PRP* has been proposed [39]. Some cases resemble classical PRP, but others show a filiform pattern of keratoses on the face and upper trunk and often have marked acne conglobata [36–39]. Hypogammaglobulinaemia [40] has been reported in an isolated case.

Investigation. There are no diagnostic laboratory tests for PRP. Plasma vitamin A and carotenoid levels are normal [41] and reduced serum retinol-binding protein has been disputed [42,43]. Elevated cellular retinol-binding protein (CRBP) and cellular retinoic acid-binding protein (CRABP) levels similar to those found in plaques of psoriasis are reported [44]. Elevation of parathyroid hormone level [45] was not confirmed in five patients (W.A.D. Griffiths, unpublished data). Takematsu *et al*. [46,47] reported a normal level of leukotriene B_4 (LTB_4) and low levels of anaphylotoxins in scale extracts from PRP, within the range found for normal and non-inflamed skin, and differing from psoriatic scale. Shvili *et al*. [48] reported activated suppressor T cells and impairment of helper T-cell function.

Associated disorders. Many associations of uncertain significance have been reported. PRP has preceded leukaemia [49], metastatic carcinoma [50] and Sézary syndrome [51]. Conversely, Sézary syndrome and chronic T-cell lymphomas can mimic PRP [52,53]. A PRP-like eruption may also be seen in dermatomyositis (reviewed in [54]). Seronegative arthritis is recognized [55–57]. A patient with classical adult-onset PRP (type I) and lichen planus, alopecia universalis, vitiligo and chronic viral hepatitis C was reported [58]. Another patient with type I PRP developed Kaposi's varicelliform eruption from herpes simplex virus (HSV) type I [59]. Photosensitivity and worsening with UVB and UVA have been noted [60,61]. Other reported associations have been reviewed [3].

Treatment. Intensive topical and supportive treatment is needed for the erythrodermic state. Rest and emollient applications reduce exfoliation, and help to restore the skin barrier. Topical and systemic corticosteroids are ineffective. No systematic trials have been conducted, but oral retinoids are widely used. In the erythrodermic phase, acitretin or isotretinoin are used [62–65]. Results with systemic retinoids are unpredictable, with some patients showing dramatic clearing while others appear to be resistant. In patients who respond, the natural history of the disease appears to be shortened [63]. In children, isotretinoin produced the best response [31]. Topical vitamin D analogues are reported to be beneficial [67]. Methotrexate has been effective as an alternative or adjunct to oral retinoids [63,68,69], but may be less efficacious in PRP than in psoriasis [3]. Phototherapy may exacerbate the condition, but narrow-band UVB, UVA1, PUVA, bath PUVA and extracorporeal photopheresis have all been reported as beneficial [68,70–73]. Phototherapy may be combined with acitretin [74,75], and capsaicin was used to relieve phototherapy pruritus [76]. Success [77–79] and failure [63,80] with ciclosporin are reported. Antiretroviral therapy, of value in the PRP-like eruption of HIV disease [81], did not help three non-HIV cases [82]. Oxholm *et al*. [83] reported a patient receiving cytostatics, retinoids, PUVA and ciclosporin who developed a squamous cell carcinoma of the parotid.

Darier's disease and related disorders

Darier's disease (MIM 124200)

SYN. KERATOSIS FOLLICULARIS; DARIER–WHITE DISEASE

Darier's disease, described independently by White and Darier in 1889, is an autosomal dominant condition characterized by a persistent eruption of hyperkeratotic papules, histological examination of which shows suprabasal acantholysis with a distinctive overlying dyskeratosis [1,2]. Expressivity is variable but penetrance complete in adults [3]. Sporadic cases are common. It has a worldwide distribution. Reported prevalence varies from to 1 in 100 000 in Denmark [4] to 1 in 30–35 000 in northern England and Scotland [3,5].

Aetiology. Darier's disease is caused by mutations in the *ATP2A2* gene at chromosome 12q24.1, which encodes the sarco- and endoplasmic reticulum calcium ATPase type 2 (SERCA2) [6–10]. SERCA2 is member of a family of ion pumps that maintain high calcium concentration in the endoplasmic reticulum [11–13]. It has two isoforms: SERCA2a is expressed in cardiac and smooth muscle, whereas SERCA2b is more widely expressed, including in epidermis. Darier's disease is caused by both nonsense and insertion and/or deletion mutations, likely to produce haploinsufficiency, and missense mutations, likely to result in an abnormal expressed protein [6–9].

Pathology. In the earliest papular lesions, lacunae appear above the basal layer [1,2], and extend irregularly throughout the Malpighian layer. Small groups of cells around the lacunae become separated from their neighbours, enlarge and present a darkly staining nucleus surrounded by clear cytoplasm and a glistening ring simulating a membrane. These 'corps ronds' show premature partial keratinization (dyskeratosis); they give rise to the grains, small cells with shrunken cytoplasm, seen in the upper layers of the epidermis. This abnormal terminal differentiation appears also to be distinct from apoptosis [14]. Lesions are not exclusively follicular [15], as acantholysis and dyskeratosis appear to occur preferentially around sweat ducts and mucous and salivary glands as frequently as around follicular openings. With the electron microscope, the lacunae can be seen to result from changes in the tonofilaments, which become separated from the desmosomes [16]. Immunocytochemical studies confirm that desmosomal proteins of affected cells are not localized to the membranes but diffusely distributed in the cytoplasm [17–19] and their intra- and extracellular domains are dissociated [20]. Defects in SERCA2 may produce these changes as a result of impaired processing of cell membrane proteins in the endoplasmic reticulum.

Fig. 34.40 Darier's disease: profuse keratotic papules in the seborrhoeic region of the back.

Focal acantholytic dyskeratosis also occurs in other conditions, such as solitary dyskeratoma, and transient and persistent acantholytic dermatoses. Hailey–Hailey disease (chronic familial benign pemphigus; see Chapter 40), may overlap clinically and histologically, although there is more suprabasal clefting and acantholysis, and grains and corps ronds are less evident, in Hailey–Hailey disease.

Clinical features [1,3]. The distinctive lesion of Darier's disease is a firm rough papule, which is skin-coloured, yellow-brown or brown. Seborrhoeic areas of the trunk (Fig. 34.40) and face, particularly the scalp margins, temples, ears and scalp, are most often involved. Many lesions are subtle; the occurrence of multiple minute acanthomas is easily overlooked. Flat and freckle-like lesions may appear as pale macules in pigmented skin [21]. Coalescent papules form irregular warty fissured plaques or papillomatous masses, which, in the flexures, become vegetating

Fig. 34.41 Darier's disease: acrokeratosis verruciformis in a 4-year-old child.

and malodorous [1]. Flexural involvement most notably affects the anogenital region, the groins and the natal cleft. On the scalp, the heavy crusting simulates seborrhoea, but has a characteristic spiny feel to palpation. Loss of hair is exceptional. The external auditory meatus may be blocked by keratotic debris [22]. Limb involvement usually takes the form of scattered papules, but confluent lesions on lower legs and arms may be a problem [23]. On the dorsa of the hands and feet, discrete papules are clinically indistinguishable from acrokeratosis verruciformis of Hopf [24,25]. These may be the earliest manifestations of the disease (Fig. 34.41) [3]. In Darier's disease, the palms and soles may show minute pits or, in older subjects, punctate or filiform keratoses [25,26]. Lesions of the mucous membranes are uncommon, but white umbilicate or cobblestone papules on the palate resembling nicotinic stomatitis may be seen [27]. Lesions of the tongue, buccal mucosa, epiglottis, pharyngeal wall, vulva, oesophagus or rectum may occur, as may gingival hypertrophy [28–30]. Confluent buccal lesions may simulate leukoplakia. Characteristic nail changes include red or white longitudinal bands of varying width, often ending in a pathognomonic notch at the free margin of the nail. The nails are often brittle.

The majority of patients first become aware of lesions in the second decade [1], although minor lesions or nail or palmar changes may be detected earlier [3]. The condition is typically exacerbated by heat and light, especially sunburn, and lesions can be experimentally induced by UVB exposure [31]. The disease usually runs a chronic relapsing course, and general health is normally unaffected. Exacerbations of keratosis follicularis have also been reported following steroids in naevoid disease [32]. Spontaneous remissions do occur.

Clinical variants. Most patients have the classical seborrhoeic distribution of papules, but there is considerable variation in the severity, from isolated nail or palmar changes to universal and grossly disfiguring involvement. A minority of patients have predominantly vesicobullous [33], flexural or erosive disease or hyperkeratotic lesions, particularly of the distal limbs [23]. The most malodorous cases occur in these patients. Some patients present with multiple comedones or nodulocystic acne with deep pitted scars, and typical histology of Darier's disease may be found in these lesions [34]. Haemorrhagic macules occasionally seen on the hands and feet seem to represent a true genetic variant, as they occur consistently within families [35] and may be caused by specific mutations [8]. Atypical or unusually severe Darier's disease is usually a result of missense mutations [7,8].

Acantholytic dyskeratotic epidermal naevi. Following the lines of Blaschko, these are commonly of late onset and display photoaggravation, suggesting they are a naevoid form of Darier's disease [32,36,37]. It has now been shown that is the case in at least some such naevi [38], a finding that implies the potential for transmission of the disorder if the gonads are affected by somatic mosaicism.

Associated features. Despite the wide expression of SERCA2, the phenotype of Darier's disease is largely confined to the skin. However, patients have an increased susceptibility to herpes simplex [39]. Kaposi's varicelliform eruption has occurred [40,41], as has poxvirus infection [42]. There may also be an increased incidence of chronic pyogenic infection [43]. There is evidence for and against a defect in cell-mediated immunity [44–47]. Salivary duct narrowing can cause recurrent salivary gland swelling, and subclinical narrowing may be common [27,48,49]. Most patients are of normal intellect, but clinical experience suggests that mild degrees of learning difficulty are common. There are numerous reports of cases of Darier's disease with a range of neuropsychiatric disorders, including a high prevalence of epilepsy [1,4,50–52]. Transgenic mice haplo-insufficient for SERCA2 display impaired cardiac contractility [53] and an increased incidence of gastro-oesophageal and other squamous cancers [54]. However, SERCA2 function in humans appears to be largely compensated by other genes or epigenetic factors, as there is no evidence of a consistent cardiac problem in Darier's disease [55] and an increased incidence of cancer has not been documented.

Differential diagnosis. In mild forms, acne and seborrhoeic dermatitis may be confused, unless the warty papules are carefully sought. Confluent lesions resemble discoid eczema and may respond to treatment for this. Flexural Darier's disease may overlap clinically and histologically with benign familial pemphigus (Hailey–Hailey disease) but patients with intertriginous Darier's disease have changes typical of Darier's disease elsewhere,

Table 34.4 Focal and follicular keratoses.

	Age of onset	Distribution	Morphology	Associated features
Keratosis pilaris				
Physiological	Childhood or adolescence	Extensor limbs	Horny follicular plugs	None or erythrocyanosis
Ichthyotic	Early childhood	Extensor limbs	Horny follicular plugs	Ichthyosis—autosomal dominant type
Keratosis pilaris atrophicans (including atrophoderma vermiculatum)	Childhood	Eyebrows, cheeks	Erythema, follicular plugs, alopecia	Miliary cysts
Keratosis pilaris spinulosa decalvans	Childhood	Face, scalp, trunk	Follicular plugs, scarring alopecia	
Phrynoderma	Any age; usually childhood	Elbows, thighs, buttocks	Horny follicular plugs	Skin dry, pigmented
Pityriasis rubra pilaris	Childhood or middle life	Especially dorsa of fingers, knees, elbows; may be widespread	Fine, red papules with central horny plug	Plaques of erythema and scaling; palmoplantar keratoderma
Darier's disease	Usually above 10 years	Seborrhoeic areas	Yellow-brown, greasy papules	Nail and palmoplantar lesions
Kyrle's disease	50–70 years	Mainly arms and legs	Large irregular horny plugs	

and the age of onset is usually earlier. In Dowling–Degos disease or acanthosis nigricans, lesions are flexural and pigmented. In confluent reticulate papillomatosis (see below), the lesions are flat and largely confined to the upper trunk. Other follicular keratoses are listed in Table 34.4. The harshness on palpation distinguishes the disorder from many visually similar disorders such as the reticular erythematomucinous syndrome and prurigo pigmentosa [56].

Treatment [57]. Many patients with mild disease require no treatment other than emollients, simple hygiene and advice to avoid sunburn. Topical tretinoin and isotretinoin, adapalene and tazarotene have been reported as effective [58–61]. In practice, irritancy limits the value of most topical preparations and extra emollients are needed. Antiseptics may help with infected plaques, which may respond to topical steroid–antibiotic combinations. For those with more severe disease, oral retinoids are usually effective. Both acitretin and isotretinoin may be used [62,63]. Dermabrasion in limited areas may prove useful [64]. Severe inflammatory exacerbations of Darier's disease occur in some patients, and have responded to ciclosporin [65,66]. Knulst reported 2 and 6 months' remission in two patients treated with topical 5-fluorouracil [67].

Transient and persistent acantholytic dermatosis

SYN. GROVER'S DISEASE; PAPULAR ACANTHOLYTIC DERMATOSIS

These papular acantholytic dermatoses mainly affect the trunk in middle-aged or elderly people, and typically present as an eruption of pruritic papules or papulovesicles with focal acantholytic dyskeratosis on histology [1–4]. Distinction between transient and persistent forms of disease may be artificial [2,4].

Aetiology. The cause is unknown. Heat and sweating are predisposing factors [5,6]. The condition has been regarded by some as a minimal expression of Darier's disease [7] but mutations in the *ATP2A2* gene were not found in four patients [8].

Pathology. Many conditions show histology of focal acantholytic dyskeratosis [9]. In transient acantholytic dermatosis, the histology mimics Darier's disease, pemphigus and Hailey–Hailey disease, and there is also a spongiotic form in which acantholytic cells are contained within spongiotic foci in the epidermis [2,5,10]. Acantholysis may only be related to the acrosyringium in a subset of cases [11,12]. Darier-type [2] or pemphigus-type histology [5] appears to predominate in the more persistent type of lesion. Dermal eosinophilia and degranulation is sometimes seen [10]. Immunofluorescent studies are negative [13]. Electron microscopic studies have shown intradesmosomal separation, diminution in the number of desmosomes and perinuclear aggregation of tonofilaments [14]. Cells with the electron microscopic features of corps ronds have also been seen [15]. In a study of the focal

acantholytic dermatoses, Hashimoto *et al*. [16] reported that the attachment plaque proteins dissolved and diffused into the acantholytic cells. Internalized desmosomal structures were seldom found in acantholytic cells of non-immune diseases.

Clinical features. Transient acantholytic dermatosis presents as an acute eruption of pruritic discrete greyish pink papules or papulovesicles. Lesions most commonly occur on the trunk, and mostly affect middle-aged or elderly men, especially those with a fair skin. The initial lesion may be mistaken for a solar keratosis. The disease may occur on a background of pre-existing skin disease [17]. It is common in hospitalized patients [18]. The rash is usually transient, lasting from 2 weeks to several months. Exposure to sun [1,2], ionizing radiation [19] and 2-chlorodeoxyadenosine [20] have been noted as precipitating factors. An association with internal malignancy has been reported several times [10,19,21,22], but may be non-specific.

The prognosis is variable, and the disease may run a chronic relapsing course. Most patients with persistent disease are men with significant solar damage.

Differential diagnosis. Darier's disease and Hailey–Hailey disease are distinguished by the late onset of scattered truncal lesions without a tendency to confluence, and the absence of family history. Pemphigus is clinically distinct and is also excluded by negative immunofluorescence, although coexistence with pemphigus foliaceus has been recorded [23]. Other conditions in which focal acantholysis can occur include actinic keratoses or PRP [24], and these may need to be differentiated.

Treatment. In mild cases, symptomatic treatment of pruritus and topically applied steroids may be all that is required. The successful use of calcipotriol is recorded [25]. In more troublesome cases, etretinate [2,26], isotretinoin [27], systemic steroids [5] and PUVA [28] have been used.

Acrokeratosis verruciformis

Acrokeratosis verruciformis of Hopf [1] is characterized by multiple flesh-coloured or lightly pigmented papules on the dorsa of the hands and feet and other sites. Its existence as an independent entity has been debated [2–4] and recent genetic data suggest that it is allelic with Darier's disease [5].

Aetiology. The lesions are typical of acral lesions in Darier's disease, but may occur as an isolated autosomal dominant trait. Causative mutations in *ATP2A2*, the gene implicated in Darier's disease, have been found in a pedigree of acrokeratosis verruciformis, but the occurrence of

similar lesions in other conditions (see below) suggests that there could be multiple causes.

Pathology. Hyperkeratosis, acanthosis and a prominent granular layer may be accompanied by papillomatosis and discrete pointed epidermal upgrowths said to resemble church spires. It has been claimed that the absence of suprabasal clefts distinguishes this entity from Darier's disease [2], but in practice lesions from the latter do not show always show clefting [4].

Clinical features. Flat or convex skin-coloured warty papules are present on the dorsa of the hands and feet, on the knees and elbows, and on the forearms [6]. Small groups or isolated papules may develop in other sites. Friction of the lesions may cause blister formation. The eruption affects both sexes and is usually present at birth or appears in early childhood; however, the onset may be delayed until the fifth decade [7]. Transformation to squamous cell carcinoma has been reported [2,8]. Nail or palmar lesions may suggest the diagnosis of Darier's disease, even in the absence of the rash [5,6]. In addition to Darier's disease, cases have been recorded in association with Hailey–Hailey disease [9], naevoid basal cell carcinoma syndrome [10], congenital poikiloderma [11], and steatocystoma multiplex and hypertrophic lichen planus [12]. The condition resembles extensive plane warts. In more severe cases, epidermodysplasia verruciformis can be differentiated by histopathology and virological studies (see Chapter 25).

Treatment. Systemic treatment of isolated acrokeratoses is not usually justified, but oral retinoid treatment failed in one case [13].

Other focal disorders

Perforating keratotic disorders [1]

The nature and number of perforating (epidermal elimination) disorders is uncertain. They present as keratotic papules, but epidermal involvement may be secondary to dermal disease. A case has been made for unifying some or all disorders because, with the exception of elastosis perforans serpiginosa, all have been reported in association with diabetes mellitus or renal failure [2]. The term acquired perforating dermatosis has been proposed.

Kyrle's disease (hyperkeratosis follicularis et parafollicularis in cutem penetrans). Keratinous 1-cm nodules are seen mainly on the limbs (Fig. 34.42). Kyrle's case was a young diabetic female in whom keratotic nodules appeared around the axillae and later became generalized [3].

Acquired perforating dermatosis. This may be synonymous with Kyrle's disease [4–6], and is most often seen with diabetes or before, during or after dialysis for renal failure [7]. Eleven per cent of 72 British patients on renal dialysis developed a perforating dermatosis [8]. Trauma from scratching is thought to initiate the lesions. Histology shows follicular and non-follicular lesions with broad or narrow ulcer craters, and evidence of perforation of both collagen and elastic fibres. Degenerate collagen, elastic tissue and keratin are seen mixed with an unidentified

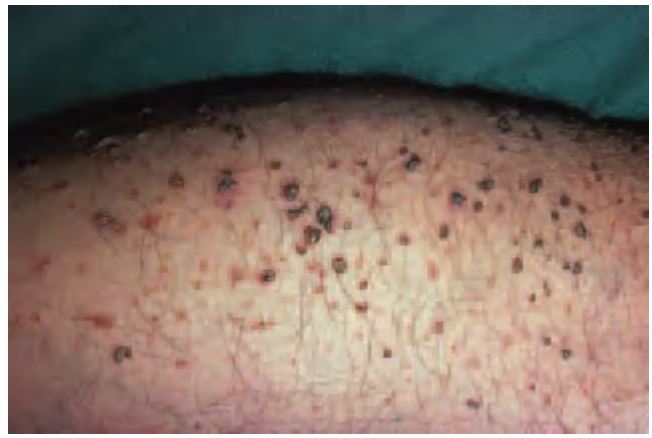

Fig. 34.42 Kyrle's disease: large keratinous plugs on the thigh.

Fig. 34.43 Flegel's disease: polygonal keratotic lesions on legs.

clear material, which has been regarded by some as an accumulation of a metabolite [2]. Lucke *et al*. [9] reported two cases of a disorder characterized by transepidermal elimination of negatively birefringent needle-shaped crystals similar to monosodium urate. In most cases of acquired perforating dermatosis, lesions could be cleared by treatment with potent topical or intralesional steroids. Topical tretinoin was also helpful in reducing the lesions. Successful use of allopurinol has been reported [10].

Flegel's disease (hyperkeratosis lenticularis perstans). This is inherited as an autosomal dominant condition (MIM 144150). Lesions differ markedly from Kyrle's disease [11]. In the third or fourth decade, 2–3 mm keratotic papules with discrete irregular margins ('cornflake sign', Rowland–Payne) appear over the calves and extensor surfaces of the ankles (Fig. 34.43). Lesions may spread to the arms and the concha of the ears. The keratotic scale separates from many lesions, leaving a non-exudative red base. Irritation may be severe. Histologically, there is hyperkeratosis, sometimes with foci of parakeratosis. The underlying epidermis alternates between atrophy and acanthosis, and there is a dermal infiltrate of mononuclear cells [11,12]. Despite the strong genetic component in the disorder, no reports identifying a candidate gene have appeared to date. The profusion of lesions and poor response to cryotherapy, topical and systemic retinoids, and to 5-fluorouracil make management difficult.

Reactive perforating collagenosis (see Chapter 46). This affects children, with the formation of 2–5-mm papules, usually on the limbs. Lesions in all stages of eruption and resolution are present at one time [13].

Perforating folliculitis. This affects the limbs of young adults with erythematous follicular papules, 2–8 mm diameter, which are usually asymptomatic. Histologically, a plug of keratin disrupts the infundibular portion of the follicular epithelium [14].

Elastosis perforans serpiginosa (see Chapter 46). This presents as grouped arcuate or serpiginous keratotic papules and is associated with Down's syndrome, disorders of connective tissue and penicillamine treatment. Histologically, amorphous masses that bind elastic tissue stains can be seen traversing the epidermis.

Porokeratosis

Porokeratoses are characterized by marginate scaling lesions, histologically showing a column of parakeratotic keratinocytes (the coronoid lamella). Various forms are recognized, but terminology and classification are debated [1,2]. Some forms appear to be premalignant [3].

Aetiology. Loci at chromosomes 12q23.2–24.1 and 15q25.1–26.1 have been reported in familial disseminated superficial (actinic) porokeratoses (MIM 175900) [4,5]. The latter

locus includes a candidate gene, basonuclin [5]. The centrifugal progress of individual lesions is thought to reflect the migration of a clone of abnormal cells [6]. There is keratinocyte dysplasia and Otsuka *et al*. [7,8] have reported aneuploidy and chromosomal abnormalities in lesional keratinocytes. The tumour suppressor protein p53 is over-expressed in the coronoid lamella [9–11]. Cytogenetic anomalies in fibroblasts, particularly chromosome 3, are also recorded [12]. An association with immunosuppression [1] suggests impaired immunity is permissive, perhaps by reduced immune surveillance of dysplasia, but the possibility of an infective aetiology [13] remains.

Pathology [14]. Lesions may or may not involve the eccrine sweat duct. The characteristic histopathology is seen in the edge of the lesion. The stratum corneum is hyperkeratotic, and at the raised border a column of poorly staining parakeratotic stratum corneum cells, the cornoid lamella, is seen running through the surrounding normal-staining cells. The underlying keratinocytes are oedematous with spongiosis, shrunken nuclei and a moderate dermal lymphocytic infiltrate under the lamella [14]; a lichenoid reaction pattern may be present. The central area of a lesion is usually atrophic, but may occasionally show gross hyperkeratosis [15]. Cornoid lamellae may also be found in other conditions, such as viral warts, some ichthyoses and naevoid hyperkeratoses.

Clinical features

Disseminated forms. Clinical distinction between the various forms of disseminated porokeratosis may not be justified [16]. *Disseminated superficial actinic porokeratosis* (DSAP) is the most common presentation, with very many lesions of up to 10 mm predominantly in sun-exposed sites in middle-aged individuals, especially those with sun-sensitive skin (Fig. 34.44). They are easily mistaken for actinic keratoses, with which they may coexist. Lesions were not induced by artificial light exposure [17], but have been provoked by photochemotherapy [18]. No evidence that skin cancer arises in the porokeratotic lesions was found in one study of 29 patients [19]. *Disseminated superficial porokeratoses of immunosuppression* are recognized after renal, hepatic, cardiac and bone marrow transplantation, and in AIDS [1]. The distribution is similar to DSAP, but a history of sun exposure is less likely [20]. *Disseminated superficial porokeratosis of childhood* may be inherited as an autosomal dominant condition, but sporadic cases are seen. Widely disseminated, flat lesions usually begin in childhood, the majority between the ages of 5 and 10 years, but may be present at birth or may first appear at puberty or later. Palmoplantar lesions may be associated (porokeratosis palmaris et plantaris disseminata) [21]. Widespread lesions appeared first at the age of 1 month in a male infant with craniosynostosis and other congenital abnormalities [22].

Fig. 34.44 Disseminated superficial actinic porokeratoses: annular keratotic lesions with a raised margin.

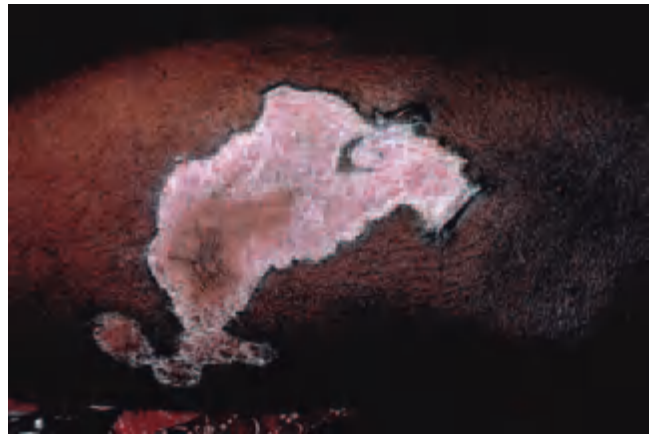

Fig. 34.45 Porokeratosis of Mibelli.

Porokeratosis of Mibelli [23,24]. The eponym Mibelli is sometimes used generically for porokeratoses, but usually refers only to the form with single or scanty and larger lesions. These develop as annular dry plaques (Fig. 34.45) surrounded by a raised, fine keratotic wall and sometimes also a furrow. Lesions are most common on the limbs and by centrifugal spread may achieve several centimeters in diameter. The centre is usually atrophic but may be hyperkeratotic [15]. The face, genitalia, oral mucosa and cornea may also be affected. The condition may be familial, inherited as an autosomal dominant with onset in childhood (MIM 175800), or sporadic and of later onset.

Giant porokeratoses (up to 20 cm in diameter with a surrounding wall of 1 cm). These are very rare [25], and are most often found on the foot. Large lesions are said to have the highest malignant potential [3,26,27].

Palmoplantar porokeratosis (of Mantoux). Parakeratotic hyperkeratosis histologically reminiscent of the cornoid lamella occurs in some punctate keratodermas, but the absence of marginate lesions distinguishes from true porokeratosis [28]. Nonetheless, annular lesions of palms and soles with a cornoid lamella are recognized [21,29].

Linear porokeratosis [27,30,31]. Linear porokeratoses showing typical cornoid lamellae and following the lines of Blaschko usually appear in childhood. These lesions probably result from a predisposition to porokeratosis in an abnormal clone of epidermal precursors. Malignant degeneration and metastasis has been reported in this variety [28,32]. Linear accentuation of disseminated actinic porokeratosis is reported [33,34].

Treatment. Treatment of disseminated superficial porokeratoses is usually unnecessary, but cryotherapy, carbon dioxide and pulsed dye laser therapy have all been used [35,36]. Keratolytics offer little relief but successful use of tacalcitol has been reported [37]. In some cases 5-fluorouracil ointment is effective [38,39]. Consistent results appear to be given by etretinate, but the symptoms may not justify treatment [40].

Minute and filiform keratoses

Clinical discrimination of multiple minute and filiform keratoses remains unsatisfactory, but a number of entities have been described [1]. Filiform palmoplantar keratoses are also recognized (see below).

Filiform keratoses. Multiple discrete fine keratotic lesions, variously described as spiked, filiform or hairy, have been reported, including familial [2] and sporadic [3], follicular and non-follicular [4], drug-associated [4,5] and myeloma-associated [6,7] cases. Filiform keratoses occur

Fig. 34.46 Digitate hyperkeratosis. (Courtesy of Dr F.A. Ive, Dryburn Hospital, Durham, UK.)

with a PRP-like eruption and acne conglobata in association with HIV infection [8].

Minute aggregate keratoses [9]. This is characterized by the truncal distribution of multiple minute keratotic papules. Morphologically, these may be spicular or dome-shaped, and aggregation of the latter may create the impression of annular and crateriform lesions. Histologically, there are focal areas of hyperkeratosis and orthokeratosis with no dermal infiltrate. Odland bodies are present on electron microscopy of lesional skin.

Multiple minute digitate hyperkeratoses (Fig. 34.46). Goldstein [10] reported a 32-year-old black patient with multiple small finger-like projections on the anterior chest and anterolateral aspects of the arms and legs. The non-follicular lesions were less than 1 mm in diameter and 1–2 mm in length. Family history was negative. Familial cases with probable autosomal dominant inheritance [11,12], or sporadic and transient [13–15] cases occur. The condition has been seen following X-irradiation [11,16]. Histologically, there are focal areas of compact orthohyperkeratosis with few dermal changes and keratohyalin granules, which were thought to be smaller than normal [12], athough Pujol found columnar parakeratosis resembling porokeratosis [16]. One case associated with carcinoma of the larynx cleared following surgery [17].

Miscellaneous circumscribed keratotic disorders

Waxy keratoses of childhood. Three children in two families were reported with a disorder consisting of generalized discrete domed keratotic papules, which were flesh-coloured or yellowish [1]; two young patients reported earlier with 'disseminated hypopigmented keratoses', appear to be identical [2]. Histological findings were marked orthokeratotic hyperkeratosis, tenting of the epidermis and mild acanthosis. Differential diagnosis includes the leukodermic macules in Darier's disease in dark skin [3].

Facial Afro-Caribbean childhood eruption. A monomorphic, mildly hyperkeratotic, papular facial eruption in black children was reported by Marten *et al*. [4] in 1976. Further cases in children were termed granulomatous perioral dermatitis [5]. Williams *et al*. [6] suggested the name and acronym FACE. The eruption shows a predilection for the perioral and periorbital regions and nose. The condition is of unknown cause, and does not appear to be a rebound phenomenon from the use of topical steroids. Histology shows peri-follicular inflammation with foci of granuloma formation. It does not respond to topical steroids, but resolution within a year without scarring was usual.

Florid cutaneous papillomatosis [7,8]. This term was used to describe the appearance of multiple acuminate keratotic papules in association with an underlying gastric adenocarcinoma. The first patient also had acanthosis

nigricans and eruptive seborrhoeic warts (Léser–Trelat sign). Worret's case also had acquired hypertrichosis lanuginosa from metastatic bronchial carcinoma.

Hyperkeratosis of the nipple [9]. Marked hypertrophy of the nipple and areola was noted in association with a T-cell lymphoma, which resolved following chemotherapy.

Knuckle pads [10,11]. These are classified with the fibromatoses (see Chapter 46). Nevertheless, it appears that the dry, rather fleshy lesions occurring over the knuckles and interphalangeal joints differ from the acanthotic grossly hyperkeratotic lesions seen in association with some keratodermas. In Morginson's series of 30 patients [10], seven showed hyperkeratosis, keratodermas and fissuring of varying degree involving the palms and soles. Confusion sometimes occurs with pachydermodactyly (see Chapter 46). Knuckle pads may be seen also in the Papillon–Léfèvre syndrome, and in epidermolytic keratoderma resulting from keratin 9 mutation [12]. The *Bart–Pumphrey syndrome* (MIM 149200) is an autosomal dominant condition associating knuckle pads, leukonychia and mixed sensorineural and conductive deafness [13].

Palmoplantar keratodermas

Classification of palmoplantar keratodermas

PPKs are a diverse group of hereditary and acquired disorders defined by excessive epidermal thickening of palms and soles. Many keratoderma syndromes are restricted to palms and soles, but other ectodermal or systemic abnormalities may be associated. Palmoplantar involvement may also be seen in generalized disorders of keratinization such as ichthyosis vulgaris, epidermolysis bullosa or EHK. Genetic defects have been identified in some inherited keratodermas (Table 34.1), but clinically homogeneous entities may have distinct molecular pathogenesis, and different mutations in one gene can give rise to distinct syndromes. Consequently, although a number of classifications of keratodermas have been published [1–7], none unite satisfactorily clinical presentation, pathology and molecular pathogenesis. Inherited keratodermas described in this chapter are outlined in Table 34.5, but many isolated reports of unusual or unique associations are necessarily excluded.

Keratodermas are often grouped by clinical pattern as diffuse, focal (areate), striate or punctate, but there are no absolute boundaries between these groupings. The presentation of a single disease may vary with site, age, gender or occupation. Plantar skin tends to be more severely or diffusely affected than palmar skin. In assessing an isolated case of keratoderma, it may be inappropriate to confine the differential diagnosis to one clinical grouping. However, the following definitions may offer some guidance. In *diffuse keratodermas*, the whole of the palmar or plantar epidermis, usually including the centripalmar skin and the instep, is abnormally but uniformly thickened. In *focal (areate or nummular) keratoderma*, the areas of palmoplantar skin under most pressure are disproportionately thickened, for example at either end of the metatarsal arch, the sides or points of the toes, or the margins of the heel. Focal lesions may be painful. *Striate keratoderma* overlaps clinically with focal keratoderma, but the lesions are conspicuously longitudinal, particularly on the fingers, where keratoderma overlies flexor tendons. *Punctate (papular or disseminated) keratoderma* consists of multiple scattered discrete round lesions, not bearing a consistent relationship to pressure points.

Transgredient keratoderma extends beyond palmoplantar skin, contiguously or as callosities on pressure points on the fingers or knuckles, or elsewhere. Confluent hyperkeratosis may extend round whole digits. *Cicatrizing keratodermas* (the term 'cicatrizing' is suggested in preference to the more emotive 'mutilating') are those in which constricting bands appear around digits, usually distal to proximal interphalangeal joints. Such constrictions ('pseudo-ainhum') are found in many severe transgredient keratodermas, and are not diagnostic of any one syndrome. *Hyperhidrosis* is also a commonly used descriptor, as many keratodermas, particularly on the feet, are spongy and malodorous. There may be a real increase in sweat excretion, or simply water retention and microbial overgrowth in abnormally keratotic and porous stratum corneum.

Table 34.5 Prinicipal hereditary palmoplantar keratodermas (fuller descriptions and references are given in the text).

Type	Eponym(s)	Inheritance (presumed)	Gene or locus	Onset (years)	Transgredient/ cicatrizing	Comments/special features
Keratodermas and ectodermal dysplasias						
Diffuse group						
Epidermolytic keratoderma	Vörner	AD	Keratin 9	0–3	N	Most common but histology needed to confirm
Diffuse non-epidermolytic keratoderma*	Thost–Unna	AD	some 12q11–q13; Keratin 1	2–5 or later	N	Likely to be heterogeneous
Loricrin keratoderma	Camisa; variant Vohwinkel	AD	Loricrin	2–5	Y	Mild ichthyosis; honeycomb pattern keratoderma
Autosomal dominant transgredient keratoderma*	Greither; Sybert	AD	some 1p	3–8	Y	Likely to be heterogeneous
Keratoderma with scleroatrophy	Huriez	AD	4q23		Y	Squamous carcinomas
Mal de Meleda		AR	*SLURP-1*	0–3	Y	Dermatophyte infection common
Autosomal recessive transgredient keratoderma*	Gamborg–Neilsen	AR	–	8–10	Y	Likely to be heterogeneous
Palmoplantar and periorificial keratoderma	Olmsted	?AR	–	0–1	Y	Periorificial and flexural erythema and hyperkeratosis
Focal or areate group						
Focal/areate/nummular keratoderma*	Wachters	AD	–			Includes painful hereditary callosities Likely to be heterogeneous
Focal keratoderma with oral leukokeratosis		AD	Keratin 16	3–5	N	Oral leukokeratosis
Pachyonychia congenita type 1	Jadassohn–Lewadowsky	AD	Keratins 6a, 16	3–5	N	Oral lesions, follicular keratoses
Pachyonychia congenita type 2	Jackson–Lawler	AD	Keratins 6b, 17	3–5	N	Natal teeth, multiple cyst, follicular keratoses
Striate keratoderma	Brunauer–Fuhs–Siemens	AD	Desmoplakin Desmoglein Keratin 1		N	
Hidrotic ectodermal dysplasia	Clouston	AD	Connexin 30		Y	Nail and hair dystrophy

Keratodermas with extracutaneous features						
Keratoderma with oesophageal carcinoma	Howel–Evans	AD	17q23		N	Focal PPK with oral lesions
Striate keratoderma, woolly hair and arrhythmogenic cardiomyopathy	Naxos disease	AR	Plakoglobin		N	
Striate keratoderma, woolly hair and dilated cardiomyopathy		AR	Desmoplakin		N	
Cicatrizing keratoderma with hearing loss	Vohwinkel	AD	Connexin 26	5–10	Y	Papular lesions becoming confluent, starfish keratoses. Mild hearing impairment
Keratoderma with prelingual deafness		AD	Connexin 26	0–5	Y	Mild diffuse PPK but profound deafness
Mitochondrial hearing loss with keratoderma		Matrilineal	*A7445G*		N	Variable mild focal PPK
Keratoderma with neuropathy*		Varies	–		N	Peripheral neuropathy; spastic paralysis
Keratoderma with periodontitis	Papillon–Léfèvre	AR	Cathepsin G		N	Severe periodontal and other pyogenic infections
Keratoderma with eyelid cysts	Schöpf–Schulz–Passarge	AR	–		N	Diffuse keratoderma, hypotrichosis, nail fragility, loss of deciduous teeth, adnexal tumours
Oculocutaneous tyrosinaemia	Richner–Hanhart	AR	Tyrosine aminotransferase		N	Corneal ulcers, painful keratoses, progressive mental impairment
Punctate group						
Punctate keratoderma*	Brauer–Buschke–Fischer	AD	–	10–40	N	Possible association with malignancy in some families
Punctate keratoderma of palmar creases		AD	–	10–40	N	Palmar creases, sometimes marginal lesions Patients usually of African origin
Acrokeratoelastoidosis	Costa	AD	–	Childhood	N	Marginal crateriform papules with elastorrhexis
Focal acral keratoderma	Dowd	AD	–	Childhood	N	Marginal crateriform papules without elastorrhexis or palmar creases
Papuloverrucous keratoderma	Touraine; Jakac–Wolf	AR	–	2–6	N	Follicular keratoses; dysplastic teeth

* These are pragmatic clinical groupings likely to encompass a variety of genetically distinct syndromes.

Diffuse keratodermas

Epidermolytic palmoplantar keratoderma (MIM 144200)

SYN. VÖRNER'S KERATODERMA

Vörner described diffuse palmoplantar keratoderma with an autosomal dominant inheritance, clinically indistinguishable from that described by Thost and Unna but with histological features of EHK in the affected palms and soles [1]. Thost's original family in fact had epidermolytic histology; indeed Vörner's is probably the most common form of diffuse keratoderma [2,3]. A prevalence of 4.4 in 100 000 was found in Northern Ireland [4].

Aetiology. Epidermolysis with tonofilament clumping suggested an intermediate filament defect, and the type I epithelial keratin 9 (K9), preferentially expressed in palmoplantar skin, was a strong candidate [5,6]. Linkage of epidermolytic PPK to the type I keratin gene cluster on chromosome 17 and causative mutations in highly conserved regions of K9 have been demonstrated, including in Vörner's original pedigree [7–11]. Most mutations are in the helix initiation peptide, but a 3-bp insertion in the helix termination motif has also been identified [12]. In a pedigree with subconfluent diffuse keratoderma and only mild epidermolysis on histology, a splice-site mutation causing insertion of 18 amino acids into the 2b rod domain of keratin 1 was identified [13]. Disruption of intermediate filament integrity consequent on these mutations is predicted to reduce the resilience of the cytoskeleton to minor external trauma, leading to blistering and hyperkeratosis. Possible autosomal recessive inheritance was reported in two children born to consanguineous parents [14].

Pathology. Histologically, Vörner's PPK shows epidermolytic change in suprabasal keratinocytes, with large tonofilament aggregates visible on electron microscopy. There are secondary changes in the expression of markers of cornified envelope formation [15]. The morphological appearance of keratin filament bundles in palmoplantar epidermis is different from other epidermis, with thicker bundles in a distinct orientation, so care must be undertaken in the assessment of filament aggregation [8]. A pedigree with EPPK resembling Vörner PPK but with an unusual ultrastructure, showing tonotubular keratin, has been reported [16].

Clinical features [1,17–19]. Diffuse keratoderma develops in infancy. In adults, there is confluent keratoderma, sparing dorsal surfaces, with a sharp demarcation and erythematous edge (Fig. 34.47). Blistering is not a major feature, but a history of blisters [19] or fissuring of the palms may hint at reduced structural strength. Hair, teeth and nails are normal, but knuckle pads and nail changes were found in Vörner's original families [1], many of whom have K9 mutations. Families with a tendency to develop internal solid tumours [20] or breast and ovarian cancer [21] probably represent coincidence.

Treatment. Response to oral retinoids is good, but excessive peeling may be a problem [22]. Topical calcipotriol has been helpful [23].

Non-epidermolytic palmoplantar keratoderma

SYN. THOST–UNNA KERATODERMA

Thost and Unna separately described keratoderma characterized by even, thick, yellow hyperkeratosis over the whole palm and sole [1,2]. The eponym refers specifically to non-epidermolytic keratoderma, although the original Thost family is now known to have epidermolytic keratoderma [3]. It is inherited as an autosomal dominant disorder but may be genetically heterogeneous.

Aetiology. Studies of a family from Bothnia in northern Sweden and three English pedigrees showed linkage centromeric to the type 2 keratin gene cluster on chromosome 12 [4–6], but the cluster itself was excluded. In another family with diffuse PPK, a mutation occurred in a highly conserved lysine residue in the V1 domain of keratin 1 [7]. This residue is thought to be important in cross-linking in the cornified envelope formation [8].

Fig. 34.48 Thost–Unna keratoderma: even yellow hyperkeratosis of sole with red border.

Pathology. The histological changes are non-specific: orthokeratotic hyperkeratosis, hypergranulosis or normogranulosis and moderate acanthosis [2]. There is usually a mild perivascular infiltrate. A biopsy serves mainly to exclude epidermolytic keratoderma. Although vesiculation secondary to dermatophyte infection may be a confounding factor, the large Bothnian pedigree of diffuse PPK showed no evidence of true epidermolysis in 91 biopsies [9].

Clinical features [10,11]. The condition may present in the first few months of life and is usually obvious by the age of 4 years. It rarely appears in the third decade. An even, very thick, yellow hyperkeratosis occurs over the whole of the foot, starting on the heel and anterior arch, spreading later to the palms (Fig. 34.48). There is a sharp cut-off at the wrist, and no tendency to spread to the extensor surfaces. The margins show a livid red border, which can be seen also to underly the hyperkeratosis. Hyperhidrosis is usual, and dermatophyte infections and pitted keratolysis are frequent. The nails are usually normal, but may be thickened without evidence of dystrophy. Hair and teeth are normal.

Treatment. Keratolytic therapy, such as 6% salicylic acid in white soft paraffin, or a gel of 6% salicylic acid in 70% propylene glycol may be used. Occlusion with polythene for a few nights enhanced the efficacy of these preparations. Benzoic acid compound ointment is mildly keratolytic, and is useful in reducing fungal and bacterial overgrowth. Topical retinoids have little effect. Acitretin may be effective for patients with marked functional impairment, but response is unpredictable and in some

patients the loss of the thick keratin leaves the foot markedly hypersensitive.

Transgredient keratodermas

Loricrin keratoderma (MIM 604117)

SYN. VARIANT VOHWINKEL'S SYNDROME; MUTILATING KERATODERMA WITH ICHTHYOSIS; CAMISA'S SYNDROME

In two related pedigrees, Camisa and Rossana delineated a diffuse transgredient honeycomb keratoderma with annular constrictions around digits, accompanied by a mild ichthyosis (Fig. 34.49) [1–3]. In true Vohwinkel's syndrome, there is impaired hearing but no generalized ichthyosis [4].

Aetiology. The disorder is caused by mutations in the gene encoding loricrin, a glycine-rich cornified envelope protein [3–6]. Several different single nucleotide insertions have been identified in this gene, but all shift the reading frame and lead to expression of an abnormal protein with a foreign, arginine-rich C-terminal peptide containing nuclear recognition signals [4]. The mutant protein is transported to the nucleus, where it can be identified from the upper spinous layer upwards, and is thought to interfere with regulation of cornification

Fig. 34.49 Loricrin keratoderma.

[7]. In one Japanese father and son, a loricrin mutation analogous to that producing human disease produced a phenotype resembling progressive symmetrical erythrokeratoderma [8]. Transgenic mice in whom loricrin has been knocked out are largely asymptomatic [9], but mice expressing a pathogenic loricrin mutation showed generalized scaling, thickened footpads and a constricting band causing autoamputation of the tail [10,11].

Pathology. A particular feature is the presence of retained nuclei in the thickened stratum corneum [1]. Immunoelectron microscopy shows the presence of loricrin in these nuclei [3,4]. Camisa noted elevated serum levels of the lysosomal enzyme β-glucuronidase [2].

Clinical features [1–6]. Generalized desquamation may be noted at birth, and a collodion baby has been reported [6]. However, the ichthyosis is generally mild and may pass unnoticed. A rugose keratoderma develops during childhood, gradually extending to confluence, with a 'honeycomb' pattern. The edges of the keratoderma are diffuse (in contrast to true Vohwinkel's syndrome) and cicatricial bands (pseudo-ainhum) may develop around digits. Knuckle pads and warty keratoses have been reported, but are not a prominent feature. There are no consistent extracutaneous features.

Treatment. The successful use of isotretinoin has been reported [1].

Autosomal dominant transgredient keratoderma

SYN. GREITHER'S SYNDROME; PALMOPLANTAR KERATODERMA TRANSGREDIENS ET PROGREDIENS

Transgredient autosomal dominant keratodermas are distinguished by involvement of the extensor surfaces of hands, knees and elbows, including the Achilles tendon. Greither described a syndrome with gradual onset and a tendency to improve in the fifth decade [1], but cases reported under this eponym are likely to be genetically heterogeneous [2]. There is clinical overlap with erythrokeratoderma [3]. One pedigree mapped to chromosome 1p [4], but this was not confirmed in another family [5].

Pathology. In Greither's syndrome, the changes on light microscopy are non-specific, with orthohyperkeratosis and absence of granular cell degeneration. Immunohistochemical staining with the marker Ki-67 showed pronounced proliferation of keratinocytes [6]. Beylot-Barry *et al*. [7] found numerous desmosomes and abnormal imbricated cell–cell junctions on electron microscopy.

Clinical features. Onset of Greither's syndrome is at 8–10 years old, and it may improve with age. There is diffuse but transgredient hyperkeratosis with patchy lesions of knees and elbows. Erythema at the margins and hyperhidrosis may be present. Some patients experience Raynaud-like vasomotor disturbances.

Sybert's keratoderma. A more severe transgredient keratoderma reported by Sybert *et al*. [8] resembled mal de Meleda but had dominant inheritance. Onset was earlier than in Greither's. Glove and stocking hyperkeratosis, including autoamputation of toes, extended also to the elbows, knees, posterior aspects of the forearms, shins, groins and natal cleft. Histologically, excessive accumulation of lipid-laden cells was seen in stratum corneum. Electron microscopy showed keratohyalin granules that were abnormal in distribution and structure. Abnormal filaggrin staining suggested that the association of filaggrin and keratin filaments in the stratum corneum was disturbed. Isotretinoin was used with benefit.

Other transgredient keratodermas. Magro *et al*. [9] reported several cases with a milder phenotype clinically resembling that of Sybert, but characterized ultrastructurally by perinuclear accumulations of ribosomes and abnormal keratohyaline granules. In one case, a father and child were affected. The histological features were felt to resemble IH of the Curth–Macklin type. Sprecher *et al*. [10] described an African American family with a more severe, dominant disorder of keratinization diagnosed as Curth–Macklin IH. The main feature was a gross palmoplantar hyperkeratosis, with cobbled papular hyperkeratoses mainly over extensor surfaces. Ultrastructural studies showed retraction of the cytoskeleton to the nucleus and failure of loricrin transport to the cell membrane. They identified a causative frameshift mutation in the V2 domain of Keratin 1 [10]. Linkage to keratin gene clusters has been excluded in another family with IH Curth–Macklin [11].

Keratoderma with scleroatrophy (MIM 181600)

SYN. HURIEZ SYNDROME

This rare autosomal dominant transgredient keratoderma, first reported in three Franco-Belgian families, is

characterized by scleroatrophy of the fingers and a high frequency of squamous carcinomas in affected skin [1–4].

Aetiology. The causative gene maps to chromosome 4q23, but has not been identified [5]. Excision repair of UV damage to lymphocytes was normal [6].

Pathology [6]. Acanthosis, an accentuated granular layer and orthohyperkeratosis were seen in keratodermatous skin. There was no dermal infiltrate, and connective tissue was normal. On electron microscopy, the dermal–epidermal junctions and desmosomes were normal, but dense bundles of tonofilaments were seen in all epidermal layers. The granular layer showed large, coarse, clumped keratohyalin. In the scleroatrophic area, similar changes were seen, with the addition of thinning of the elastic fibres, which on electron microscopy had irregular borders and looked non-homogeneous. There is a reduction in Langerhans' cells in affected palmar epidermis [3,7].

Clinical features [1–4,6,7]. Palms are more often affected than the soles, the keratoderma lacks an underlying erythema, and dermatoglyphics are often absent (Fig. 34.50a). Atrophic parchment-like skin over the dorsal surface of the hands, associated with diffuse keratoderma, is present from birth (Fig. 34.50b). Dense hyperkeratosis gives a pseudosclerodermatous appearance with nail atrophy. Nail changes include hypercurvature, longitudinal ridging, onychorrhexis and koilonychia. Squamous cell carcinomas of the affected skin developed in six cases, and internal malignancy was the cause of death in six out of 33 deaths in the original report. One of the original families was re-examined and reported in 1995 [6]. Only two of the 23 deaths in the family resulted from internal malignancy.

Other scleroatrophic keratodermas. Pujol *et al.* [8] and Vahlquist *et al.* [9] reported cases of sclerosing keratoderma associated with ichthyosis, and bizarre striate keratoses of the flexures. Inheritance appears to be autosomal recessive. A scleroatrophic keratoderma has been reported in association with sex reversal in a 46,XX subject with a male phenotype [10].

Mal de Meleda (MIM 248300)

SYN. KERATODERMA PALMOPLANTARIS TRANSGREDIENS; ACROERYTHROKERATODERMA

Mal de Meleda is a rare autosomal recessive transgredient keratoderma named after the Croatian island of Meleda (Mljet) where it was described [1,2]. It has been reported from other sites in the Mediterranean littoral; maritime dissemination is inferred.

Fig. 34.51 Mal de Meleda.

Aetiology. Mal de Meleda is caused by homozygosity for mutations in the ARS (component B) gene, encoding SLURP-1 (secreted Ly-6/uPAR related protein 1) [3–6], a member of a superfamily of secreted and receptor proteins implicated in transmembrane signal transduction, cell activation and cell adhesion, which has homologues to reptilian and amphibian toxins. The mechanism of disease remains obscure. Families from Croatia (including Meleda), Algeria and Tunisia share very few ancestral haplotypes [3,6,7], indicating founder effects. Almost all cases occur in consanguineous pedigrees.

Pathology. There is a greatly thickened corneal layer, increased stratum lucidum, with marked acanthosis, pseudospongiosis, and a prominent perivascular lymphohistiocytic infiltrate. Sweat glands are enlarged. Electron microscopy showed a less abrupt than normal transition from stratum granulosum to stratum corneum [8].

Clinical features [2,9–12]. Onset is in early childhood, and the development of hyperkeratosis is preceded by erythema. Patches of waxy ivory–yellow hyperkeratosis (Fig. 34.51) extend across the whole palms and soles, and on to the dorsal surfaces of hands and feet. Similar lesions of knees and elbows may develop. The erythematous component often persists in central palms and soles, with hyperhidrotic maceration and malodour. Fungal superinfection is common and should be excluded [10]. Circumferential hyperkeratosis of fingers may lead to sclerodactyly and digital constrictions; nail changes include hypercurvature, thickening and koilonychia [10–12]. Angular cheilitis is common. There is clinical overlap with Olmsted's syndrome, keratosis lichenoides chronica striata and progressive symmetrical erythrokeratoderma [3,12].

Treatment. Oral retinoids are effective but the hyperkeratosis may respond better than the erythema [12–16].

Other autosomal recessive transgredient keratodermas. Other pedigrees of autosomal recessive transgredient PPKs, such as the mutilating keratoderma with knuckle pads identified by Gamborg-Nielsen [17,18], are reported. Some such cases may prove to be forms of mal de Meleda, but multiple disease entities are likely and linkage to the *SLURP-1* locus, or mutations of the ARS coding sequence, have not been found in pedigrees with this phenotype [19,20]. Akiyama *et al*. [21] reported siblings with a recessive transgredient keratoderma in whom linkage excluded mutation in the epidermal differentation complex.

Congenital palmoplantar and perioral keratoderma

SYN. OLMSTED'S SYNDROME

The inheritance of this rare severe transgredient keratoderma with periorificial lesions is uncertain [1–4]. Most cases are male and sporadic, although in one case the mother was also affected [5]. The pathogenesis is unknown, but there is cytochemical evidence of hyperproliferation of the epidermis [6,7]. Onset is in the first year of life, with symmetrical, sharply defined palmar and plantar keratoderma surrounded by erythema, and flexion deformities, constriction or spontaneous amputation of the digits (Fig. 34.52a). Other abnormalities include periorificial erythema and warty hyperkeratosis (Fig. 34.52b) and linear keratoses on the flexor forearms [3,4]. Universal alopecia, nail and tooth anomalies and joint laxity and corneal dystrophy have been reported [8]. The condition can be confused with acrodermatitis enteropathica, hidrotic ectodermal dysplasia of the Clouston type, mal de Meleda and Vohwinkel's keratoderma. Etretinate has been used in several cases with variable effect [9,10]. Topical tretinoin slightly improved the keratosis but proved irritant in one case [11].

Focal keratodermas

SYN. WACHTERS' KERATODERMA; PALMOPLANTAR KERATODERMA VARIANS

Focal, areate or nummular, and linear or striate keratodermas have been distinguished. The occurrence of both areate and striate forms within a family led Wachter [1] to suggest a single entity, keratoderma varians. Although focal and striate may coexist (Fig. 34.53), several distinct disorders can now be discriminated clinically and genetically. The pattern and severity depends on both the underlying defect and environmental factors, such as the stresses on the tissue. Blisters may be a feature [2]. Striate forms are particularly but not uniquely associated with desmosomal defects (see below). Focal keratoderma may also be associated with other cutaneous or ectodermal disorders, including Dowling–Meara epidermolysis bullosa simplex, or with disease in other systems. Focal keratoderma with oesophageal carcinoma (Howel-Evans' syndrome) and keratodermas with deafness are described separately.

Painful hereditary callosities [3–5]. Plantar callosities of sufficient size are inevitably painful, and the term is probably non-specific. Painful callosities are a feature of conditions corresponding to keratoderma nummularis of Brunauer and Fuhs and keratoderma areata of Siemens, but also pachyonychia congenita and type II oculocutaneous tyrosinaemia (Richner–Hanhart syndrome).

Focal keratoderma with oral leukokeratosis (MIM 600962)

Focal non-epidermolytic keratoderma, inherited as an autosomal dominant trait, may be associated with white plaques on the sides of the tongue and buccal mucosa. This syndrome is clinically and genetically a mild variant of pachyonychia congenita; subtle associated nail changes include splinter haemorrhages and a widening of the onychocorneal band, and causative mutations in the helix initiation motif region of keratin 16 identified [1]. An isolated patient with leukoplakia and florid oral papillomatosis, and keratoderma without nail changes has been recorded [2]. Oral lesions without nail changes are also seen in Howel-Evans' syndrome [3].

Pachyonychia congenita

SYN. JADASSOHN–LEWANDOWSKY SYNDROME; JACKSON–LAWLER SYNDROME

Pachyonychia congenita (PC) is characterized by subungual hyperkeratosis of the distal nails and focal palmoplantar hyperkeratosis. A large number of associations have been reported [1], but only the simplest clinical classification into PC-1 (Jadassohn–Lewandowsky) and PC-2 (Jackson–Lawler) syndromes is borne out genetically [2].

Aetiology. Autosomal dominant inheritance is usual, but a recessive form is reported [3]. Tonofilament aggregates seen on electron microscopy suggest an intermediate filament disorder [4,5]. The distribution of lesions in PC-1 corresponds to the expression patterns of keratins K6a and K16, and causative mutations have been found in both these genes [5–8]. By contrast, K17 is constitutively expressed in the pilosebaceous unit and basal appendage keratinocytes, with lesser basal expression in palmoplantar skin and a number of other minor epithelial populations, but not in mucosae [9–11]. Point mutations in the K17 gene have been reported from many families with PC-2 [2]. Identical mutations may also present as isolated steatocystoma multiplex with or without mild nail

changes [12]. Mutations in the K6b isoform of keratin 6 also cause PC-2, suggesting this is the expression partner keratin of K17 [13]. The prominent nail involvement of pachyonychia reflects the expression of these keratins in the ventral nail [14].

Pathology. Palmoplantar epidermis shows gross hyperkeratosis with alternating ortho- and parakeratosis. Acanthosis is present with patchy hypergranulosis, in which large and misformed keratohyalin granules are present, but there is no gross epidermolysis [4]. In PC-2, the cysts may be keratinous epidermoid cysts, eruptive vellus hair cysts or true steatocysts. Different histologies may be seen within a family, an individual, or even a single cyst.

Clinical features [1,15,16]. Hyperkeratosis of the nail bed appears in the first year or two of life, followed by focal thickening of palms and soles. Late onset has been termed pachyonychia congenita tarda [17–19]. Frictional blisters may occur on the feet, especially in hot weather in childhood. In adults, focal hyperkeratosis may produce marked pain on walking. Severity varies, even within families. The mildest nail changes are similar to those seen in focal keratoderma with oral leukokeratosis, with which PC-1 is allelic.

PC-1 (Jadassohn–Lewandowsky type; MIM 167200). Thick yellow keratoses are found on sites of pressure (Fig. 34.54a), associated with wedge-like thickening of distal finger- and toenails (Fig. 34.54b), keratosis pilaris and follicular keratoses on the knees and elbows. Patchy white thickened areas are seen on the tongue and oral mucosa (oral leukokeratosis). Severe oral lesions resemble candidiasis [20]. Laryngeal involvement may produce hoarseness and in infancy even fatal respiratory obstruction [21]. Kansky *et al*. [14] have given the frequency of these changes as follows: palmoplantar keratoderma 89%, pachyonychia 69%, follicular hyperkeratosis 53%, hyperhidrosis 53%, leukokeratosis 30% and blisters 19%. Squamous carcinoma has been reported in a persistently ulcerated area [15].

PC-2 (Jackson–Lawler type; MIM 167210). Findings are similar to PC-1 but palmoplantar keratoses are possibly less severe. Despite the absence of mucosal lesions, hoarseness is a feature. Teeth are present at birth in the majority of cases [22]. Unruly hair and milia may be seen in infancy, and adults have protuberant eyebrows. Multiple epidermal cysts appearing after puberty include both epidermoid and steatocysts. Axillary cysts may mimic hidradenitis suppurativa [23]; extensive and infected vulval, scrotal or scalp cysts also cause significant disability for some patients. Within families, some patients may have only nail changes and some only cysts.

(a)

(b)

Fig. 34.54 Pachyonychia congenita: (a) keratoderma on weight-bearing areas; and (b) typical wedge-shaped nail.

Other clinical variants. For a review of reported associations of PC see Feinstein *et al*. [1], although the classification they propose has been superseded. All mutations yet found, even in previously suggested variants, correspond to either PC-1 or PC-2 phenotypes [2]. Nonetheless, thickening of the nails may occur in a variety of ectodermal dystrophies and some suggested PC variants may merit further genetic study. Involvement of the nails alone has been reported [24,25]. Heterozygous missense mutations in the connexin 30 gene, normally associated with Clouston's syndrome (see below), have been identified in a number of families with pachyonychia-like nail changes and no other phenotype [26]. Schafer and Brunauer reported corneal leukokeratosis [27]; Buckley and Cassuto [28] and Tidman *et al.* [29] flexural pigmentation and amyloid.

Treatment. Emollients and keratolytics may help kerato-

derma in milder cases. Acitretin 25–35 mg/day make the keratin more flexible and less pronounced without complete clearing [30,31], but treatment is generally unsatisfactory [4]. Retinoids produce a degree of flattening of the nails if given for prolonged periods. Surgical excision of the keratotic masses is sometimes attempted, but recurrence around the margins is frequent.

Striate keratoderma (MIM 148700)

SYN. BRUNAUER–FUHS–SIEMENS

Striate keratoderma in isolation, usually inherited as an autosomal dominant trait, can be caused by defects in at least three different genes.

Aetiology. Autosomal dominant striate keratoderma was mapped to the desmosomal cadherin cluster on 18q12.1 in a German pedigree [1]. In a Dutch family in whom linkage data favoured this locus, an N-terminal deletion mutation predicted to cause haploinsufficiency was identified in the desmoglein 1 gene [2]. Similar mutations were reported by Hunt *et al*. [3]. Earlier, Armstrong *et al*. [4] had found linkage to 6p21 in another pedigree and identified a heterozygous nonsense mutation in the desmoplakin gene. Other nonsense mutations in desmoplakin also produce the phenotype, which is again thought to result from haploinsufficiency [5]. Compound heterozygosity for nonsense and missense mutations in desmoplakin were found in two patients with keratoderma, skin fragility and woolly hair [6]. Other mutations in desmoplakin cause recessive and dominant cardiomyopathy with or without keratoderma (see p. 34.97). Striate keratoderma has also been reported in two pedigrees with frameshift mutations in the V2 tail domain of keratin 1 which may be important in cross-linking to cornified envelope proteins [7].

Pathology. In the family studied by Armstrong *et al*. [4], electron microscopy of involved skin showed abnormal bunching of keratin filaments and reduction in the peripheral keratin network, with loss of connections with desmosomes. A proportion of desmosomes were small and rudimentary and the intercellular spaces were widened. Uninvolved skin was normal.

Clinical features. As the name implies, there is a linear pattern of skin thickening on the palms and flexor aspects

of the fingers (Fig. 34.53b). However, lesions on the soles may be more areate or confluent, and striate lesions can be seen in affected members of pedigrees in which other patterns of keratoderma predominate. The presence of other features, especially woolly hair, should be specifically sought, and the possibility of cardiac disease considered.

Hidrotic ectodermal dysplasia (MIM 129500) [1]

SYN. CLOUSTON'S SYNDROME

This autosomal dominant ectodermal dysplasia, characterized by dystrophic nails and sparse hair, is described in Chapter 12 but is mentioned here because a papillomatous and fissured transgredient keratoderma is a significant feature, and because the disorder is now known to be caused by mutations in gap junction beta-6, encoding connexin 30 [2,3].

Keratodermas with extracutaneous features

Extracutaneous features in cases of hereditary keratoderma are often reported. Unusual associations with well-recognized syndromes may be coincidental, and in isolated cases it is rarely possible to establish their significance. Some associations are tabulated in Table 34.6. Readily recognizable or clinically important syndromes are described below.

Keratoderma with oesophageal carcinoma (MIM 148700)

SYN. HOWEL-EVANS' SYNDROME; TYLOSIS WITH OESOPHAGEAL CANCER

Howel-Evans described two families of autosomal dominant keratoderma associated with later development of oesophageal cancer [1]. The term tylosis has been used for this syndrome, but was originally synonymous with (diffuse) keratoderma, and should not be used to describe the syndrome without qualification. Clinical reappraisal has shown that this should be considered a focal PPK, as the lesions predominantly affect pressure points of the sole (Fig. 34.55a), and less so the palm [2,3]. There is variable oral leukokeratosis (Fig. 34.55b) and follicular prominence, but the disorder can be distinguished from PC type 1 by the absence of even mild nail changes [3]. Thirty-seven per cent of the original affected family members developed oesophageal cancer 30–40 years later. A further extensive German American family has been reported, also with an increased (38-fold) risk of oesophageal cancer [3]. In both families, the disorder maps to chromosome 17q23 [3,4], a locus named *TOCG* (for tylosis with oesophageal cancer gene). Envoplakin, a cornified envelope precursor whose gene is in this region, has been excluded by mapping [5,6]. The region is commonly deleted in oesophageal carcinomas [7], but despite sequencing of several candidates in the region, the tumour suppressor gene which this implies has not yet been identified [8].

Keratoderma, woolly hair and cardiac disease

The occurrence of congenital heart disease in patients with keratoderma has been reviewed [1]. The possibility of cardiomyopathy or conduction disorders should be particularly considered in patients with keratoderma and woolly hair. Defects in proteins of the desmosomal plaque are common to the two clearly identified genetic syndromes.

Naxos disease (MIM 601214). An autosomal recessive syndrome of arrhythmogenic right ventricular cardiomyopathy, keratoderma and woolly hair was reported in seven pedigrees from the Greek island of Naxos [2,3]. These families have been found to share a 2-bp deletion causing premature termination in the gene encoding plakoglobin [4], a cell junction protein found in association with desmosomes in the epidermis and in striated and cardiac muscle. Homozygous but not heterozygous individuals show an increased incidence of arrhythmias, cardiac failure or sudden death [5]. A similar autosomal dominant syndrome has been reported [6]. The association may be genetically heterogeneous [7].

Keratoderma, woolly hair, and dilated cardiomyopathy (Carvajal syndrome; MIM 605676). In three Equadorian pedigrees, striate keratoderma and woolly hair were associated with dilated left ventricular cardiomyopathy developing in teenage years. Histology of keratoderma showed wide intercellular spaces, clustering of desmosomes and a collapsed intermediate filament network [8]. Affected cases were all homozygous for a deletion mutation producing a premature stop codon in the tail of the desmoplakin gene [9].

Another mutation in desmoplakin, in an N-terminal domain that binds plakoglobin, causes dominant arrhythmogenic right ventricular cardiomyopathy without cutaneous phenotype [10]. Skin fragility and woolly hair resulting from compound heterozygosity for nonsense and missense mutations in desmoplakin are also reported [11].

Keratoderma and hearing impairment (MIM 148350)

The association of disordered keratinization with impaired hearing is most commonly caused by defects in genes encoding members of the connexin family of gap junction proteins [1], but mitochondrial defects may also be responsible [2].

Keratoderma and prelingual deafness. Premature termination codons in connexin 26 are the single most common cause of non-syndromic autosomal recessive deafness [1,3–5]. Connexin 26 is expressed in the cochlea where it may permit the recycling of potassium to endolymph [5]. In skin, connexin 26 is found in palmoplantar epidermis and sweat glands, and is up-regulated in conditions such as psoriasis [6,7], but patients homozygous for mutations causing non-expression of connexin 26 have no discernible cutaneous phenotype. However, in several pedigrees with diffuse or transgredient autosomal dominant keratoderma and varying degrees of prelingual deafness, missense mutations in connexin 26 have been found [8–11]. Other mutations in connexin 26 cause cicatrizing keratoderma with impaired hearing (see below) and KID syndrome [12,13]. Mutations that cause skin disease may exert a transdominant effect, disrupting gap junction communication by interfering with the function of other epidermal connexins [10].

Cicatrizing keratoderma with hearing impairment (MIM 124500)

SYN. KERATOMA HEREDITARUM MUTILANS; VOHWINKEL'S SYNDROME

Vohwinkel [1] and Wigley [2] independently reported honeycomb-like keratoderma associated with stellate keratoses on the knuckles and the formation of circumferential bands around digits ('pseudo-ainhum'). Vohwinkel's family also had moderate sensorineural deafness [3], and subsequent cases have confirmed autosomal dominant inheritance [4–7].

Aetiology. In three unrelated English, Spanish and Italian pedigrees with true Vohwinkel's syndrome, Maestrini *et al*. [8] found the same mutation, D66H, in the gap junction beta-2 gene encoding connexin 26. This mutation was also found in another English family [9]. Other mutations in the same gene cause KID syndrome or keratoderma with prelingual deafness (see above). The probable mechanism, transdominant inhibition of gap junction function, can be reproduced *in vitro* [10], but the reason for the less profound deafness but more severe cutaneous phenotype with this specific mutation is not understood.

Clinical features [1–8,11]. PPK begins in childhood as shiny or translucent papular hyperkeratosis, gradually becoming confluent on hands and feet. Striate lesions may be seen in some individuals. Warty papules on the knuckles and other extensor sites coalesce into the pathognomonic 'starfish' keratoses (Fig. 34.56a). The edge of the keratoderma at the wrists and Achilles tendon consists of spiky digitate hyperkeratotic projections onto normal skin, sometimes showing koebnerization. This contrasts with the diffuse edge seen in loricrin keratoderma [10]. Multiple keratoses on digits produce circumferential hyperkeratosis, which predisposes to the formation of cicatricial bands (Fig. 34.56b) and auto-amputation. The little finger and fifth toe are most commonly affected. A high-tone sensorineural hearing loss [6] is probably present from birth, but is relatively subtle and may escape detection in childhood unless specifically sought. It does not appear to be progressive. A reported association with craniofacial anomalies [11] proved coincidental [8].

(a)

(b)

Fig. 34.56 Cicatrizing keratoderma with deafness: (a) 'starfish' lesions; and (b) pseudo-ainhum.

Treatment. Vohwinkel's syndrome has been successfully treated by etretinate [7] and the cicatricial bands released surgically [12].

Keratoderma with hearing impairment caused by mitochondrial mutation (MIM 590080)

In a Scottish family, Reid *et al*. [1] reported familial progressive post-lingual deafness caused by specific mutation in mitochondrial DNA encoding a serine transfer RNA. The same point mutation (A7445G) was identified in a New Zealand family who also had keratoderma, and in a previously reported Japanese pedigree of keratoderma and deafness [2,3]. One of the authors (CSM) has examined members of the original Scottish family, confirming variable plantar keratoderma (Fig. 34.57). A further French pedigree of this association has been reported [4].

Keratoderma with neuropathy

Various reports associate neuropathy or spastic paralysis with keratoderma. These include striate keratoderma with spastic paraplegia, pes cavus and mental retardation in four brothers [1]; autosomal dominant punctate keratoderma and spastic paralysis [2]; autosomal dominant focal keratoderma with nail dystrophy and motor and sensory neuropathy [3], and Charcot–Marie–Tooth disease [4]. Atypical erythrokeratoderma with deafness has also been associated with peripheral neuropathy [5]. Connexin genes seem good candidates for causative mutations [6].

Keratoderma with periodontitis (MIM 245000)

SYN. PAPILLON–LÉFÈVRE SYNDROME

In this syndrome, redness and thickening of the palms and soles is associated with periodontosis and frequent pyogenic skin infections. The prevalence has been estimated as 1–4 in 1 million [1].

Aetiology. Neutrophil phagocytosis and reactivity to T- and B-cell mitogens are impaired [2–4]. Inheritance is recessive, and the condition is caused by homozygous mutations in the gene encoding the lysosomal protease cathepsin C [5]. This finding explains the predisposition to pyogenic infection, but the mechanism of keratoderma is not established.

Pathology. Histopathological changes are non-specific, but show hyperkeratosis with irregular parakeratosis and a moderate perivascular infiltrate [6]. Electron microscopic findings include lipid-like vacuoles in the corneocytes and granulocytes, reduction in tonofilaments and irregular keratohyalin granules. These changes improve during retinoid therapy [7].

(a)

(b)

Fig. 34.58 Papillon–Léfèvre syndrome: (a) loss of dentition; and (b) diffuse plantar hyperkeratosis.

Clinical features [8,9]. Periodontosis resulting in severe gingivitis (Fig. 34.58a) in children leads to the loss of deciduous teeth by the age of 4–5 years unless treated; permanent teeth may be lost in the same fashion. Transgredient palmoplantar keratoderma, preceded by erythema, appears in the first year of life (Fig. 34.58b), and spreads to dorsal surfaces and up the Achilles tendon. Psoriasiform plaques on the knees and elbows may be present, but in a survey of 47 patients cutaneous involvement was not related to the severity of periodontal disease and did not correlate with age [9]. Virulent Gram-negative organisms invade the alveolar socket, usually including *Actinobacillus actinomycetemcomitans* [10–12]. Frequent pyogenic infections of the skin and internal organs occur. Associated hyperhidrosis causes an unpleasant odour [13]. The hair is usually normal but may be sparse [14]. Dural calcification, especially in the attachment of the tentorium and choroid, has been noted in some cases.

Haim–Munk syndrome (MIM 245010). This variant syndrome combines the features of Papillon–Léfèvre syndrome with onychogryphosis, arachnodactyly and acro-osteolysis [15,16]. The syndrome is allelic with Papillon–Léfèvre syndrome, and all reported cases may be members of a single family of Cochin Jews [17]. Van Steensel *et al*. [18] reported a mother and daughter with a syndrome resembling Haim–Munk syndrome, but with hypotrichosis and an unusual linear and reticulate keratoderma, apparently not caused by mutations in cathepsin C.

Treatment. Before the advent of retinoids, dental clearance and antibiotic therapy was advised. Etretinate [14,19,20], isotretinoin [21] and acitretin [7] have all been successful in improving the keratoderma, lessening the gingival inflammation and saving the teeth.

Schöpf–Schulz–Passarge syndrome (MIM 224750)

SYN. KERATODERMA WITH EYELID CYSTS, HYPODONTIA AND HYPOTRICHOSIS

In this rare autosomal recessive syndrome, diffuse palmoplantar keratoderma is associated with hypotrichosis, nail fragility and early loss of deciduous teeth [1,2]. Hydrocystomas of the eyelids but also follicular and other adnexal tumours occur in older patients [3,4].

Oculocutaneous tyrosinaemia (MIM 276600) [1–5]

SYN. TYROSINAEMIA TYPE II; RICHNER–HANHART SYNDROME

Tyrosine aminotransferase deficiency causes palmoplantar keratoderma, dendritic corneal ulcers and progressive mental impairment.

Aetiology. This autosomal recessive condition is caused by homozygous defects of the tyrosine aminotransferase gene at 16q21.1–q22.3 [6]. Deficiency of the enzyme leads to increased levels of serum tyrosine [6–8]. Urinary reducing substances and aminoaciduria are found.

Pathology. Biopsy shows acanthosis with hyperkeratosis and hypergranulosis. At ultrastructural level, the keratinocytes contain clumped tonofilaments with adherent globoid keratohyalin granules resembling 'dew drops on a blade of grass' [9].

Clinical features (Fig. 34.59). In the first year of life, photophobia and corneal ulcers occur, and the diagnosis may be made by slit-lamp examination showing tyrosine crystals in ocular lesions [10]. Corneal lesions may be misdiagnosed as herpes simplex keratitis [11]. A year or two later, erythematous areas appear on the pressure-bearing areas of the soles, followed by painful circumscribed hyperkeratoses, making the child walk on the toes. Onset of the keratoderma may be delayed until the second decade

Fig. 34.59 Oculocutaneous tyrosinaemia (Richner–Hanhart syndrome). Callosity-like hyperkeratoses.

[12]. The keratoses vary from gross keratoderma to dry lamellar patches. Bullous lesions and hyperhidrosis are sometimes seen. Unless correctly treated, behavioural problems arise within a few years and progressively worsen, ending in inanition or death. Chitayat *et al*. [13] reported two siblings with tyrosinaemia, only one of whom showed signs of the Richner–Hanhart syndrome.

Treatment. Early institution of a diet low in phenylalanine and tyrosine causes prompt resolution of the ocular and cutaneous symptoms and prevents the development of mental disorder [4,8,14–16].

Punctate and porokeratotic keratodermas (MIM 148600)

SYN. BRAUER–BUSCHKE–FISCHER KERATODERMA

Punctate keratodermas differ from focal ones in showing a random distribution of small rounded papular lesions, but clinical differentiation is not always possible. The various terms used for morphological patterns of punctate keratoderma—keratoma dissipatum; keratoderma punctata, papulosa; disseminated clavus; papulotranslucent acrokeratoderma—probably do not justify distinction [1]. Excepting pedigrees with parakeratotic histology, the delineation of entities is uncertain.

Punctate keratoderma [1–3]. This autosomal dominant condition has a much later onset than other hereditary keratodermas, with lesions appearing in the second or third decades or later. Linkage to keratin loci has been excluded in two unrelated pedigrees of punctate keratoderma [4]. The sexes are equally affected with an incidence reported as 1.2 in 100 000 [1]. Pinpoint, hard keratotic papules, initially translucent but later opaque and warty, appear on the palms and soles (Fig. 34.60). In many families, small

Fig. 34.60 Punctate keratoderma: small even keratotic papules on the palms.

(a)

(b)

Fig. 34.61 (a) Punctate keratoderma of the palmar creases; and (b) plantar lesions in the same patient.

and large lesions coexist, including broader focal plantar callosities. Lesions are more florid in manual workers. There is no hyperhidrosis. In most cases, punctate lesions are orthokeratotic on histology. Some pedigrees show crateriform lesions or keratoses that can be picked out; histology of these lesions shows parakeratosis [5,6]. The term porokeratosis of Mantoux has been used, but the parakeratosis is columnar rather than lamellar. A linear distribution of punctate lesions is seen in porokeratotic eccrine ostial and dermal duct naevus (see Chapter 15). Multiple associations of punctate keratoderma have been described, including association with diverse Lynch type II malignancies [6–8]. Topical retinoids and calcipotriol have only a slight effect on softening the keratoses but may be tried. Results with systemic retinoids are better but variable. Etretinate 0.5–1 mg/kg/day produced good results in three patients, moderate in four and no effect in two patients [9]; acitretin was rapidly effective in another case [10].

Punctate keratoses of the palmar creases [10–13]. This is characterized by hard warty lesions of the finger and palmar creases (Fig. 34.61a), often with a clavus-like lesion at the medial border of the distal palmar crease. The absence of marginal lesions distinguishes this entity from marginal

papular acrokeratodermas. It is inherited as an autosomal dominant trait and has been reported mainly in patients of African origin. Lesions may coexist with punctate or nummular keratoderma (Fig. 34.61b) [14].

Filiform keratodermas

SYN. MUSIC BOX SPINE KERATODERMA

Fine keratotic lesions that project a millimetre or so from the palmoplantar surface are variously described as filiform, spiked, spiculate, spiny, minute digitate, minute aggregate and music box spine keratodermas. Like disseminated filiform keratoses, large morphological differences within this group probably reflect distinct aetiologies. Lesions may be inherited as an autosomal dominant trait, when they appear in the second or third decade [1]. They may be sporadic, and may involve other parts of the skin or palms and soles alone. Histology may show compact orthohyperkeratosis or parakeratosis resembling porokeratosis [2]. Attempts have been made to provide a unifying clinical classification based on histological features and distribution [3–5]. Tosti *et al*. [6] found dyskeratotic foci in the nail matrix. Hashimoto *et al*. [7] demonstrated the presence of hair-type keratin immunostaining in the lesions, suggesting that spiny keratoderma may represent ectopic hair formation. Reported associations include polycystic kidneys and liver [8], Darier's disease [3,9], epidermodysplasia verruciformis [10], renal failure [11], tuberculosis [12], hyperlipidaemia [13] and malignancy including nodular melanoma [5], carcinoma of the oesophagus [14] and lymphoproliferative disorders [15]. Profuse filiform keratoses are also associated with multiple myeloma and with HIV-associated PRP.

Treatment. Keratolytics are usually prescribed but are rarely successful. Etretinate gave variable slight improvement [10] or good results [6]. Topical 5-fluorouracil ointment cleared the lesions temporarily in one patient [2] but failed in another [8].

Marginal papular keratodermas [1,2]

The relationships between marginal papular acrokeratodermas are debated, but Rongioletti *et al*. [1] suggest a pragmatic division into the hereditary type with elastorrhexis (acrokeratoelastoidosis), or without it (focal acral hyperkeratosis), and the acquired type (degenerative collagenous plaques).

Acrokeratoelastoidosis [2–4]. Costa [3] reported 13 cases with cornified and umbilicated papules distributed along

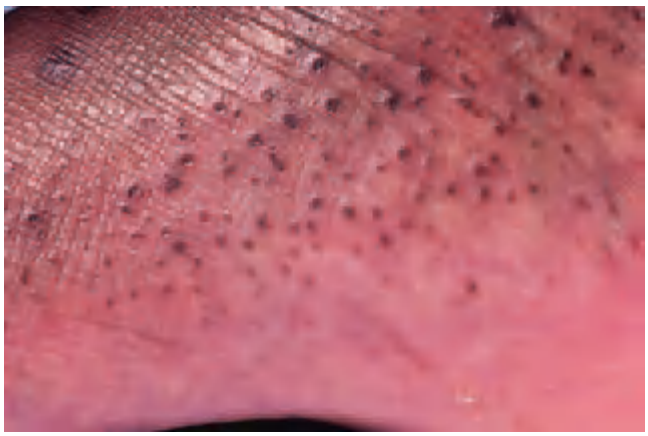

Fig. 34.62 Focal acral hyperkeratosis: crateriform punctate keratoses at the margin of the sole (Wallace's line).

the borders of the hands and feet (Fig. 34.62). He noted fragmentation and rarefaction of elastic fibres in the dermis, and introduced the term acrokeratoelastoidosis. Fiallo *et al*. [5] argued that the primary defect is in the elastic tissue.

Focal acral hyperkeratosis. Dowd *et al*. [6] reported 15 cases with oval or polygonal crateriform papules along the borders of the hands and feet but without solar damage or elastorrhexis, and termed these focal acral hyperkeratosis. However, eight of Costa's 13 patients [3] appear identical. One patient illustrated by Dowd *et al*. [6] also had marked punctate keratoses of the palmar creases, suggesting a relationship. Many patients with these disorders are of Afro-Caribbean origin, but a Filipino patient with focal acral hyperkeratosis and hearing loss has been reported [7].

Degenerative collagenous plaques [8–11]. These are firm plaques, sometimes concave, forming a linear band principally around the web of the thumb and index finger at the margin of the volar and dorsal surfaces. There is marked clinical and histological evidence of solar damage. Pathogenesis and a possible relationship with knuckle pads is discussed by Abulafia and Vignale [11].

Mosaic acral keratosis. Jacyk and Smith [12] reported African patients with widespread polygonal papular lesions over the ankles and shins under the title mosaic acral keratosis. It is not a marginal keratoderma [13] but is included here for convenience, as Costa's case 13 [3] had similar features.

Miscellaneous keratoderma syndromes

Papillomatoverrucous palmoplantar keratoderma. The association of a florid warty keratoderma, dysplastic teeth and follicular keratoses was reported by Jacak and Wolf in four siblings in one family, with a possible autosomal recessive mode of inheritance [1]. Baran and Juhlin [2] reported a similar case, which responded to etretinate.

Keratosis multiformis. Under this title, Salamon and Marinkovic [3] presented a patient with gross warty PPK, shiny atrophic skin on the dorsa of the feet and hands, follicular keratoses, punctate pigmentation around the neck, forearms and buttocks, and skeletal abnormalities. The parents were consanguineous.

Acral poikiloderma of Weary. A curious, dry, leather-grained appearance of the palms and papular keratotic lesions on the dorsa of the hands is seen in the Weary syndrome [4,5]. This condition overlaps clinically and may be allelic with Kindler's syndrome.

Acro-osteolysis with keratoderma (Bureau–Barrière syndrome) [6,7]. Marked diffuse keratoderma is associated with osteolysis in the forefoot area, polyneuropathy of the lower legs and painless ulcers of the feet. Finger clubbing is a feature of this syndrome [8–10]. Cases associated with benign symmetrical lipomatosis [11] and angiodysplasia [12] are reported.

Aquagenic syringeal acrokeratoderma. Several patients are reported in whom a subtle keratoderma is revealed by sweating or immersion [13–16]. Patients typically present with a hand immersed in water to demonstrate the signs [16]. The painful whitish papular lesions are associated with dilated acrosyringeal ostia.

Symmetrical interdigital keratoderma. This is a sporadic condition of the hands, in which thickening of the interdigital spaces occurs from the second decade. The absence of occupational or other factors and the poor response to corticosteroids or keratolytics were said to be features supporting the diagnosis [17,18].

Keratodermas and associated disorders

Many of the disorders reported in association with keratoderma in isolated cases may be fortuitous, but those that occur repeatedly may be significant. Table 34.6 lists many of them according to the systems involved.

Keratoderma and cancer

Cancers may arise in keratodermatous skin. Squamous and verrucous carcinomas are common in Huriez's syndrome [1], and isolated cases are reported in mutilating keratoderma [2], porokeratosis [3] and Clouston's syndrome [4]. Melanoma has occurred in different keratodermas [5–7]. Predisposition to internal cancer may be part of a keratoderma syndrome, of which the Howel-Evans' syndrome (see p. 34.96) is best known. A reported association between epidermolytic keratoderma caused by keratin 9 mutation and breast and ovarian cancer [8–10] is not a general feature of this syndrome. Familial punctate keratoderma has been reported with a variety of malignancies [11–13].

Acquired keratoderma may be paraneoplastic. In addition to tripe palms (see p. 34.108), and Bazex's acrokeratosis paraneoplastica (see Chapter 59), reports include acquired diffuse PPK with cancer of the bronchus [14–16], and filiform PPK with cancer of the breast, colon and kidney [17–19].

Carcinogens, of which the best documented example is arsenic, may produce both keratoderma and internal malignancy [20,21]. One survey showed that palmar keratoses occur four to five times more frequently in patients with cancer than in controls [22]. An increased incidence of keratoses in patients with lung or bladder cancer has been debated [23–25]. Smoking [23] and papillomavirus infection [24] are suggested culprits. Keratoses associated with cancer are histologically distinct from arsenical keratoses [26].

Chemotherapeutic agents used in cancer treatment commonly cause palmar erythema and may cause keratoderma [27].

Other acquired keratodermas

Callosities or more extensive thickening of plantar epidermis is a common concomitant of obesity [1], and symptomatic plantar hyperkeratosis occurs with age or orthopaedic problems.

Keratodermas caused by other dermatoses. Palmar or plantar lesions occur in a wide range of dermatoses [2]. In psoriasis, both diffuse gross and centripalmar hyperkeratosis are seen. A scalloped margin (*Festonné*), Caro–Senear lesions (depressed plaques) on the sides of the fingers and involvement of the knuckles may suggest the diagnosis. The lesions of Reiter's disease are compact, heaped up and resemble the heads of nails (keratoderma blenorrhagica). The even yellow hyperkeratosis of PRP is associated with an acute follicular eruption in adults and by lesions on the knees and elbows in children. Extensive hyperkeratotic eczema may be difficult to distinguish on clinical and histological grounds from keratoderma but marked itching may indicate eczema. Trichophytosis, especially resulting from *Trichophyton rubrum*, may be unilateral and lacking in inflammatory signs. Keratoderma may be seen in crusted scabies (Fig. 34.63). The tendency of secondary syphilis lesions to involve the palms is well known, and

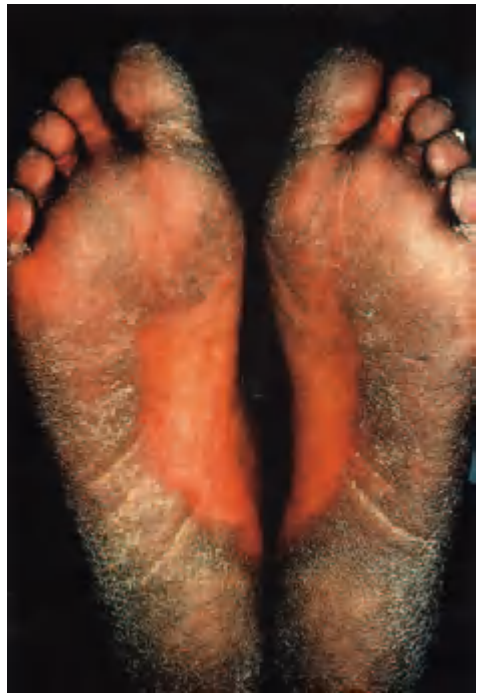

Fig. 34.64 Keratoderma produced by lupus erythematosus. (Courtesy of Dr I. Sarkany, Royal Free Hospital, London, UK.)

hyperkeratotic late syphilides may be warty or focal [3]. In late yaws, keratoderma may induce a peculiar crab-like gait in those affected. In immunocompromised patients, viral warts may be confluent on the palms or soles. Lupus erythematosus may show dry and atrophic [4], hypertrophic (Fig. 34.64) [5] or ulcerative [6] palmar lesions. In lichen planus, warty lesions may be mistaken for viral warts, and it and lichen nitidus may mimic punctate keratoderma [7]. Keratoderma may be seen as a result of hypersensitivity to drugs such as iodine. Keratoderma may result from tegafur [8], glucan [9], lithium [10] and halogenated weed-killers [11], and dioxin intoxication

[12]. Arsenicals induce irregular warty keratoses, or more even glassy lesions, still occasionally seen [13].

Keratoderma climactericum (Haxthausen's disease) [14,15]. The specificity of this syndrome described in women over the age of 45 is uncertain, as many patients are obese. Pressure areas of the heel and the forefoot are involved first (Fig. 34.65). Erythema and heavy hyperkeratosis with fissuring make walking painful. The condition slowly extends to become confluent. Later, the central palms may be affected. Symptoms may be worse in winter. Deschamps *et al*. [15] excluded endocrine dysfunction, contact dermatitis and fungal infection, and found normal serum vitamin A levels. However, Wachtel [16] described three young women in whom an identical condition arising following bilateral oophorectomy was reversed by oestrogen replacement. Laurent *et al*. [17] implicated keratinization of the acrosyringium by the finding of composite keratohyaline granules in the granular cells of the interductal granular cells, believed to serve as a marker for acrosyringeal differentiation [18]. Low-dose etretinate produces improvement in several weeks. In this age group, hypertension, cardiovascular disease or lipid abnormalities may prove contraindications. In one report, topical 0.05% oestradiol in a water-in-oil base was successful where keratolytics and emollients had failed [19].

Myxoedema. Palmoplantar hyperkeratosis with myxoedema, improving with treatment, has been reported on several occasions [20,21].

Lymphoedema and other circulatory disorders. In chronic lymphoedema, the skin overlying the lymphoedematous area first becomes diffusely thickened, and then develops a velvety papillomatous surface, which is ultimately covered by large irregular warty projections (lymphostatic verrucosis; mossy foot) [22–24]. The condition may simulate chromoblastomycosis. Lymphoedematous keratoderma occurs most characteristically in filariasis, but may develop in chronic lymphoedema of any origin. Histologically, there is hyperkeratosis, acanthosis and papillomatosis. The dermis is oedematous with dilated lymphatics, conspicuous new-vessel formation, some sclerosis and a variable infiltrate of inflammatory cells. Both the hyperkeratotic component and the lymphoedema improved in three cases given etretinate 0.6 mg/kg/day [22]. Keratoderma is also reported in association with acrocyanosis and livedo reticularis [25].

Acanthosis nigricans [1–3]

Skin affected by acanthosis nigricans is hyperpigmented, with papillomatous hyperkeratosis giving a velvety texture. Neck and flexures are most severely affected. Palms may be involved by papillomatous hypertrophy ('tripe palms').

Aetiology. Acanthosis nigricans has a variety of known causes whose common mechanism is likely to be stimulation of tyrosine kinase growth factor receptor signalling pathways in epidermis [4]. In insulin resistance syndromes, high levels of circulating insulin directly or indirectly activate the insulin-like growth factor 1 receptor (IGF1R) [5,6]. IGF1R is a transmembrane protein related to the insulin receptor, which is present in many tissues, including keratinocytes and some ovarian compartments. Specific activating mutations in fibroblast growth factor receptors (FGFRs), and tyrosine kinase receptors, are associated with acanthosis nigricans in Beare–Stevenson syndrome (FGFR2), Crouzon's syndrome with acanthosis nigricans (FGFR3) and thanatophoric dwarfism (FGFR3) [7]. Tumour-derived growth factors, in particular transforming growth factor-α acting through the epidermal growth factor receptor (EGFR), are presumed to be involved in malignant acanthosis nigricans [8–11], although anti-insulin receptor antibodies have also been implicated [12].

Pathology. Hyperkeratosis and irregular spiky papillomatosis alternating with areas of attenuation are seen [3,13].

Clinical features [1,3,13]. The essential clinical features are common to all forms of the disease, but vary in distribution and degree. In congenital forms, skin lesions may be present at birth, but usually develop during childhood or puberty. The earliest changes are usually pigmentation, dryness and roughness of the skin, which in the affected areas is grey–brown or black, palpably thickened and covered by small papillomatous elevations, which give it a velvety texture (Fig. 34.66). As the thickening increases, the skin lines are further accentuated and the surface becomes mammillated or rugose, and larger warty excrescences develop. The sites most commonly involved are the axillae, the back and sides of the neck, the anogenital region and the groins, but the other flexures, the submammary region, the umbilicus and, in some cases, almost the entire skin may be affected. The distal extremities are usually spared. Involvement of the mucous membranes is uncommon, but the oral mucous membrane may show a velvety pattern of delicate furrows [14].

Fig. 34.66 Benign acanthosis nigricans: velvety thickening with skin tags.

Inherited forms of acanthosis nigricans. Acanthosis nigricans without other abnormalities may be inherited as a Mendelian dominant trait (MIM 100600) [15,16], but acanthosis nigricans has been reported in many genetic syndromes [1]. Known causes include insulin receptor defects such as leprechaunism, Rabson–Mendenhall syndrome, lipodystrophies and other causes of hyperinsulinaemia, and activating mutations of FGFRs [4].

Benign acquired acanthosis nigricans. The term 'pseudo'-acanthosis nigricans is obsolete, as it is clear that this condition differs only in severity from other forms. As a complication of obesity, it is seen most often in adults [17,18], but also occurs in childhood [18], and is likely to become more common with increasing obesity in prosperous countries. Small patches of pigmentation and velvety thickening, often with multiple skin tags, are present in all or any body folds, especially the axillae (Fig. 34.66), groins and natal cleft. Stuart [19] examined 1412 unselected American high school children and found acanthosis nigricans in 7%, which correlated well with severe obesity. In a study of native Americans, subjects affected by acanthosis nigricans had twofold higher fasting insulin levels than weight-matched controls [18]. With weight

reduction, the skin changes may slowly regress, although the pigmentation often persists. In the tropics, the condition may occur in those who are not overweight.

HAIR–AN syndrome. The triad of *h*yper*a*ndrogenism, *i*nsulin *r*esistance and *a*canthosis *n*igricans in women is known as the HAIR–AN syndrome [2,6], and may be seen with insulin resistance of various causes. Chronic hyperinsulinism is thought to induce ovarian hyperandrogenism [6], and *in vitro* ovarian tissue from hyperinsulinaemic diabetic women responds to supraphysiological insulin concentrations by enhanced steroidogenesis [20]. The finding of pubic hair before the age of 8 years (premature adrenarche) with acanthosis nigricans was associated with insulin resistance [21].

Autoimmune acanthosis nigricans. Acanthosis nigricans disorder may occur in autoimmune disease, including systemic lupus erythematosus, caused by antibodies to the insulin receptor [2,22].

Drug-induced acanthosis nigricans. Nicotinic acid [23,24] and fusidic acid [25] have induced the cutaneous changes of acanthosis nigricans. Acanthosis nigricans has also been reported as a complication of stilboestrol therapy in young males [26] and as a complication of oral contraceptive therapy. Triazinate, which is a folic acid antagonist, has also been reported to cause acanthosis nigricans in two patients [27]. Acanthosis nigricans with insulin resistance has been reported in patients receiving treatment with protease inhibitors [28].

Malignancy-associated acanthosis nigricans. This is comparatively rare, and lesions are more severe and extensive. Pigmentation is conspicuous and is not confined to hyperkeratotic areas. Thickening of the palms is frequent and the nails may be brittle or ridged. The hair may be shed. Irritation is common and may be severe. The mucous membranes and mucocutaneous junctions are involved in at least 50% of the cases, and warty papillomatous thickening around the lips and eyes may be a presenting symptom (Fig. 34.67). The sexes are equally affected. There is usually an underlying adenocarcinoma, especially of stomach, but other tumours are sometimes found, including those of oesophagus, rectum, bronchus, urinary tract, bile duct and thyroid [1]. Acanthosis nigricans may precede other symptoms by as many as 5 years, but the interval is usually shorter. Removal of the tumour may be associated with regression of the clinical signs, but relapses are common. Rendon *et al*. [29] provide a practical algorithm for investigating these patients. Malignant acanthosis nigricans has very rarely occurred in childhood—rapidly progressing lesions and mucous membrane involvement are useful warning signs. An unusual source of diagnostic confusion is an associated hypertrophic osteo-arthropathy simulating pachydermoperiostosis.

Fig. 34.67 Malignant acanthosis nigricans: warty thickening of the oral margins in a patient with carcinoma of the breast.

Tripe palms. Velvety rugose thickening of the palms, resembling tripe (the villous lining of ruminant stomach), is almost always associated with internal malignancy [30,31]. By contrast, familial keratoderma associated with malignancy is compact and non-rugose. An elevated level of epidermal growth factor was described in a patient with tripe palms and carcinoma of the bronchus [32]. Tripe palms with malignancy may occur alone (25%) or associated with acanthosis nigricans [33].

Naevoid acanthosis nigricans [34]. This rare variety is unilateral and localized and is not associated with endocrine abnormalities.

Treatment. Treatment is of the underlying cause, or is otherwise symptomatic and of little help. Removal of the tumour in the malignant form may allow some improvement but is rarely complete. A case of hereditary benign acanthosis nigricans improved dramatically with etretinate [35].

Fig. 34.68 Confluent and reticulate papillomatosis: red–brown reticulate papules with a fine scale in the central area of the chest. (Courtesy of Professor R.J. Hay, St John's Institute of Dermatology, London, UK.)

Confluent and reticulate papillomatosis [1]

SYN. GOUGEROT–CARTEAUD SYNDROME

This syndrome of mild truncal hyperkeratosis is included here in view of its improvement with retinoids, but there is stronger evidence of an infective aetiology.

Aetiology. Most cases are sporadic, although a genetic predisposition has been proposed [2]. The hyperkeratosis may represent an abnormal response to microbial products. *Pityrosporum orbiculare* has been implicated [3], but anti-yeast therapy is unreliable. Response to several antibiotics supports a bacterial contribution [4].

Pathology. Histologically, hyperkeratosis and papillomatosis are present without acanthosis. Amyloid has been reported [5].

Clinical features [1,6]. The condition is seen predominantly in girls, beginning around puberty. Flat dry papules up to 5 mm in diameter commonly appear between the breasts and in the interscapular area. Neighbouring papules become confluent in the centre of the affected areas, but only partially so at their periphery to form an irregular network (Fig. 34.68). The lesions gradually extend over the breasts and up and down the epigastrium and back, sometimes reaching the shoulders and the sides of the neck. They cause no symptoms and little disfigurement. The age of onset and the distribution of lesions differentiate the condition from acanthosis nigricans, athough their coexistence in childhood has been noted [7]. Darier's disease and reticulate pigmentary disorders [8] (see Chapter 39) must also be considered.

Treatment. Various antibiotics may be effective [4,9,10] especially where PAS-positive materials are present in the stratum corneum [11]. Minocycline has been most used [4]. The response to antifungal agents is variable, even if yeasts are demonstrated [12,13]. Systemic or topical retinoids, or topical vitamin D analogues may also be effective [14–16].

Chapter 35

Psoriasis

C.E.M. Griffiths, R.D.R. Camp & J.N.W.N. Barker

Definition. A common, chronic, disfiguring, inflammatory and proliferative condition of the skin, in which both genetic and environmental influences have a critical role. The most characteristic lesions consist of red, scaly, sharply demarcated, indurated plaques, present particularly over extensor surfaces and scalp. The disease is enormously variable in duration, periodicity of flares and extent. Morphological variants are common.

Epidemiological aspects

Incidence and prevalence

Accurate figures concerning epidemiology and morbidity of psoriasis are difficult to obtain given that diagnostic criteria have never been validated, different methodologies have been employed and patient ascertainment techniques have varied. Nevertheless, it is clear that psoriasis is a very common disease. Most robust prevalence data comes from northern Europe and Scandinavia where studies of white people indicate population prevalence between 1.5 and 3% (Table 35.1) [1–9], although prevalence as high as 4.8% has been reported [10]. There are considerable racial variations, with most other populations having a lower prevalence of disease. In China, psoriasis is estimated to affect 0.3% of the population [7], while the disease has not been observed in Samoans [8] or Latin American Indians [9]. It appears to be more common in East than West Africa. Climate appears to affect psoriasis prevalence, with higher rates recorded in single countries at greater latitudes from the Equator [11].

Table 35.1 Worldwide studies on prevalence of psoriasis.

Place and reference	Sample size	Percentage with psoriasis
Faroes [1]	10 984	2.84
Sweden [2]	159 200	2.3

The incidence of the disease (the number of new cases occurring in a given population in a defined time) has only been accurately assessed in a single study. This indicated that 60 individuals per 100 000 per year were seeking medical care for psoriasis for the first time [12]. The study also provided support for seasonal variation, with 68% of cases first diagnosed in winter and spring months.

All figures quoted above relate primarily to psoriasis vulgaris (chronic plaque psoriasis). Estimates of disease variants are much less robust. They probably account for approximately 10% of all cases.

Age of onset

Considerable variation exists between studies in age of onset, perhaps in part reflecting the lack of strict criteria used. Lomholt [1] reported average age of onset as 12

years in his study in the Faroe Islands. In a large USA survey [5], the average age of onset was 28 years, while in the largest study reported in China, average age of onset was 36 years [7]. It has been reported that 35% of cases have disease onset before age 20 years and 58% before age 30 [8]. In a recent UK study [4] of a defined population, mean age of onset was 33 years with the mode in the second decade. Seventy-five per cent had disease onset before the age of 46 years.

However, these studies hide the fact that it appears that psoriasis has a bimodal distribution of age of onset. In a German study, two peaks were identified: the larger, early peak between 16 and 22 years and the later one at 57–60 years [13]. Several other studies including from the UK [14] broadly support this observation. Those individuals with early onset appear, in general, to have more severe disease and are much more likely to have an affected first-degree relative with psoriasis (see below) [1,5,15].

Sex effects

Males and females are equally affected by psoriasis vulgaris. Many studies indicate that age of onset is younger in females. Thus, one German study demonstrated a peak age of onset of 22 years in males and 16 years in females in early-onset disease [13]. However, results of studies are highly dependent on sampling techniques used and are variable in their results. There is no evidence that the disease is phenotypically different between the sexes.

Aetiology and pathogenesis

Genetic epidemiology

There is overwhelming evidence that psoriasis has an important genetic component. Lomholt's [1] classic epidemiological study of psoriasis in the Faroe Islands (1963), in which he examined more than 10 000 inhabitants, made the key observation that the incidence of psoriasis was much greater amongst first- and second-degree relatives of patients than unaffected control subjects.

A further large-scale study performed in Sweden supported these data, showing the prevalence of psoriasis to be 7.8% in first-degree relatives, compared with a prevalence of 3.14% in matched controls and 1.97% in the overall population [2]. Based on population data, several investigators have calculated the risk for a child to develop psoriasis. In a German study, the risk was 14% if one parent was affected, 41% if both parents affected and 6% if one sibling affected, compared to 2% when no parent or sibling was affected [3]. Henseler and Christophers [4] demonstrated that the bimodal peak in disease onset (see above) could be taken as evidence for the existence of two pathogenetically distinct forms of the disease, similar to the model for diabetes mellitus. Thus, type 1 is hereditary, strongly HLA associated (particularly HLA-Cw6), early onset and more likely to be severe. Type 2 is sporadic, HLA unrelated, of late onset and usually mild. A recent study in Iceland has confirmed many of these data [5]. However, others have suggested that the true situation is more complex [6] and certainly there are many individuals in extended family pedigrees with late-onset disease.

Support for these population studies comes from analysis of various family pedigrees in which psoriasis appears throughout multiple generations [7]. Although some authors have argued that the data are most consistent with an autosomal dominant pattern of inheritance with reduced penetrance and others that the best fit is a double recessive model, most regard the data as consistent with a polygenic or multifactorial pattern (see below). Interestingly, the development and severity of psoriasis may be influenced by the sex of the contributing parent. Thus, several studies have noted evidence for a preferential paternal effect, while one Scottish study further showed earlier age of onset when the disease was inherited from the father, consistent with 'genetic anticipation' [8].

Perhaps the most robust data supporting a genetic basis to psoriasis come from studies examining concordance for

the disease in twins. Examination of individuals from the Danish Twin Registry has shown concordance for psoriasis in 64% of monozygotic (identical) twins compared to 15% for dizygotic twins, corresponding to an estimated heritability of 91% [9]. Very similar figures (73% and 20%, respectively) were found in the retrospective study of Farber *et al.* [10] although in more recent Australian studies lower concordance rates were observed: 35% in monozygotic twins compared to 12% in dizygotic twins [11]. Of interest, when monozygotic twins are concordant for psoriasis the age of onset, distribution of the disease and severity are very similar, suggesting that genetic factors have a role in these parameters. However, it is self-evident from the data that concordance rates do not reach 100%, even when older twins are examined, indicating that the environment plays a key part in disease expression. Based on the variable extent and pattern in which it is inherited through families, it is suggested that psoriasis represents a spectrum of genetic diseases. At one end are the rare families in which changes in a single gene may be sufficient to cause the disease. At the opposite end of the spectrum is the more common form in which an obvious family history may be lacking. In these individuals, it is likely that changes in multiple genes, interacting both with each other and the environment, are required for disease expression [12].

All the above studies have concentrated upon chronic plaque psoriasis, the most common variant. Little is known of the epidemiology of other forms. Guttate psoriasis (see below) is almost invariably HLA associated [13] and thought to be closely linked pathogenetically to type 1 plaque psoriasis.

Environmental risk factors

Present evidence indicates that interactions between genes and the environment are important in disease causation. Many environmental factors have been linked to psoriasis, and have been implicated in, for example, initiation of the disease process and exacerbation of pre-existing disease. However, conclusive evidence is so far lacking.

Trauma

Psoriasis at the site of an injury is well known (Koebner phenomenon; see below). A wide range of injurious local stimuli, including physical, chemical, electrical, surgical, infective and inflammatory insults has been recognized to elicit psoriatic lesions [1].

Infection

Acute guttate psoriasis is strongly associated with preceding or concurrent streptococcal infection, particularly of the throat [2]. There is evidence that streptococcal infection may be important in chronic plaque psoriasis [3], and that treatment with rifampicin and penicillin may lead to clearance of skin lesions. Further, acute episodes of guttate psoriasis are much more common in individuals with a family history of plaque psoriasis [4] and one-third of cases of guttate psoriasis progress to the chronic plaque form [5]. Guttate and chronic plaque psoriasis share strong HLA associations, particularly with HLA-Cw6.

Human immunodeficiency virus (HIV) infection has also been associated with psoriasis (see below).

Drugs

There are many drugs reported to be responsible for the onset or exacerbation of psoriasis [6]. Chief amongst these are lithium salts, antimalarials, β-blocking agents, non-steroidal anti-inflammatory drugs (NSAIDs), angiotensin-converting enzyme (ACE) inhibitors and the withdrawal of corticosteroids. However, their risk has never been formally assessed in controlled epidemiological studies. The adverse effect of β-blockers is based on early experiences with practolol [7], although data implicating those in current usage are lacking. Likewise, the risk of withdrawal of systemic or potent topical corticosteroids requires careful re-evaluation.

Anecdotal personal experience of the authors and questioning of colleagues have suggested that β-blockers and NSAIDs have little, if any, adverse effects on psoriasis but that the effect of lithium salts or antimalarials may be severe. Patients with unstable psoriasis should receive appropriate advice before travelling to countries where antimalarial prophylaxis is required.

Fig. 35.1 Psoriasis exacerbated by sun exposure. (Courtesy of St John's Institute of Dermatology, London, UK.)

Sunlight

Although sunlight is generally beneficial, in a small minority of patients, psoriasis may be provoked by strong sunlight (Fig. 35.1) and cause summer exacerbations in exposed skin. In a questionnaire study of 2000 patients in Sweden, the prevalence of photosensitivity in psoriasis was estimated at 5.5% [8]. Approximately 40% of these patients gave a history of polymorphic light eruption (PLE) with psoriasis appearing as a secondary phenomenon with PLE lesions. The remainder of the photosensitive psoriatics slowly developed psoriasis after sun exposure with PLE. Photosensitive psoriasis was associated with skin type I, advanced age and female sex. Photochemotherapy (PUVA) can be helpful in these patients.

Metabolic factors

The early onset of psoriasis in women, with a peak around puberty, changes during pregnancy and provocation of psoriasis by high-dose oestrogen therapy potentially indicates a role for hormonal factors in the disease. A questionnaire study has provided data from 65 females who had one or more pregnancies after the diagnosis was made. Psoriasis improved in approximately 40% of pregnancies, and worsened in 14% [9]. In contrast, in the 3-month postpartum period, 11% improved and 54% deteriorated. Thus, if psoriasis changes in pregnancy, it is more likely to improve than worsen, while in the postpartum period it is more likely to deteriorate. These results have been broadly supported in more recent studies [10]. Although rare, generalized pustular psoriasis precipitated by pregnancy has repeatedly been reported [11].

Hypocalcaemia (e.g. following accidental parathyroidectomy) has been reported to occur in severe forms of psoriasis, particularly generalized pustular psoriasis [12,13] and may be a predictor of poor outcome.

Psychogenic factors

Considerable clinical evidence exists for the role of stress in onset and exacerbation of psoriasis. Seville [14] reported consistent links between major stressful life events and disease manifestation. In a recent UK study, over 60% of a sample of psoriasis patients believed stress was a principal factor in the cause of their psoriasis [15]. Gupta [16] reported that several psychocutaneous characteristics, including more exacerbations and worse disease, correlated with stress reactivity. However, not all studies have supported these observations and prospective epidemiological studies, using appropriate psychometric instruments, are required to answer these important issues.

It is without doubt, however, that psoriasis has a detrimental effect on the psychosocial quality of life of patients and that stress management programmes significantly shorten the time to clearance with standard therapies [17]. Furthermore, psoriasis in patients who are categorized as being high or pathological worriers is less likely to clear with photochemotherapy (PUVA) than in those patients with low worry [18].

Alcohol and smoking

It has long been suspected that both cigarettes and alcohol have a detrimental effect on psoriasis. Although recent large epidemiological studies are not conclusive, support for an association is observed [19]. When controlled for confounding variables, studies suggest that alcohol may exacerbate pre-existing disease but does not appear to induce psoriasis [20]. This effect seems greater in men than women. Heavy drinkers tend to have more extensive and inflamed disease [21,22]. Increased alcohol consumption is a recognized stress response. Excess drinking is undoubtedly also a consequence of the disease and leads to treatment resistance and reduced therapeutic compliance. Abstinence has been reported to induce remission [23].

In the Rochester incidence study [24], female patients at first diagnosis smoked more than a random sample of the population, in contrast to male patients who were comparable. These data were confirmed by Naldi [25] in a case–control study. In women who smoked more than 15 cigarettes/day, the odds ratio for association with psoriasis was 3.9 (men = 1.4). Most striking is the link between smoking and pustular forms of psoriasis, particularly palmoplantar pustulosis, a disease most frequently observed in females (see below). Individuals smoking more than 15 cigarettes/day had an odds ratio of 10.5 for association with palmoplantar pustulosis.

Acquired immune deficiency syndrome

The association between severe psoriasis, psoriatic arthropathy and HIV infection is well recognized [26–29]. In a study of 13 HIV-positive psoriasis patients followed over 2.5 years, psoriasis was found to flare severely or to appear *de novo* in explosive form as features of HIV infection developed. The prognosis of acquired immune deficiency syndrome (AIDS) in patients with psoriasis also appeared poor, nine out of 13 patients having died during the course of the above 2.5-year study [26]. The mechanism of worsening of psoriasis in these circumstances is unclear. Furthermore, the knowledge that psoriasis may be aggravated by AIDS, a disease in which the helper T cell is the major target, and the evidence that psoriasis may be greatly improved by ciclosporin, which inhibits helper T-cell function, create a paradox that remains to be fully explained.

Pathogenetic mechanisms

The cardinal features of lesional psoriatic skin are:
1 Epidermal hyperproliferation with loss of differentiation
2 Dilatation and proliferation of dermal blood vessels
3 Accumulation of inflammatory cells, particularly neutrophils and T lymphocytes.
A vast array of growth factors, cytokines, inflammatory mediators and other biological markers have been shown to be altered in lesional psoriatic skin. Far more contentious is whether any of these alterations persist in non-lesional skin.

Modern molecular techniques such as microarray gene profiling allow a more comprehensive analysis of transcriptional changes involved in various stages of disease progression and will provide new insights into disease pathogenesis and potentially mechanisms of drug activity [1].

Epidermal proliferation

A variety of techniques have demonstrated that the increased keratinocyte proliferation observed in psoriasis is a consequence of an increase in the proliferating cell compartment in the basal and suprabasal levels of the epidermis, and not because of shortened cell cycle time. The number of cycling cells is increased approximately sevenfold [2]. These changes are not specific for psoriasis as, for example, increased numbers of proliferating keratinocytes are also seen in wound healing and atopic dermatitis. Multiple growth factors, which experimentally have been shown to modulate keratinocyte proliferation, are present in lesional skin [3]; in particular, transforming growth factor-α (TGF-α) appears to be an important autocrine mediator of these events [4].

Vascular changes

Vertical dermal capillary loops in lesional skin are dilated, elongated and twisted. Image analysis quantification of immunostained microvessels has demonstrated a four-fold increase in endothelium of superficial but not deep microvasculature, indicating that these changes are confined to the upper plexus [5]. These vascular changes occur early in lesional development [6]. Autoradiographical and immunohistochemical studies have demonstrated proliferating endothelial cells in pustular and plaque forms of psoriasis, with a proliferation index of approximately 3% [5], indicating that vascular growth, or angiogenesis, is an important component of this process.

Using various *in vivo* models of angiogenesis, it has been demonstrated that epidermal keratinocytes are the primary source of angiogenic activity [7]. These cells produce an array of soluble mediators with angiogenic activity including interleukin-8 (IL-8), TGF-α, tumour necrosis factor-α (TNF-α), thymidine phosphorylase and endothelial cell-stimulating angiogenesis factor and, perhaps most importantly, vascular endothelial growth factor (VEGF). VEGF is overexpressed in psoriatic epidermis as are its receptors on lesional psoriatic microvasculative [8]. Transgenic mice, which overexpress VEGF in basal epidermis, have an expanded superficial dermal vasculature similar to that observed in psoriasis [9]. Interestingly, some patients with erythrodermic or severe plaque psoriasis have evidence of systemic capillary leak such as proteinuria. In such patients, circulating VEGF is detectable and correlates with proteinuria [10].

Angiopoietins 1 and 2 and their receptor Tie 2 are involved in the stabilization of blood vessels, once formed. Altered regulation of these molecules has been reported in psoriasis [11].

In addition to vascular growth, dermal capillaries contribute to the inflammatory process actively through surface expression of molecules involved in leukocyte homing, induced by inflammatory mediators such as histamine, neuropeptides, IL-1 and TNF-α. Importantly, E-selectin is induced and intercellular adhesion molecule-1 (ICAM-1) up-regulated on dermal vessels in lesional tissue, thus providing a mechanism for skin homing T lymphocytes to accumulate within lesional dermis and epidermis [12].

Molecular genetics

At least eight total or partial genome scans have been reported in psoriasis, using a variety of genetic statistical approaches [13]. Eight loci giving statistical evidence of linkage to psoriasis have been identified (Table 35.2) [14–21], and several others provide partial evidence of linkage. Given the complex nature of psoriasis pathophysiology, many potential candidate genes reside at each of these genetic loci. Genetic replication and fine mapping constitute key steps still required before gene identification becomes a reality. However, much progress has been made in gene identification at *PSORS1*, which has been consistently observed across studies [13]. This locus resides within the major histocompatibility complex (MHC) on the short arm of chromosome 6, as predicted by many HLA association studies. Genetic analysis localizes the critical interval to an approximately 200 kb region containing approximately eight known genes [22]. Three genes stand out as potential psoriasis susceptibility genes: HLA-C, HCR [23] and corneodesmosin [24].

Table 35.2 Genetic loci significantly linked to psoriasis.

Designation	Chromosomal locus	Reference
PSORS1	6p21.3	[14]
PSORS2	17q	[15]
PSORS3	4q	[16]
PSORS4	1q	[17]
PSORS5	3q	[18]
PSORS6	19q	[19]
PSORS7	1p	[20]
PSORS8	16q	[21]

PSORS, psoriasis susceptibility locus; p, chromosome short arm; q, chromosome long arm.

The putative gene at *PSORS1* is undoubtedly the major genetic determinant for psoriasis, perhaps accounting for 35–50% of the heritability of the disease. However, psoriasis is genetically complex and how *PSORS1* interacts with other genes, and potentially the environment, are important issues yet to be addressed. Recent evidence indicates that palmoplantar pustular psoriasis is genetically distinct from type 1 psoriasis vulgaris which, in turn, appears genetically identical to guttate psoriasis with respect to *PSORS1* [25].

Immunology and inflammation

There is considerable evidence that T lymphocytes have an important role in the development of plaques of psoriasis:

1 Early influx of T cells into expanding lesions [26,27]
2 Strong association with the MHC, particularly HLA-Cw6 [28]
3 Ablative (albeit temporary) effect of anti-T-cell therapy [29]
4 Increased antigen presentation in psoriatic plaques [30]
5 Anecdotal evidence of development of psoriasis after syngeneic bone marrow transplant [31]
6 Change in phenotype to lesional psoriatic skin in non-lesional psoriatic skin transplanted on to severe combined immunodeficient mice and injected with autologous T cells [32].

Those T cells involved in psoriasis pathogenesis express particular markers, including memory (CD45RO), activation (HLA-DR and CD25) and skin homing (CLA) surface receptors [33]. Th1 cytokines predominate, with a key role postulated for interferon-γ (IFN-γ) [34].

A critical immunological question is that, if T cells are fundamental to the disease process, what triggers their activation? Evidence has been presented implicating conventional antigens [35] and bacterial superantigens [36]. One hypothesis is that bacterial superantigens initiate the process, and that molecular mimicry between bacterial proteins and keratin 17 leads to activation of autoreactive T cells and thus disease persistence [37].

These postulated immunological mechanisms reflect changes in acquired immunity. It is increasingly clear that innate immune mechanisms involving neutrophils, monocytes and keratinocytes, in which there is a rapid non-specific response to a limited number of invariate features associated with pathogens, are important in psoriasis pathogenesis [38]. These concepts are supported by many parallels with Crohn's disease including the sharing of a genetic locus [39], the postulated role of bacteria in both diseases and the response to therapy targeted at TNF-α [40], a key mediator of innate immunity.

Fig. 35.2 (a,b) Psoriasis: Koebner's phenomenon. (Courtesy of St John's Institute of Dermatology, London, UK.)

Koebner and reverse Koebner phenomena [1]

Psoriasis is one of several conditions in which various types of trauma may elicit the disease in previously uninvolved skin (Koebner reaction) (Fig. 35.2) [2]. The Koebner reaction usually occurs 7–14 days after injury [3], and the reported incidence has varied between 38 and 76% of patients with psoriasis [4]. In a given patient, an all-or-none phenomenon occurs at multiple sites of injury (if psoriasis occurs at one site of injury it occurs at all sites of injury) [5,6]. Clearing of existing psoriasis following injury has been observed and termed the reverse Koebner reaction [5]. This reaction also obeys an all-or-none rule, and the Koebner and reverse Koebner reactions are mutually exclusive [5]. These observations suggest the presence of a circulating element controlling the expression of the disease throughout the skin, and lend support to the previous observation that serum from patients recovering from active psoriasis inhibits the Koebner reaction [7]. Using a standardized injury, one study found that 25% of patients gave a Koebner reaction and 67% a reverse Koebner reaction [5].

The Koebner reaction is often thought to be more frequent in actively spreading severe psoriasis. Although this may be true, it has yet to be established by prospective studies [1]. The reaction does, however, appear to be a marker for a subgroup of patients with a tendency to early onset and early relapse after various forms of therapy [8].

Histopathology

Early changes

Vasodilatation, papillary oedema and leukocyte infiltrates appear to precede epidermal changes in early developing lesions [1]. Compact hyperkeratosis, disappearance of the granular layer and slight epidermal hyperplasia follow. Mitotic figures in keratinocytes, and leukocytic infiltration in spongiotic foci, are seen in the lower half of the epidermis. Scattered mounds of parakeratosis, set in a still predominantly orthokeratotic stratum corneum, appear, with or without neutrophils. In the Malpighian layer, neutrophils may accumulate to form the characteristic spongiform pustules of Kogoj (Fig. 35.3) [2]. Epidermal hyperplasia with rete ridges of even length and prominently dilated, tortuous papillary capillaries associated with mixed mononuclear and neutrophil infiltrates are seen [1,3].

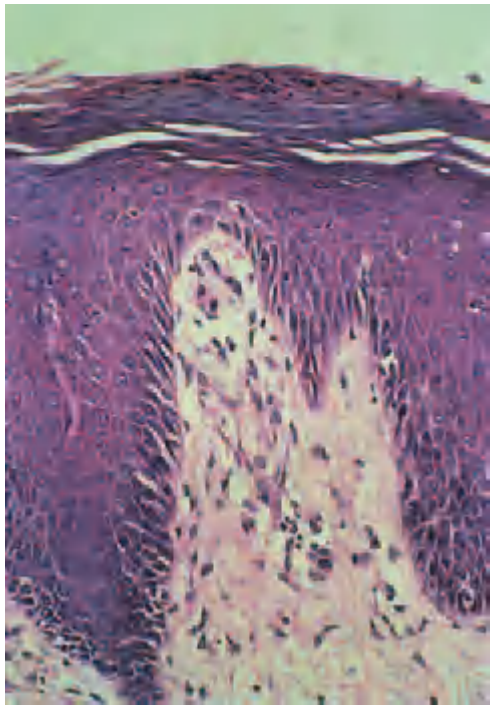

Fig. 35.4 Psoriasis: Munro microabscess formation in lesional stratum corneum. H&E, × 200. (Courtesy of St John's Institute of Dermatology, London, UK.)

Changes in fully developed plaques

There is parakeratosis associated with focal orthokeratosis and Munro microabscess formation (Fig. 35.4), near absence of the granular layer, spongiform pustules in the Malpighian layer [2], hyperplasia with elongation of rete ridges and suprapapillary epidermal thinning (Fig. 35.5). The rete ridges are often clubbed, branched or fused at their bases, with mononuclear leukocyte infiltrates in the lower half of the epidermis. Dilated, tortuous papillary blood vessels almost touch the undersurface of the thinning suprapapillary epidermis and are surrounded by a mixed mononuclear and neutrophil infiltrate, as well as extravasated erythrocytes. Invasion of the epidermis with leukocytes takes place particularly in the suprapapillary region [1,3,4].

Clinical features

Modes of onset

The first manifestation of psoriasis may occur at any age. The common ages of onset, and the tendency for females to develop psoriasis earlier than males, are described above. Its duration may vary from a few weeks to a whole lifetime. The course is unpredictable and the variations numerous. Certain patterns are, however, more common than others.

The patterns of onset in childhood, including congenital psoriasis, are discussed below [1]. Acute guttate attacks characteristically occur in this age group. Nail changes may herald the development of psoriasis elsewhere, or remain localized for several years. Most forms of psoriasis present before the fourth decade, although pustular psoriasis of the palms and soles is extremely rare before adult life.

Post-traumatic psoriasis is not uncommon in young, athletic men, who develop psoriasis initially at the site

of injury, later elsewhere. Minor lacerations of the legs during shaving are believed to precipitate psoriasis in some women. Flexural varieties make their appearance either alone or following a pre-existing intertrigo from other causes. Flexural lesions become increasingly common in obese middle-aged subjects. Psoriasis entirely limited to the groins, perineal and perianal regions may develop insidiously and often remains undiagnosed for several years.

In old age, psoriasis may appear unexpectedly for the first time, either spontaneously or following a pre-existing skin disease. Onset at the age of 108 years has been reported [2].

Morphology of common chronic stable plaque psoriasis (psoriasis vulgaris) [1,2]

The appearance of a typical lesion is characteristic (Fig. 35.6). The diagnostic features may not all be present at the same time or in every case, and are sometimes obscured or evanescent.

The colour, a full rich red (often referred to as 'salmon pink') (Fig. 35.7) has a particular depth of hue not normally seen in eczema, seborrhoeic dermatitis or lichen simplex. This quality of colour is of special diagnostic value in lesions on the palms, soles and scalp. On the legs, a bluish tint is often present, but this differs from the violaceous hue of lichen planus. In the fair-skinned individual, the colour is less rich and almost magenta pink. In dark-skinned races, the quality of the colour is lost (Fig. 35.8).

The amount of scaling is variable. It may, as in rupioid forms, be waxy yellow or orange-brown. A similar colour occurs in nails ('oil drop sign'), but most psoriatic lesions are surmounted by the very characteristic silvery white scaling, which varies considerably in thickness (Fig. 35.8). The successive removal of psoriatic scales usually reveals an underlying smooth glossy red membrane with small bleeding points where the thin suprapapillary epithelium is torn off (Auspitz's sign) (Fig. 35.9). When scaling is not evident, it may often be induced by light scratching, a useful sign in diagnostically uncertain lesions.

(a) (b)

Fig. 35.6 (a,b) Extensive chronic plaque psoriasis. (Courtesy of St John's Institute of Dermatology, London, UK.)

Fig. 35.8 Psoriasis: in the darker-skinned individual, the characteristic red colour is lost, although silvery scaling is readily seen. (Courtesy of St John's Institute of Dermatology, London, UK.)

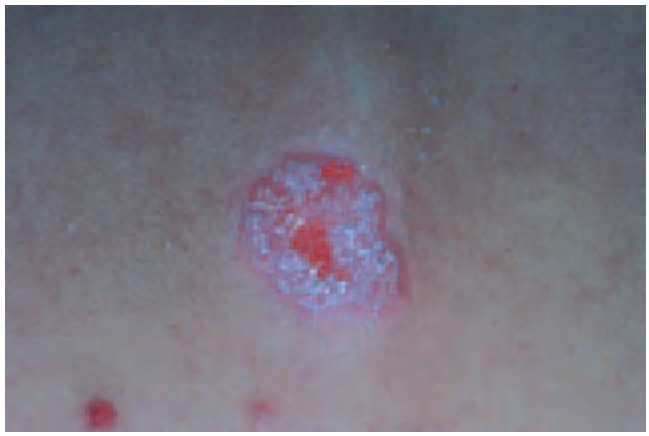

Fig. 35.9 Auspitz's sign: removal of the thinned suprapillary epidermis, by gentle scraping, reveals vascular bleeding points.

Psoriatic lesions exhibit a considerable degree of uniformity, modified little by site except on the palms and soles. The colour remains consistent, although the scaling varies in degree.

The lesions are well defined, with a sharply delineated edge. When they merge, annular and gyrate figures may be produced. This definition is of special diagnostic value on the scalp and penis, when other evidence of psoriasis is absent, and in the flexures.

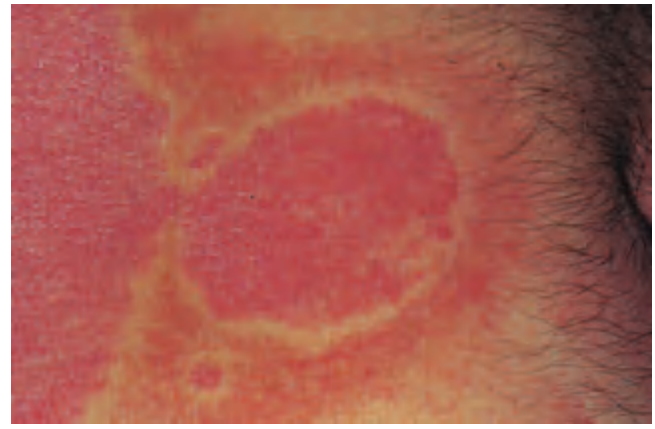

Fig. 35.10 Woronoff's ring: vasoconstriction around active plaques of psoriasis.

The epidermal thickening characteristic of the psoriatic process causes the lesions to be raised from the adjoining skin, and easily palpable. When the hyperkeratosis is removed by thorough washing or treatment, this character may sometimes be lost temporarily.

Discs and plaques of varying sizes are often found on the trunk and limbs. They vary in diameter from one to several centimetres and are oval or irregular in shape. There may be any number of lesions or only a single one and, when multiple, may be symmetrically distributed. Large plaques form by their coalescence and are commonly seen on the legs and sacral region. When plaques occur across the line of joint movement, fissuring may occur.

The psoriatic plaque may be encircled by a clear peripheral zone, the halo or ring of Woronoff (Fig. 35.10) [3].

Clinical variants

Guttate psoriasis

This describes the shower of small lesions, appearing more or less generally over the body, particularly in children and young adults, and after acute streptococcal infections (Fig. 35.11). In the early stages, there may be little scaling. The lesions are from 2 or 3 mm to 1 cm in diameter, round or slightly oval. They are scattered more or less evenly over the body, particularly on the trunk and proximal part of the limbs, rarely on the soles but not infrequently on the face, ears and scalp. The lesions on the face are often sparse, difficult to see and disappear quickly. Although guttate lesions are normally profuse, there are occasionally no more than half a dozen present on the body, and in the early stages the colour is not specific. The diagnosis is made chiefly on the nature of the scaling, the general distribution and evidence for preceding infection. In one series, only 1.9% of all affected psoriatics showed this form [2].

Fig. 35.11 Guttate psoriasis. (Courtesy of St John's Institute of Dermatology, London, UK.)

Fig. 35.12 Elephantine psoriasis: large plaques with gross hyperkeratosis. (Courtesy of St John's Institute of Dermatology, London, UK.)

Rupioid, elephantine and ostraceous psoriasis

These terms describe plaques associated with gross hyperkeratosis. Rupioid psoriasis refers to limpet-like cone-shaped lesions. The term elephantine psoriasis might be used to describe unusual but very persistent, thickly scaling, large plaques that sometimes occur on the back, limbs, hips or elsewhere (Fig. 35.12). Ostraceous psoriasis, an infrequently used term, refers to a ring-like hyperkeratotic lesion with a concave surface, resembling an oyster shell.

'Unstable' psoriasis

This term, which has no aetiological connotation, may be usefully employed to describe phases of the disease in which activity is marked and the course and immediate outcome unpredictable; for example, in stages when a previously stable and chronic form is exacerbated by inappropriate management and threatens to become erythrodermic or pustular, or when localized pustular or ill-defined erythematous lesions appear spontaneously for the first time. Patients may develop such unstable phases repeatedly, settling back again into the classical forms of the disease. Withdrawal of intensive systemic or topical corticosteroid therapy, hypocalcaemia, acute infection, overtreatment with tar, dithranol or UV irradiation, and perhaps severe emotional upset, may precipitate this condition.

Pustular psoriasis

See below.

Erythrodermic psoriasis [1–3]

Two forms exist [4]. In the first form, chronic lesions may evolve gradually into an exfoliative phase, and can be regarded as extensive plaque psoriasis involving all, or almost all, the cutaneous surface (Fig. 35.13). There are usually some areas of uninvolved skin. The psoriatic characteristics are retained, mild treatment is well-tolerated and the prognosis is good.

The second form is part of the spectrum of 'unstable' psoriasis (Fig. 35.14). It may occur at any time, either presenting suddenly and unexpectedly, or be ushered in by a period of increasing intolerance to local applications, UV therapy, and of loss of control over the disease. It is more frequent in arthropathic psoriasis [5]. Generalized pustular psoriasis may revert to an erythrodermic state. It can be precipitated by infections, hypocalcaemia, antimalarials, tar [6] and classically by withdrawal of corticosteroids [7]. The characteristics of the disease are often lost, the whole skin is involved, the patient may be febrile and ill, the course is often prolonged, relapses are frequent and there is an appreciable mortality. In contrast to the stable form, itching is often severe.

Metabolic complications of erythroderma [2]

Persistent universal inflammation of the skin may have important consequences for thermoregulation, haemody-

Fig. 35.13 Extensive chronic plaque psoriasis with coalescence of lesions and the potential to evolve into an erythrodermic form. (Courtesy of St John's Institute of Dermatology, London, UK.)

Fig. 35.14 Acute unstable erythrodermic psoriasis. (Courtesy of St John's Institute of Dermatology, London, UK.)

namics, intestinal absorption, protein, water and other metabolism.

Under normal environmental conditions, radiant and convective heat loss from the body surface is increased, occasionally leading to dangerous hypothermia [7]. An increase in metabolic activity provides compensatory increases in body heat production, but at the expense of tissue catabolism and muscle wasting if prolonged. At the same time, the psoriatic or erythrodermic skin is hypohidrotic or anhidrotic [8], because of intraepidermal occlusion of the sweat duct [9]. Hyperthermia is a hazard in very high (e.g. tropical) ambient temperatures.

Skin blood flow, blood volume and cardiac output may all be increased, and if these changes persist, they may lead to failure of a cardiovascular system already compromised by hypertension, myocardial or valvular heart disease, or anaemia (particularly in old people). A healthy cardiovascular system will tolerate the increased metabolic demand for years. Malabsorption (dermatogenic enteropathy) may occur, reverting as the psoriasis remits, but earlier reports of structural small bowel changes have not been confirmed [10].

The principal loss in the profuse scaling of exfoliative psoriasis is of protein (keratin) but some iron is also lost. In fulminating psoriasis, further protein loss may be attributable to enteropathy, as well as leakage from the circulation into the skin [11]. Eventually, hypoalbuminaemia may contribute to the oedema caused by the skin inflammation itself, or cardiac failure. Mild anaemia is prone to develop, because of a combination of iron loss and possibly impaired absorption and utilization of iron. Serum and red cell folate and serum B_{12} may also be low.

The barrier efficiency of the skin in psoriatic erythroderma is impaired, the chief effect being increased transepidermal water loss. The urine output tends to drop and, if water intake is inadequate for any reason, dehydration results.

Modification by site

Scalp

Often, very thick plaques develop, especially at the occiput. The whole scalp may be diffusely involved, or multiple discrete plaques of varying size may be seen [1]. A morphological entity consisting of plaques of asbestos-like scaling, firmly adherent to the scalp and associated hair, has been termed pityriasis (tinea) amiantacea [2] (Fig. 35.15). It is most common in children and young adults, and is best regarded as a non-specific reaction pattern, which may be seen in other scaling scalp conditions. It may be an early manifestation occurring before the other stigmata of psoriasis. Hair loss, sometimes cicatricial, is seen in pityriasis amiantacea. Otherwise, common scalp psoriasis is not a frequent cause of alopecia, although it may occur [3]. Psoriatic erythroderma is associated with severe hair loss, as is vigorous local treatment. Hair-shaft abnormalities have been described on electron microscopy [3], but the rate of hair growth is normal [4].

Penis (Fig. 35.16)

A solitary patch on the glans of the uncircumcised male lacks scales, but its colour and well-defined edge are usually distinctive. Where confirmatory signs elsewhere are absent, a diagnostic biopsy may be necessary, as it may resemble erythroplasia or Zoon's plasma cell balanitis (see Chapter 68).

Fig. 35.15 Pityriasis amiantacea in a patient with psoriasis. (Courtesy of St John's Institute of Dermatology, London, UK.)

Fig. 35.16 Psoriasis: circumcised penis. (Courtesy of St John's Institute of Dermatology, London, UK.)

Fig. 35.17 Psoriasis: vulval region. (Courtesy of St John's Institute of Dermatology, London, UK.)

Flexural (inverse) psoriasis

Psoriasis involving the groins, vulva (Fig. 35.17), axillae, submammary folds, gluteal cleft and other body folds is more common in older adults than children. The frequency with which the genital area alone is involved appears to be low, but this area is not uncommonly involved together with other areas [5].

Scaling is greatly reduced or absent, and an assured diagnosis may therefore be difficult. Flexural psoriasis may occur as a primary disorder or as a Koebner phenomenon on top of infective or seborrhoeic intertriginous

Fig. 35.18 Psoriasis of soles. (Courtesy of St John's Institute of Dermatology, London, UK.)

dermatoses. Failure to respond to antibacterial or antifungal preparations should arouse suspicion. Although the lesions are themselves anhidrotic [6], the effect of hyperhidrosis of the surrounding skin, maceration and friction alter the appearance of the psoriasis, which retains its characteristic colour. The surface has a glazed hue and fissuring at the depth of the fold is common, especially in the gluteal cleft. The edges of the lesions are usually well-defined, unless secondary infection or medicament dermatitis, both quite common events, have occurred. Psoriasis of the retro-auricular fold or the external auditory meatus may be particularly difficult to distinguish from infective or seborrhoeic dermatitis.

Hands and feet [7]

On the palms and soles (Fig. 35.18), psoriasis may present as typical scaly patches on which a fine silvery scale can be evoked by scratching; as less well-defined plaques resembling lichen simplex or hyperkeratotic eczema; or as a pustulosis. Mixed forms occasionally occur. It may often be difficult to distinguish the psoriasis from eczema, with which it may sometimes alternate. A sharply defined edge at the wrist or forearm (Fig. 35.19) and absence of vesiculation are helpful. On the dorsal surface, the knuckles frequently show a dull red thickening of the skin. Elsewhere on the hands and feet, psoriasis retains its typical

Fig. 35.19 Psoriasis of palms and fingers with sharply demarcated edge on forearms. (Courtesy of St John's Institute of Dermatology, London, UK.)

character. There may be a relationship to trauma or occupational irritants.

Nail involvement [8,9]

This is seen in association with all types of psoriasis of the skin, and is frequently present with psoriatic arthropathy [10,11]. Figures for its incidence vary considerably. Minor degrees of involvement (e.g. pitting) are difficult to define and may occur in apparently normal subjects. If looked for carefully, nail changes are present in 25–50% of all cases [12]. There is no sex predilection, but patients over 40 years of age are affected twice as often as those under 20 years. A recent study has shown that nail disease is more likely to be severe if psoriasis is early onset and familial [13].

Although pitting (Fig. 35.20) is the most frequent change seen, discolouration, subungual hyperkeratosis (Fig. 35.21) and onycholysis are common, and splinter haemorrhages occur. Longitudinal biopsy of the nail bed and matrix has clarified understanding of these changes [14,15]. Pits, ridges and grooves are a result of psoriasis of the nail matrix, whereas onycholysis, subungual hyperkeratosis and splinter haemorrhages are attributable to disease of the nail bed or hyponychium [16]. Circular areas of discolouration of the nail bed and hyponychium may resemble an 'oil drop' below the nail. Histologically, these are areas of psoriatic change in the hyponychium [14]. *Candida* species frequently contaminate the psoriatic nail and bed, but dermatophytes are rare. In one series, 19 of 105 patients with candidal paronychia were found to have psoriasis [17].

Psoriasis in children [1–4]

Psoriasis is quite common in children, although congenital psoriasis is very rare [5]. Guttate psoriasis is discussed below. Apart from the common forms, several other patterns of psoriasis occur in childhood. Interdigital tinea is uncommon in children and a toe cleft intertrigo may be psoriatic. Other flexural forms also occur (Fig. 35.17). The disease may mimic chronic blepharitis or perleche, usually unilaterally, with a small plaque of psoriasis on one eyelid extending to the lid margin, or on the cheek at the angle of the mouth. Psoriasis involving the face appears more common in children than adults [6]. In an Australian study of 1262 children with psoriasis, 26% had a psoriatic rash in the napkin area and facial involvement occurred in 38% [7]. The disease often first appears in the scalp [4], where it may present as pityriasis amiantacea (Fig. 35.15). An indolent pustular acrodermatitis, sometimes of only one digit, usually eventually proves to be psoriatic. More extensive chronic lesions of the hands and feet may occur with persistent dryness, hyperkeratosis and fissuring. Pitting of the fingernails may be the only manifestation for months or even years. Follicular psoriasis occurs on the extensor prominences of elbows and knees. A child with apparently true psoriasis in a unilateral linear distribution has been reported [8].

All the more serious forms of the disease occur in childhood but are rare. Erythrodermic psoriasis [9] may be intractable for years and may or may not become pustular. Generalized pustular psoriasis is well documented in childhood [10,11]. Arthropathic psoriasis is rare but has been reported.

Atypical forms [1,2]

In a disease as common and variable as psoriasis, atypical forms are obviously frequent. Many unusual localizations have been recorded, including digital and interdigital forms. Verrucous lesions particularly affect the legs. A follicular form, especially in children, may be confused with pityriasis rubra pilaris but this form seems to be more common in the elderly [3,4]. A lichenoid variety has been reported to involve the flexures or the extremities in a 'glove and stocking' distribution [5].

Linear and zonal lesions

Linear psoriasis may occur in the presence of other typical lesions, as part of the Koebner phenomenon. Zonal lesions may represent a Koebner reaction at a site of herpes zoster. True linear psoriasis in the absence of lesions elsewhere is extremely unusual. It may be confused with inflammatory linear verrucous epidermal naevus (ILVEN) (see Chapter 15) or may occur as a Koebner response on verrucous epidermal naevi of the non-inflammatory type [5]. True psoriasis arranged in linear bands unilaterally has also been described [6].

'Seborrhoeic psoriasis'

There is no reason why a genetically constituted psoriatic should not develop seborrhoeic dermatitis. Lesions involving the scalp, eyebrows and the region of the ears are often of this type, having features of both diseases or changing during the course of observation. Difficulties also occur in the flexures as in the 'napkin psoriasis' of infants [7] and in obese, middle-aged or elderly patients.

Mucosal lesions

True mucosal involvement by psoriasis appears to be rare, but has been associated with cutaneous involvement by pustular, erythrodermic and plaque forms [8–12]. Various lesions have been described, including grey, yellowish, white or translucent plaques or annular forms, diffuse areas of erythema and the geographic tongue [8,10,12]. The association of both psoriasis and geographic tongue (benign migratory glossitis) with HLA-Cw6 provides further evidence that the two disorders are related [13].

Ocular lesions

Blepharitis, conjunctivitis, keratitis, xerosis, synblepharon and trichiasis have been recorded. Chronic uveitis has been found, particularly in patients with psoriatic arthritis [14]. Uveitis was also reported in patients with generalized pustular psoriasis or psoriatic arthritis, who were receiving treatment with methotrexate. It was unclear whether methotrexate contributed to the ocular lesions [15].

Disease associations

Studies have reported association between psoriasis and many other diseases, both cutaneous and systemic. The most frequently described is seronegative arthritis and this is discussed elsewhere.

Henseler and Christophers [1] analysed data from more than 40 000 patients and calculated expected and observed

incidence rates of associated disorders. For many diseases, particularly heart disease, hypertension and diabetes mellitus, they were able to confirm the results of smaller earlier studies showing positive association. Of particular note was the under-representation of patients with atopic dermatitis within the psoriasis population.

Although not observed in the above study, an increased prevalence of psoriasis in patients with Crohn's disease (relative risk = 7) has been reported. Further, a family history of psoriasis (10% versus 2.9% in controls) was frequently observed in Crohn's disease patients [2,3]. These observations of altered relative risk for atopic dermatitis and Crohn's disease in psoriasis patients may be of great relevance to understanding the genetic and immunological mechanisms underlying these important conditions.

Patients with psoriasis are at an increased risk of developing malignancy, particularly non-melanoma skin cancer and lymphoproliferative cancers. The risk is greatest for those with severe disease and probably reflects those treated with systemic agents and phototherapy [4]. There is no good evidence that psoriasis, *a priori*, is associated with an increased incidence of malignancy.

Acquired autoimmune blistering diseases have been reported in association with psoriasis, particularly bullous pemphigoid [5]. Based on a small series of patients, it has been suggested that treatment of psoriasis, especially phototherapy, triggers the bullous disease. Vitiligo is a further cutaneous autoimmune disease seen more frequently in psoriasis [6].

Psoriasis has been reported rarely to occur more frequently in certain metabolic disorders including gout [7], although whether this is a true association requires formal epidemiological study. It has been suggested that gout may be precipitated by systemic antipsoriatic therapy [8]. Hypocalcaemia has been reported in association with severe and pustular forms of psoriasis, including certain syndromes [9] and following thyroidectomy [10].

Chronic recurrent multifocal osteomyelitis is an unusual sterile inflammatory entity of unknown cause, characterized by pain and swelling in affected bones. Association with pustular and non-pustular forms of psoriasis has been reported [11,12]. Closely related to this entity is the SAPHO (synovitis, acne, pustulosis, hyperostosis, osteitis) syndrome most frequently described in the radiological and rheumatological literature [13].

Complications

These are uncommon.

Infection

Secondary infection of psoriatic lesions is rarely a problem except during topical steroid therapy under occlusive dressings, when folliculitis and furunculosis are a hazard. However, staphylococci are carried by 50% of psoriatics, especially on the lesions [1]. This relative 'resistance' of psoriatic skin to infection despite the carriage of staphylococci is probably in part caused by the presence of endogenous antimicrobial peptides—cathelicidins and β-defensins—in the skin [2]. This may prove to be a problem if a surgical procedure is to be carried out through a psoriatic plaque. Because of exfoliation, these patients may disseminate infections in hospital wards. A series of postoperative deaths resulting from sepsis was caused by a psoriatic anaesthetist carrying *Staphylococcus aureus* [3]. Rarely, flexural psoriasis may become clinically infected, especially if fissuring occurs (e.g. in the natal cleft).

Itching

This is very variable in psoriasis, ranging from complete absence to severe pruritus in a minority of patients. It is more common in unstable forms. One study from Poland reported that 80% of patients complain of itching [4]. Pustular and erythrodermic patterns are more usually accompanied by sensations of burning or tightness. Often, the degree of itching reflects the emotional state of the patient and, if severe, may be a symptom of anxiety or depression.

Arthritis

See below.

Alcoholism

Heavy drinking was found significantly more commonly in male patients with severe psoriasis than in other groups with the disease, and could be a symptom of stress caused by severe skin disease [5,6].

Nephritis and renal failure

The role of streptococcal infection, especially in the throat, in provoking acute guttate psoriasis is discussed above. It is exceptionally rare for post-streptococcal guttate psoriasis to be associated with glomerulonephritis. One such case has been reported [7], as well as a case of concomitant onset of diffuse psoriasis and mesangiocapillary glomerulonephritis [8]. Renal failure brought about by acute tubular necrosis may rarely result from the oligaemia after loss of albumin into and from the skin in acute pustular psoriasis [9].

Hepatic failure

Severe abnormalities of liver function may occur in erythrodermic or pustular psoriasis, and are likely to be related to drugs, alcohol intake and oligaemia [5,6,10,11].

Apical pulmonary fibrosis

This has been established as a non-articular complication of ankylosing spondylitis, and has been reported in association with a case of psoriatic spondylitis [12]. Two further patients with chronic plaque psoriasis, one with peripheral arthropathy and one free of joint disease, have been reported with apical pulmonary fibrosis typical of that found in association with ankylosing spondylitis. Extensive investigations and follow-up observation showed no evidence of other disease [13].

Amyloidosis

Amyloidosis of the secondary type is a rare sequel of arthropathic, generalized pustular and severe non-pustular psoriasis [14–17]. It is an additional cause of renal failure in association with psoriasis, and may follow an aggressive fatal course [16].

Laboratory findings

There is no constantly present laboratory abnormality in uncomplicated psoriasis. The erythrocyte sedimentation rate (ESR) is unaffected. Modest hyperuricaemia may be found and has been attributed to enhanced epidermopoiesis. The occasional finding of low folate levels can be similarly explained [1]. The laboratory abnormalities associated with erythrodermic psoriasis and arthropathic psoriasis are described in the relevant sections. Immunoglobulins are generally normal, but selective IgA deficiency [2] and monoclonal IgG gammopathy [3] are documented in association with psoriasis.

Differential diagnosis

The characteristics already defined are usually sufficient to enable the diagnosis to be made, but doubt may arise in atypical cases, in particular sites, and when psoriasis is complicated by or alternates with other diseases. In seborrhoeic dermatitis, the lesions are lighter in colour, less well-defined and covered with a dull or branny scale. Eczema at times develops a psoriasiform appearance, especially on the legs. Hyperkeratotic eczema of the palms is a common cause of misdiagnosis. Colour, scratch-evoked scaling and well-defined margins are suggestive of psoriasis, and nail changes may be diagnostic. Lichen planus should give rise to difficulty only when the two

diseases alternate or coexist, especially when present as hypertrophic lesions on the legs, as penile lesions and on the palms. The violaceous colour, glistening surface and presence of oral changes are usually decisive. Lichen simplex can resemble psoriasis closely, particularly on the scalp and near the elbow. The intensified skin markings, rather ill-defined edge and the marked itching are characteristic, and the point of the elbow tends to be avoided. Pityriasis lichenoides chronica can closely resemble guttate psoriasis, but the lesions are usually less evenly scattered, have a brownish red or orange-brown colour and are capped by an opaque soft 'mica-like' scale. Candidiasis shows a glistening deep red colour suggestive of psoriasis, particularly in the flexures, but scaling tends to be confined to the edge, and small satellite pustules and papules are usually evident outside the main area. Tinea cruris has a well-defined, often polycyclic edge, but *Trichophyton rubrum* infections, especially of the palm, cause difficulty. If corticosteroids have been applied, scaling may be absent and the diagnosis must be made by microscopy and culture.

Less common causes of confusion are pityriasis rubra pilaris and secondary syphilis. The resemblance to pityriasis rubra pilaris may be close, especially in the erythrodermic phase. The colour is generally less distinct, and dark red follicular lesions are apparent, and the acquired palmar and plantar keratoderma has a yellow-orange tinge. The psoriasiform lesions of syphilis may cause difficulty to the inexperienced; condylomas, mucosal lesions and other signs of the disease are usually found, if sought. Porokeratosis of Mibelli on the palms and soles, patches of Bowen's and Paget's disease and penile erythroplasia may resemble psoriasis, but the lesions are usually solitary except in chronic arsenical poisoning. A biopsy may be necessary. The rare recurrent circinate erythematous type of psoriasis of Bloch and Lapiere may pose considerable diagnostic difficulties. It is to be distinguished from erythema annulare centrifugum, and from the annular migratory necrolytic erythema associated with carcinoma of the pancreas [1], and sometimes with subcorneal pustular dermatosis. The distribution, course and histology will usually be sufficiently decisive to distinguish these. Psoriasiform drug eruptions must be distinguished from psoriasis.

Parakeratosis pustulosa is an eczematoid eruption seen in young children and commonly mistaken for psoriasis, atopic dermatitis or tinea. It affects the skin around one or more fingernails or toenails, causing subungual hyperkeratosis and thickening of the free edges of the nail. Scaling is more marked than pustulation, the course is often protracted and recurrences are the rule, whatever the treatment. A large series has been reported [2]. Histology shows hyper- and parakeratosis, acanthosis, papillomatosis and a marked infiltrate around dilated capillary loops [3].

Course and prognosis [1–5]

This remains as unpredictable as it was 150 years ago. 'Psoriasis is at all times and under all forms a very troublesome and, often, an intractable disease, but it is rarely dangerous to life' [6]. 'It is impossible to say, in any particular case, how long the disease will last, whether a relapse will occur, or for what period of time the patient will remain free from psoriasis' [7]. Guttate attacks carry a better prognosis than those of a slower and more diffuse onset, and have longer remissions after treatment [3]. Few studies have assessed the long-term prognosis for first episodes of guttate psoriasis. In one study, only five (33%) of 15 patients followed up 10 years after an initial episode of guttate psoriasis had developed chronic plaque disease [8]. At the other extreme, erythrodermic and pustular forms carry an appreciable mortality and arthropathic forms a considerable morbidity. Early onset and a family history of the disease appear to worsen the prognosis [2].

Among environmental factors, sunlight and hot weather are favourable [1,2,4]; pregnancy had no effect in approximately half of patients [2,4], but improvement was more common than worsening. The influence of stress or 'worry' is more difficult to determine. Patients' beliefs on the importance of stress are probably dependent on cultural and linguistic differences. Sixty per cent of patients studied in Manchester, UK, believed that stress was an important trigger of their psoriasis [9]. In one series [10], 50% reported worsening with 'worry', in others 33–42% reported worsening [1,4]. Common experience suggests that stress is of considerable importance in some patients, but may be too easily accepted as a general cause of variations in this disease.

Complete remissions of psoriasis over 1–54 years were reported by 39% of patients in a large series [4], often without treatment. An even higher figure applied to Japan [11], but lower figures are also quoted [12].

In one follow-up study of 'napkin psoriasis', two out of 67 had developed true psoriasis in 5.4 years [13]; four developed seborrhoeic dermatitis. In another study [14], 123 infants were reviewed 5–13 years later. Of 71 who had shown psoriasiform napkin eruptions, 12 had developed psoriasis; of 40 who had a predominantly seborrhoeic pattern of flare, none had shown later signs of psoriasis but 15 (37%) had atopic eczema. Most of the psoriatic cases occurred within the first 3 months of life.

Relapse

Relapse is the rule, however completely the lesions are treated and by whatever method. Only three of 260 patients in one series [2] were clear for 5 years or more and most of the rest for only 6 months. In another series [15], only three out of 95 were clear for 5 years or more and 11.5% relapsed rapidly. A 7-year follow-up of 142 patients [3] indicated that intensive outpatient treatment gave longer remissions than those treated at home, or the presumably more severe cases admitted to hospital. Guttate lesions had the best prognosis.

There is no doubt that even severe cases can be maintained in prolonged remission by the use of methotrexate, PUVA, ciclosporin or oral retinoids.

Management

Every psoriatic patient presents an individual problem. Treatment depends upon age, sex, occupation, personality, general health, intelligence and resources, as well as the type, extent, duration and natural history of the disease. Extensive psoriasis may be ignored by the phlegmatic, yet trivial lesions on exposed areas can be ruinous for the sales executive or artiste. With this in mind, an assessment tool for psoriasis severity has been developed —the Salford Psoriasis Index—which takes into account physical extent of disease, psychosocial difficulty and previous therapy as a means of measuring difficulty in treatment [1]. Reassurance and emotional support are invaluable, stressing the non-contagious and benign nature of psoriasis, the possibility of spontaneous remission, and the availability of a wide range of therapeutic weapons for all psoriatic seasons. Fears for the future of children need to be allayed. The physician must take a long-term view. Treatment must always be appropriate to its severity and importance in that individual. It should never be more unpleasant, intolerable or dangerous than the disease itself. Its details must be commensurate with the patient's intelligence, physical capacity, time and socio-economic circumstances.

General and non-specific measures

Attention to the patient's general, physical and psychological health is always worthwhile. Mild anaemia, minor but untreated arthritis, an anxiety state or depression, especially in the elderly patient, may all critically lower the patient's tolerance of his or her disability. Physical extent of psoriasis and psychosocial disability produced by the disease do not correlate [2]. Rest, mild sedation, removal from a troublesome environment, a holiday or a short stay in hospital may all help to turn the therapeutic tide. The importance of talking to patients, trying to allay their concerns, coupled with advice on how to handle negative beliefs about their disease cannot be overestimated. A study of cognitive–behavioural therapy (CBT) as an adjunct to pharmaceutical therapies in patients with psoriasis showed a significantly greater reduction in psoriasis severity in the CBT group as compared to pharmaceutical therapy alone, both at the end of 6 weeks' intervention and 6 months later [3]. Indeed, high worry appears to have a significant detrimental effect on response to PUVA therapy and is the best predictor of outcome [4]. Harmless placebos may give comfort and should not be despised.

Diet is unimportant. Diets rich in zinc [5] and turkey meat [6] or low in tryptophan [7], protein [8] or calories [9] do not influence the disease. Spa treatment, involving rest and relaxation in an area where high sunlight exposure is possible, such as the Israeli Dead Sea coast, can undoubtedly induce remissions [10].

General approach

Most stable discoid psoriasis should first be approached with outpatient topical therapy, which disrupts the patient's routine as little as possible. Tar preparations and vitamin D analogues are appropriate, but corticosteroids can be used for localized psoriasis. If necessary, dithranol can be introduced later but is more difficult to handle. If sunlight or UVB phototherapy are available, light can be added at this stage or earlier. Special routines may be necessary for the scalp. If the psoriasis is severe and

extensive and the above initial measures have failed, more intensive tar or dithranol therapy should be considered, in a day-care unit or a hospital if such facilities exist, with or without UV phototherapy. The indications for intralesional corticosteroid injections, PUVA therapy, retinoids, cytotoxic drugs and ciclosporin are discussed in the appropriate sections below but, in general, the more hazardous measures should be restricted to those patients whose psoriasis is physically, socially, economically or emotionally disabling, and in whom conventional and conscientious topical therapy has failed. Each of the available modalities is discussed in detail below. The management of psoriatic erythroderma has been reviewed [11].

Local therapy

Tar [1,2]

Coal tar is a complex mixture of thousands of substances produced by primary condensation during the carbonization of coal [3]. Some 400 known substances comprise 55% of tar by weight [2,3]. Standardization is impossible and, because great variation in biological activity of various samples of tar has been demonstrated [4], therapeutic results achieved in different centres may not be comparable.

Tar has been used in topical therapy for more than a century. It is assumed to have an antimitotic effect but this is not proven [5]. Its use in psoriasis was popularized by Goeckerman [6] and, for more than half a century since, his regimen of daily application of 2–5% crude coal tar, combined with a tar bath and UV light, has been a mainstay of in-patient treatment [7]. In skilled hands, substantial clearing of stable discoid psoriasis can be achieved in 3–6 weeks in 80% of patients [7]. Many modifications of Goeckerman's regimen have been advocated, utilizing alcoholic extracts of tar (e.g. coal-tar solution) in cream or ointment bases, tar gels [8], etc., which are 'cleaner' and easier to handle, but it seems that the cruder the tar extract, the more effective it is [2]. Concentrations of coal-tar solution up to 10% can be incorporated in various vehicles for outpatient therapy, and many commercial creams, lotions, ointments, gels and shampoos containing tar extracts are available throughout the world.

Controversies surrounding the roles of tar and UV light have not yet been fully resolved [2]. Tar alone is certainly active in psoriasis [9], as is UVB alone [10]. Coal tar seems to sensitize the skin to UVA but not to UVB [11] and phototoxicity is of photodynamic type [12,13]. Nevertheless, UVB is more valuable than UVA in conjunction with tar [14] and probably UVB erythema thresholds prevent UVA exposure sufficient to cause photosensitization in the Goeckerman regimen [15].

Despite a huge literature, it is remarkably difficult to quantify success rates with tar regimens in terms of percentage of patients cleared, the number of days of treatment needed to achieve clearance or the length of remission [2,7]. Only one placebo-controlled trial of coal tar was found in a recent systematic review [16]. This short 4-week trial showed that 5% liquor carbonis detergens was more effective than emollient vehicle [17]. Exorex®—a new formulation of 1% coal tar in esterified fatty acids was no more effective than crude coal tar in a head-to-head comparative study [18]. Recent attempts at short-contact crude coal-tar treatment have shown that daily 1-h applications of 30% crude coal tar in yellow soft paraffin are effective in improving psoriasis, but less so than daily 23-h treatment with 5% crude coal tar in yellow soft paraffin. It was concluded that the former has no place in in-patient management, but that it may have a limited role in certain outpatients [19]. A combination of 5% crude coal tar and dithranol was found to be as effective as dithranol alone when used in short contact treatment of psoriasis, but was recommended in preference to the latter, as less irritancy was encountered [20]. Others have found that tar and dithranol combination regimens do not enhance the clearance rate of psoriasis and that they offer little benefit over dithranol alone [21,22].

The safety of tar has been regarded as one of its great virtues. In spite of the evidence that increased levels of 1-hydroxypyrene, polycyclic aromatic hydrocarbons and mutagenic activity (as determined by the Ames plate assay) may be detected in the urine of patients following 3 days of therapeutic exposure to coal tar [23], systemic toxicity is unknown. Primary irritation is uncommon except in unstable psoriasis, and on the face, genitalia and in the flexures. Allergic contact dermatitis does occur, but

is rare. Folliculitis is the most common side effect. Notwithstanding the undoubted carcinogenicity of coal tar in the skin of experimental animals [24] and human workers chronically exposed to tar, long experience dictates that the risk from therapeutic tar products is small [1,24]. There are certainly case reports of various scattered skin tumours developing in patients treated previously with tar [25–27], but some of these patients had been exposed to other known carcinogens. Reports of carcinoma at the site of local coal-tar treatment are few but significant [28–31]. It may, therefore, be wise to avoid prolonged application of coal tar to the anogenital area, including the scrotum, sites that have been involved in at least two case reports. In spite of negative results in several other series [32–34], a case–control study has shown that there was a significantly greater risk of skin cancer in psoriatic patients treated with high-exposure coal tar and UV light therapy, than in matched patients treated with smaller dosage therapy [35]. This association was confirmed by further epidemiological studies in which patients receiving multiple Goeckerman regimens were compared with age- and sex-matched controls [34]. Another study involved 719 psoriatic patients in the west of Scotland, all of whom had received intermittent topical coal-tar therapy over a 10-year period, but no cytotoxic drugs, ionizing radiation or prescribed UV radiation. No increase in malignancy of skin, bladder or any other organ was found in the psoriasis patients over that in the general population [35]. The increased incidence of malignancy [36,37] may, therefore, depend on exposure to high-dose UVB. It would therefore appear prudent to place patients who have received repeated intensive Goeckerman regimens under careful surveillance. The benefits of repeated Goeckerman regimens in patients with difficult psoriasis may, however, outweigh the risk of skin malignancy, which should be easy to detect and treat.

Other contraindications to tar therapy do exist. Erythrodermic or generalized pustular psoriasis will infrequently tolerate even the weakest tars. Pre-existing folliculitis or severe acne are also possible contraindications.

Dithranol (anthralin) [1,2]

The value of chrysarobin, a tree-bark extract, in psoriasis was discovered accidentally [3] a century ago. A synthetic derivative, dithranol (1,8-dihydroxy-9-anthrone) was

Fig. 35.22 Psoriasis partially treated with dithranol, showing brownish staining. (Courtesy of St John's Institute of Dermatology, London, UK.)

introduced by Unna in 1916 [4] but is unstable. The role of salicylic acid in stabilizing dithranol formulations was also an accidental discovery, and led to the development of the Ingram regimen [5], which has played a central part in psoriasis management since, especially in Europe. After a tar bath in which scales and the previous applications are removed, suberythema UVB is given, and the lesions then precisely covered with dithranol paste. The initial concentration is 0.05 or 0.1%, increasing cautiously up to 4% according to response, and aiming to avoid irritation of the normal or psoriatic skin [5–7]. The paste is kept in position with tubular gauze or stockingette. After 18–22 h, the cycle is repeated and can be on an in-patient or day-care basis. In skilled hands, most patients with discoid psoriasis can be cleared in 3 weeks, leaving deep brown staining (Fig. 35.22) of the treated skin, which soon disappears after treatment is stopped. Dithranol paste is not suitable for the head and neck, flexures or genitalia, where it is liable to spread and is too irritant; it is highly irritant if accidentally introduced into the eyes. It also stains bed linen and clothing irreversibly.

In the early 1980s, disenchantment with the side effects of cytotoxic and PUVA therapy stimulated a resurgence of interest in dithranol [2], its chemistry and pharmacology [8–10], pharmacokinetics and percutaneous absorption [11,12], and mode of action [2,13,14]. Attempts were made to modify its formulation [15] to allow easier application and removal, and relatively stable cream formulations introduced that are effective, although less so than the classical paste [16–18]. Low-strength formulations may also be active yet less irritating and staining [19–21]. Kinetic studies showing penetration of the full epidermis in 100 min or less [11,22] encouraged the notion that 'short-contact' therapy may be effective and less irritant, while being easier and more convenient for the patient. Dithranol application periods as short as 10 min/day [22–27] have been effective. One study has even shown that immediate removal of dithranol is as effective as removal at 20 min [28]. Another study showed that a 2-h short-contact regimen using dithranol in Lassar's paste was as effective as a standard 24-h Ingram regimen, but that both of these were more effective than 10–20 min contact periods using dithranol in soft paraffin base. Higher concentrations (up to 12%) applied twice daily for 30 min were surprisingly well-tolerated, but provided no advantage over 2% dithranol in Lassar's paste applied for 2 h once daily. The latter schedule was therefore recommended as optimal for home use in well-motivated patients [29]. A randomized controlled trial from the UK [30] showed that dithranol in Lassar's paste applied once daily as per the Ingram regimen was as effective as twice daily applications in clearing psoriasis in in-patients, although nursing time was longer for the twice daily group. A comparative study of short-contact dithranol versus in-patient treatment or UVB phototherapy reported that short-contact dithranol was the most cost-effective option [31].

Combination of short-contact dithranol with broad-band UVB appears to have little advantage over short-contact dithranol alone [27,32] or broad-band UVB alone [33,34]. However, dithranol or calcitriol in combination with narrow-band UVB (311 nm) were equally effective [35] and short-contact dithranol had a cumulative UVB sparing effect when used in combination with 311 nm narrow-band UVB [36].

Attempts to address the two main side effects of dithranol usage—local staining and irritation—have led to the development of combination therapy and new formulations of dithranol.

Dithranol in 0.0125% clobetasol propionate (quarter-strength Dermovate) ointment was reported to produce more rapid clearing than dithranol in Lassar's paste. The relapse period was similar in the two groups, although folliculitis was an important side effect in the steroid group [37]. In contrast, a combination of dithranol and fluocinonide in Lassar's paste, although causing more rapid initial clearing and reducing irritancy, did not reduce total clearance time when compared with dithranol in Lassar's paste alone. In this study, the steroid combination was also associated with a more rapid relapse rate [38]. Swinkels *et al.* [39] combined short-contact dithranol with clobetasol-17 propionate, each used once daily, and found that this accelerated the improvement of psoriasis produced by dithranol alone. Micanol is a microcrystalline formulation of 1% dithranol that releases the active medication at skin surface temperature [40]. This formulation reduces staining of fabrics significantly, but skin staining can still occur. A novel aqueous gel-based lipsome entrapped formulation of dithranol appears, in an open study at least, to produce no irritation and minimal staining [41].

Notwithstanding these developments, any form of dithranol therapy requires careful control and explanation

if the patient is not to become quickly disenchanted. The drug has the great virtue of lacking systemic toxicity, although if very high concentrations become general, continued vigilance will be necessary. Allergic contact dermatitis is extremely rare but has been documented [42]. Overall, the relative impracticality of dithranol therapy as compared to topical vitamin D analogues indicates that use of this effective and safe therapy will probably decline, particularly for outpatient use.

Topical corticosteroids

Topically applied corticosteroids are of established value in psoriasis [1,2]; in the USA, they are still the mainstay of topical therapy [3]. In appropriate concentrations, they are the treatment of choice on the face and neck, flexures and genitalia, where neither dithranol nor tar are well-tolerated, even in low concentrations. Diluted topical steroids are also used in unstable, erythrodermic and generalized pustular psoriasis, in preference to tar or dithranol, although bland emollients may be more suitable. On the scalp and other parts of the body, they can be tried if tar has failed and dithranol is inappropriate or unsuccessful. Corticosteroids have the merits of ease of application and removal, lack of irritancy and the absence of staining of skin or linen. The hazards of therapy are now well known, and enhancement by polythene occlusion will magnify and hasten side effects. Topical steroids under occlusion do have a limited place in the management of recalcitrant psoriasis of the scalp, hands, feet and other areas. Superior results have been claimed with topical steroids occluded by a hydrocolloid dressing as opposed to plastic film [4]. Apart from the cutaneous adverse effects, plasma cortisol levels are easily suppressed by the most potent preparations or high doses [5,6]. As little as 7 g/day of 0.05% clobetasol propionate or 0.05% betamethasone dipropionate was sufficient to suppress

morning plasma cortisol levels in 20% of patients [7]. These unwanted effects, and evidence of tolerance [8] induced by intensive therapy, have stimulated use of less frequent applications [2,3,5,9,10]. Thus, once daily applications of 0.1% halcinonide cream were as effective as thrice daily applications [2], and 0.05% clobetasol propionate used on alternate days, or even less frequently, induced and maintained remissions for up to 5 months [9]. A novel regimen of topical high-potency corticosteroid—betamethasone dipropionate—is to apply the agent three times over a 24-h period each week [10]. This so-called 'weekend therapy' was shown to maintain improvement in psoriasis in up to 60% of patients so treated. Another regimen [3] using fluticasone propionate ointment once daily for two consecutive days per week maintained control of psoriasis for up to 10 weeks.

Newer formulations of corticosteroids, particularly foams, are easier to apply than traditional creams or ointments and can be used for scalp, truncal or limb psoriasis [11]. There is evidence that intensive treatment of discoid psoriasis with the most potent preparations can induce generalized pustular psoriasis [12–14]. With less potent or diluted preparations, the volume can be increased *pro rata*. Potent preparations are likely to be needed on the scalp and knuckles particularly; conversely, the flexures and inner thighs need much weaker products, if striae formation is to be avoided. Their usefulness in conjunction with UVB phototherapy has been questioned [15]. Hydrocortisone (except as the butyrate ester) [16] is too weak to be of value, except perhaps in combination with tar for facial lesions.

Intralesional corticosteroid therapy

Triamcinolone hexacetonide (5 mg/mL) or triamcinolone acetonide (10 mg/mL) can be infiltrated intradermally into localized psoriatic lesions by needle injection. This is a valuable technique in troublesome, small, resistant lesions on the backs of hands, especially the knuckles, intensely pruritic small plaques or lichenoid lesions. The effect is long-lasting and repetition of the injection may be unnecessary for several months. In treatment of psoriasis of fingernails, the nail fold can be injected, but results are disappointing and the procedure may be painful.

Vitamin D analogues

The naturally occurring, active metabolite of vitamin D_3, 1α,25-dihydroxyvitamin D_3 (calcitriol) [1], and three synthetic analogues, calcipotriol [2–4], 1α,24-dihydroxyvitamin D_3 (tacalcitol) [5,6] and 1α,25-dihydroxyvitamin D_3 (maxacalcitol) [7], have all been shown to be effective when applied topically in psoriasis. The mechanism of action of these agents is via vitamin D receptor-mediated effects on the proliferation and differentiation of epidermal keratinocytes [1,8] and on the immunological features of psoriasis, including shifting the Th1 cytokine profile of plaques towards a Th2 cytokine profile [9]. The introduction of topical vitamin D analogues into clinical practice in the early 1990s [10] undoubtedly transformed first-line management of psoriasis. Topical formulations of calcipotriol and other vitamin D analogues are probably the most widely prescribed active topical therapy for plaque psoriasis. Systematic reviews [11,12] of calcipotriol therapy for psoriasis attest to its equivalence or superiority to other available topical therapies apart from potent topical corticosteroids [11]. The most widely prescribed analogue in current use, calcipotriol (50 μg/g) ointment, has been reported to be at least as effective as 0.1% betamethasone valerate ointment [13,14] and more effective than short-contact dithranol therapy [15] in plaque psoriasis. Calcipotriol (50 μg/g) ointment has also been shown to be effective and safe in children when administered in amounts up to 45 g/week/m^2 [16]. Side effects of calcipotriol include local irritation, which may affect up to 20% of patients, and can be particularly troublesome on the face,

leading to the need for withdrawal of treatment [14–16]. Vitamin D and its analogues all have the potential to affect systemic calcium homeostasis with hypercalciuria and hypercalcaemia [17]. Calcipotriol (50 μg/g) ointment was found to cause no significant changes in serum total adjusted calcium when used in amounts up to 100 g/week [18,19] or 50 g/week/m^2 [18] in adults, and up to 45 g/week/m^2 in children [16]. However, subsequent work showed significant rises in 24-h urinary calcium levels with calcipotriol ointment 100 g/week [19]. Significant rises in both serum and urinary calcium levels were also seen with high doses of calcipotriol ointment of up to 300 g/week [20,21]. It would therefore be prudent to restrict the amount of calcipotriol (50 μg/g) ointment used per week to less than 100 g or 50 g/m^2, and to monitor serum and urinary calcium levels carefully should these doses be exceeded.

New vehicles for calcipotriol have been introduced and calcipotriol cream appears to be slightly less effective than the ointment formulation [22] but cosmetically more appealing. Combining calcipotriol monotherapy applied in the morning with a super-potent topical corticosteroid such as halobetasol ointment applied in the evening for 2 weeks was superior to either drug used twice daily [23]. Based on this observation, a stable ointment formulation of calcipotriol 50 μg/g and betamethasone dipropionate (0.5 mg/g) has been investigated and now licensed for therapy. Used twice daily, this combination shows superior efficacy to either calcipotriol or betamethasone alone [24] with better clearance and faster onset of action. Once daily application of the combination appears no less effective than when applied twice daily [25]. Whether withdrawal of the combination following treatment leads to an increase in rebound or pustular relapse remains to be ascertained.

Long-term treatment of chronic plaque psoriasis with calcitriol (3 μg/g) ointment confirmed previous shorter term studies indicating the efficacy of this natural vitamin D_3 metabolite [1]. The relative efficacy of this agent compared with topical calcipotriol, corticosteroids or dithranol is currently unclear, although the relapse rate following withdrawal of calcitriol ointment appeared lower than that after topical corticosteroid therapy [1]. No statistically significant changes in serum or urinary calcium levels were found, even in patients using large quantities of the ointment to treat up to 35% of the body surface area for 3 months [26]. Transient local skin irritation, occasionally necessitating withdrawal of treatment, may occur but calcitriol 3 μg/g ointment is better tolerated than calcipotriol ointment for treatment of face and flexures [27].

Tacalcitol 4 μg/g ointment applied once daily is effective for the treatment of chronic plaque psoriasis [6]. A systematic review [12] indicated that it was probably inferior in efficacy to calcipotriol 50 μg/g ointment. A long-term 18-month study in 197 patients using tacalcitol once daily demonstrated efficacy and safety with no evidence of effect on calcium homeostasis [28], although 5.9% of patients discontinued because of skin irritation. Maxacalcitol 25 μg/g ointment applied once daily for 8 weeks is an effective treatment for chronic plaque psoriasis and may be more effective than once daily application of calcipotriol 50 μg/g ointment [7].

Calcipotriol and talcalcitol have been combined with other therapies. Calcipotriol ointment enhances the efficacy of PUVA and UVB phototherapy [29,30]. As UVA partly inactivates calcipotriol [31] and UVB is absorbed by calcipotriol [32], it is recommended that calcipotriol is not applied until after phototherapy sessions. Tacalcitol ointment when combined with PUVA is UVA-sparing [33] and calcitriol is UVB-sparing in combination [34]. Calcipotriol 50 μg/g ointment used in combination with methotrexate enables lower cumulative doses of methotrexate to be used [35].

Vitamin A analogues

Retinoids, with their pleiotropic effects on cellular proliferation and differentiation, would appear to be an ideal topical preparation for psoriasis. Early studies were performed with topical all-*trans*-retinoic acid (tretinoin). Efficacy was reported but local irritation was a major problem [1,2]. The development of retinoic acid receptor (RAR) selective retinoids facilitated a revisitation of the role of topical retinoids. Tazarotene is a synthetic retinoid, whose main metabolite, tazarotenic acid, binds to RARs β and γ [3]. Tazarotene in a 0.05 or 0.1% gel applied once daily for 3 months is significantly more effective than vehicle in the treatment of chronic plaque psoriasis [4,5]. The main drawback of tazarotene is local irritation at the site of application, so much so that various strategies have been devised using once daily application of a potent topical corticosteroid, such as mometasone furoate or clobetasol propionate to alleviate this problem [6,7]. More recently, a cream formulation (0.05 and 0.1%) of tazarotene has been developed. A study [8] involving 1303 patients treated once daily with tazarotene cream reported significant reduction in clinical severity of psoriasis—the 0.1% formulation was more effective but less well-tolerated. Tazarotene is probably best reserved for thick, recalcitrant plaques of psoriasis.

Topical or intralesional cytostatic therapy

Several compounds have been reported to be effective, but side effects are common and usage complicated by the practical difficulties encountered in the preparation and handling of cystostatic agents. Topical mechlorethamine (nitrogen mustard) has demonstrable activity as a 0.01–0.05% aqueous solution, the chief limiting factor being an 80% chance of allergic contact sensitization [1,2].

The chance of this hazard can be delayed and lessened by combining treatment with UVB phototherapy [3]. Thiotepa 0.4% ointment under occlusion can be effective but carries a risk of leukopenia [4]. Fluorouracil 5%, as a cream or ointment, can clear psoriasis but painful erosive necrolysis of the epidermis and dermal inflammation are common [5]. Weekly pulse doses of fluorouracil given intralesionally have been found to be effective. Treatment was well tolerated and associated with only minimal toxic effects,

including hyperpigmentation, and in one patient moderate local irritation [6]. An injectable gel formulation of fluorouracil and epinephrine has been used also [7]. The alkylating agent lomustine has been tried as a 0.1% ointment. Undoubted efficacy was unfortunately accompanied by severe and persistent pain because of irritation of unaffected skin [8]. Hydroxyurea has been found to be ineffective topically [9]. Topical methotrexate is discussed below.

Occlusive dressings alone

Improvement or clearing of psoriasis lesions has been described following prolonged occlusion with various tape products, including sticking plasters, although different tapes varied markedly in their effectiveness [1,2]. These findings have been confirmed in a prospective bilateral comparison study in which prolonged application of an adhesive hydrocolloid occlusive dressing was found to be superior to twice daily applications of a potent topical corticosteroid, and as effective as erythemogenic UVB treatment. Side effects included hyperpigmentation, pain on removal of dressings resulting from hair traction and, in a minority, a Koebner response or offensive odour [3]. Further evidence came from a 3-week study when occlusion alone was as effective as the potent topical corticosteroid—fluocinonide ointment [4]. Mechanism of action may relate to normalization of the permeability barrier [5]. This treatment appears to have potential in the management of limited psoriasis.

Treatment of the scalp

Psoriasis of the scalp can be intractable and resistant to therapy. A recent development is that of corticosteroid-containing shampoos. Tar-containing shampoos should be the first approach, carried out daily if necessary. Tar lotions or gels may be added, rubbed in at night and shampooed out the following morning. A coconut oil-based tar and salicylic acid pomade applied at bedtime, sometimes occluded overnight with a polythene shower cap, and shampooed off in the morning, is commonly used in the UK. Cream formulations of dithranol can be useful, but care should be taken to avoid irritation of the ears and eyes. Dithranol may also cause unacceptable staining of fair hair. Calcipotriol scalp application may also be of value.

If these measures fail, corticosteroid scalp lotions, gels or foams should be tried, but even the most potent (e.g. clobetasol propionate 0.05% alcoholic solution) is useless if painted on the surface of thickly heaped-up psoriasis. In these circumstances, the scalp should be copiously drenched overnight (or throughout 24 h if possible) with the coconut oil-based tar and salicylic acid pomade or similar preparation, which is shampooed out once or even twice a day. Two or three days of such treatment generally brings about marked improvement, allowing corticosteroid or calcipotriol scalp lotion to be substituted.

UV phototherapy

UVB

Goeckerman [1] first thoroughly documented the ability of crude coal-tar applications followed by exposure to UV radiation to clear psoriasis. Much later, it became clear that broad-band (290–320 nm) UV radiation (BBUVB) alone, if given in mildly erythemogenic dosage, was capable of clearing psoriasis [2–5] and can be as effective as PUVA [6]. In addition, continued maintenance BBUVB therapy after initial clearance with BBUVB significantly increased the duration of disease control, even though maintenance treatment was given at modest frequency (an average of six treatments per month) [7].

UVB therapy three times weekly is sufficient [2], and twice daily treatment is of no extra value over once daily treatment [8]. The benefit of additional tar therapy is accepted [8,9], but doubt has been cast on the value of adding topical steroid therapy [10,11] or short-contact dithranol to a UV regimen. The known carcinogenicity of

BBUVB limits enthusiasm for phototherapy. While some studies have not shown an increased skin cancer risk in UVB-treated psoriasis patients [12–14], one study suggested that high levels of exposure to BBUVB are associated with an approximately fourfold increase in the risk of genital tumours in men [15]. Protection of the genital area from BBUVB exposure would therefore be prudent in these patients.

Philips TL-01 fluorescent lamps emit a narrow-band UVB (NBUVB) at 311 ± 2 nm. Irradiation with this source has been found to be superior to conventional BBUVB in psoriasis, producing longer remissions, a lower incidence of burning and possibly a lower risk of UV carcinogenesis [16–21]. The effectiveness of NBUVB appears to be similar to that of PUVA, but it is more convenient and also probably less carcinogenic [20]. The use of higher intensity (100 W) TL-01 lamps has confirmed the superiority of narrow-band over conventional broad-band therapy, and has allowed shorter, more convenient exposure times [22]. In a randomized controlled trial, 100 patients with psoriasis were allocated to either twice weekly PUVA or NBUVB. Clearance of psoriasis occurred in a significantly greater proportion of patients on PUVA (84%) than with NBUVB (63%) and with significantly fewer treatments (16.7 versus 25.3, respectively) [23]. However, another trial of NBUVB three times weekly was of equivalent efficacy to PUVA [24]. Several studies have examined the optimal number of NBUVB treatment sessions per week. Twice-weekly treatment produced equivalent improvement in psoriasis to four times weekly, but with only 16 as compared to 32 exposures [25]. Three times weekly appears to be the optimum regimen for efficacy in that two NBUVB sessions weekly took 50% longer to clear psoriasis compared to three times weekly (88 versus 58 days, respectively) [26]. An interesting development is home NBUVB treatment based on patient training—all patients who took part in the study preferred home- over hospital-based treatment [27]. Application of dithranol also provided a substantial additional benefit [22]. The combination of NBUVB with etretinate decreased the number of treatments and the UV exposure required for clearing, but was associated with a more rapid relapse than seen in NBUVB monotherapy [27,28]. NBUVB radiation may emerge as the UV therapy of choice in psoriasis, although its long-term safety remains to be confirmed by objective clinical studies. Unlike BBUVB, TL-01 therapy has been reported to cause asymptomatic or painful blistering at the sites of psoriatic lesions towards the middle of a treatment course. This side effect appears to be very unusual, and usually resolves with continued narrow-band treatment, although this may need to be briefly interrupted or restricted [29].

A retrospective study of 1488 psoriasis patients treated for 4 weeks at the Dead Sea Clinic from 1983 to 1986 by sun exposure and bathing in mineral-rich sea has been carried out. Nearly three-quarters improved by 90% or more, results consistent with those of a prior prospective study of 110 patients. The treatment is said to be cost-effective and pleasant, the combined costs of travel, accommodation and nominal medical fees usually being less than that of in-patient treatment for the clearing of psoriasis [30].

In general, UVB therapy is valuable for discoid psoriasis and may be especially valuable in guttate and 'seborrhoeic' patterns. It is usually of little value in psoriatic erythroderma and generalized pustular psoriasis, and may aggravate these forms of the disease.

Psoralen photochemotherapy

History. Experience with coal-tar and UV therapy of psoriasis, and psoralen photochemotherapy of vitiligo, led to the suggestion that psoriasis might benefit from the same approach [1]. The first report of successful treatment of psoriasis was ignored [2] but a decade later the effectiveness of topical psoralens followed by long-wave UV radiation (UVA) in resolving plaque psoriasis was confirmed [3,4]. Within 2 years, the first report of successful use of oral 8-methoxypsoralen (8-MOP) and UVA [5] led to intense interest and the coining of the terms 'photochemotherapy' and 'PUVA' [2,6–9]. Multiple studies soon confirmed the efficacy of oral [10–18] and topical [12,19–21] PUVA therapy in various patterns of psoriasis. In the USA, Food and Drug Administration approval of PUVA therapy for severe psoriasis was granted in May 1982. In the UK, official approval is still withheld, and no psoralen preparation has a product licence. Nevertheless, PUVA is widely used in the UK. With the introduction of narrow-band UVB phototherapy and the risk-averse practice of medicine prevalent in the USA, there is a significant reduction in the number of patients receiving PUVA per annum. The National Ambulatory Medical Care Survey revealed an 85% reduction in PUVA use from 1993 to 1998 [22].

Methodology. Dosage of 8-MOP is arbitrary, as is the time interval before irradiation. Different pharmaceutical preparations of 8-MOP differ markedly in bioavailability [23,24], and there are patient variations in the rate and extent of absorption [25]. In addition, there is no simple correlation between achieved plasma levels and therapeutic response [26], although patients responding unsatisfactorily are more likely to have deviant blood levels [27,28]. Liquid formulations of 8-MOP have been reported to produce higher, earlier peak levels of drug in the plasma and more reproducible plasma concentrations [29,30].

Table 35.3 Initial dose of UVA according to skin type [6].

Type	Description	Initial dose (J/cm^2)
I	Always burn, never tan	0.5
II	Always burn, then slight tan	1.0
III	Sometimes burn, always tan	1.5
IV	Never burn, always tan	2.0
V	Moderately pigmented	2.5
VI	Deeply pigmented	3.0

Dietary influences may be important [31], absorption being delayed and reduced by a fat-rich meal. Other photoactive drugs should be avoided. Standard oral dosage using 8-MOP tablets is 0.6 mg/kg [9], given 2 h before irradiation. High-intensity fluorescent UVA tubes are used, and initial UVA dosage is based on skin type (Table 35.3). Some clinicians start with somewhat smaller doses. Treatment is given two to four times weekly. UVA dosage is increased by increments of 0.5–1.5 J/cm^2 according to response. Persistent tenderness or erythema of uninvolved skin may call for temporary reduction of UVA dosage, or cessation of treatment for a few days. Once substantial clearance has been achieved, the frequency of treatment can be reduced, so that maintenance treatment (usually the last UVA dose in the clearance phase) is given once every 1–4 weeks. Alternatively, the treatment may be stopped in many cases if the psoriasis remains clear. In either case, clearance schedules may have to be resumed to control relapses. A cost-effective modified UVA dosage schedule leading to an increased clearance rate and reduced cumulative UVA dose, and therefore possibly a lower incidence of long-term cutaneous side effects, has been proposed [32]. In this study, initial and incremental UVA doses were maximized to near erythemogenic levels by weekly testing for the minimal phototoxic dose, by using an automated skin testing UVA irradiation unit. However, the value of repeated minimum UVA phototoxicity dose testing in reducing the cumulative dose of UVA and improving the clearance rate has been questioned [33].

Eye protection [34,35]. During irradiation, UVA-opaque goggles must be worn. For the remainder of that day, UVA-blocking sunglasses should be worn outdoors (except when driving at dusk) and indoors during the daylight hours or under artificial fluorescent lighting. There is a wide variation in the efficacy of commercially available sunglasses, and the screening efficiency should always be tested with a radiometer. Detailed information is provided in published reviews [34,35].

Patient selection [6,23]. In many departments, only vertical UVA irradiation units are available as they occupy

less floor space than horizontal units, and they save time, as the entire skin is irradiated simultaneously. Some elderly or infirm patients may encounter difficulty standing in a vertical unit for a prolonged period. Contraindications to the use of PUVA are evidence of renal, hepatic or severe cardiovascular disease, cataract formation, or pre-existing light-aggravated disease such as systemic lupus erythematosus (SLE), porphyria and multiple melanocytic naevi, particularly in the presence of a family history of malignant melanoma. However, a history of previous summer exacerbation of psoriasis involving exposed areas is not necessarily a contraindication; some such patients do well with cautious PUVA treatment [36]. Previous exposure to inorganic arsenic or radiotherapy or a history of cutaneous malignancy are relative contraindications. The treatment should not be given in pregnancy nor to children under 18 years, except in the most compelling circumstances. Because the long-term carcinogenic hazard is uncertain, PUVA should only be considered as a primary treatment in those patients over 55 years of age where psoriasis covers at least 20% of the body surface, and who cannot be controlled by conventional topical therapy. In patients under 55 years or with less widespread psoriasis, other considerations may justify therapy according to individual circumstances. PUVA is of no value for psoriasis in areas where UVA access is impossible, such as the scalp (except in the bald) or certain body flexures.

Results. Therapeutic results have been uniformly good to excellent in psoriasis vulgaris. Clearance rates of up to 90% have been reported [11,13,16–18], substantial clearance being achieved by 15–25 treatments to a total of 100–200 J/cm^2. Less spectacular success rates have probably reflected selection of severe resistant cases [10,15,37] or use of lower 8-MOP or UVA doses [12,38]. The use of four treatments weekly in a European cooperative trial achieved complete clearing in 65%, and substantial improvement in another 29% in approximately 3200 patients, with a mean of 20 exposures in 5–6 weeks, a mean UVA clearance dose of 7 J/cm^2 and a cumulative UVA dose to clearance of about 100 J [18]. Although success was comparable in large US cooperative studies [13,16] in which three treatments weekly were given, higher clearance UVA doses (13–14 J/cm^2), higher cumulative doses (up to 200 J) and 10–12 weeks were needed. The European regimen of four treatments weekly possibly achieved its antipsoriatic action before increasing pigmentation necessitated higher UVA doses.

PUVA is also of value in generalized pustular psoriasis, erythrodermic psoriasis, palmoplantar pustulosis and nail psoriasis [39], but success rates are much lower in these atypical patterns of disease. The value of maintenance therapy is disputed, being thought to be of value by some authors [13,40–42] but not by others [18]. A useful compromise is to give maintenance treatment for 2 months. If the psoriasis remains clear, PUVA is stopped. Low-dose PUVA maintenance is possible after clearance has been achieved by some other modality (e.g. dithranol) [43].

Patient monitoring. Regular blood counts, renal and liver function tests are not necessary, but should be carried out occasionally as clinical circumstances demand. Eye examination, ideally by an ophthalmologist, before and at 6–12-month intervals during maintenance treatment is a prudent precaution. Long-term supervision of patients should not be entirely delegated to ancillary staff, and a thorough clinical examination of the skin at regular intervals, say every 3 months, is indicated.

Combined therapy. The simultaneous use of etretinate or acitretin and PUVA is discussed below. Dithranol and PUVA have been used together [39] and sequentially [43]. In extremely severe erythrodermic or generalized pustular psoriasis, a cytotoxic drug may be given concurrently. Methotrexate in combination with PUVA is effective; however, there is an inevitable increased risk of skin cancer [44,45]. Topical corticosteroids may be used concurrently, especially on areas inaccessible to UVA. However, it is unresolved whether this combination results in shorter remission times [46,47]. Calcipotriol combined with PUVA is more effective than PUVA alone and results in less UVA exposure [48]. Although rarely used, PUVA and UVB used together has been reported effective in patients unresponsive to either PUVA or UVB alone [49].

Adverse effects [1]. Erythema and frank 'sunburn' are the most common effects, and are seen at some stage in at least 30%. Nausea affects approximately 12% of patients and pruritus approximately 25%. A mild facial dermatitis resembling seborrhoeic dermatitis and involving the glabella, cheeks and nasolabial folds affects approximately 5% of patients. It is not very responsive to topical corticosteroids. Pigmentation is the most common cutaneous change observed, and is dose related. It may be diffuse, poikiloderma-like or in a naevus spilus-like pattern [2,3], producing gross freckling (PUVA lentigines) [4]. The melanocytes are abnormal within these lentigines, with large melanosomes and lipid accumulations [5]. These changes may be partially reversible. The nails may pigment [6] and photo-onycholysis has occurred [7,8]. Bullae occur occasionally and several cases of generalized pemphigoid have been reported. Hypertrichosis may be a problem in females. Lichenoid eruptions are documented [9] and histologically, in apparently unaffected skin, colloid or amyloid bodies may be found near the dermal–epidermal junction [10,11]. The incidence of actinic keratoses is controversial, ranging from 1.4% [12,13] or less [14] to over 50% in California [15]. A case of superficial actinic porokeratosis is on record [16].

Itching is a common problem, occurring in up to 25% of patients [17]. Severe cutaneous pain is a rare but well-recognized associated phenomenon [18,19]. The pain starts 4–8 weeks after onset of PUVA therapy, and sometimes after treatment has been stopped. Attacks may last from 15 min to several hours, and can be provoked by scratching or pressure. The buttocks, limbs and abdomen are particularly affected, especially at night. The pain is not associated with itching. It settles over a few weeks.

The concurrent administration of other photoactive drugs increases the chances of unpleasant erythematous reactions [20]. Worsening or new eruptive psoriasis, resulting from a Koebner phenomenon, occurs in about 2% of patients. A few reports of a lupus erythematosus-like syndrome [21,22] have stimulated several studies of antinuclear antibody levels during PUVA therapy, with normal findings in one study [20] but modestly raised antibody levels in others [23–25]. Circulating immune complexes may be raised [26].

No cataracts unequivocally attributable to PUVA have been reported in humans [27], although they have been induced in experimental animals by massive dosage [28]. However, bilateral punctate cortical opacities, not present prior to therapy, have been reported [29,30], and the animal changes have been in an anterior cortical location [28]. A patient, with previously normal eyes, developed cataract 4 years after a 28-month course of PUVA [31].

Liver function tests only rarely become abnormal, and no changes were found in liver biopsies after 2 years of PUVA therapy [32]. Nevertheless, there have been rare reports of hepatotoxicity [23,24,33]. Psoralens are known to induce liver microsomal enzymes [34]. The possibility of chromosomal changes has attracted inevitable attention, and the published data are conflicting. Striking increases in sister chromatid exchange frequency *in vitro* induced by 8-MOP concentrations likely to be found *in vivo* have been reported [35], but earlier workers did not find such changes [36]. Unscheduled DNA synthesis is apparently not increased in normal human skin by PUVA [13] or in psoriatic skin [37].

Various abnormalities of immune function have been recorded. Reduction in circulating T-lymphocyte numbers and function is documented [38], but there are reports of previously depressed T-cell numbers returning to normal with PUVA therapy [26,39]. However, a reduction in circulating helper–inducer T cells has also been associated with long-term therapy [40]. Inhibition of lymphocyte DNA synthesis occurs, and the effect has been demonstrated to be an immediate one on circulating lymphocytes *in vivo* [41]. Delayed hypersensitivity responses are undoubtedly reduced and delayed [38,42–45], perhaps caused by Langerhans' cell depletion [46] or damage [47] in the irradiated skin.

The carcinogenic hazard. It is undisputed that solar UV radiation is a major aetiological factor in squamous and basal cell carcinoma and malignant melanoma in humans. Tumours have been induced in the skin of hairless albino mice by PUVA exposure using both 8-MOP and 5-MOP [1]. An early report suggested that PUVA therapy accelerated the development of skin tumours in patients with xeroderma pigmentosum [2], and it appeared to have an obvious promoter effect in a patient previously exposed to X-irradiation, arsenic and several cytotoxic drugs, who developed 25 basal or squamous cell carcinomas, the first within 21 months of onset of PUVA therapy [3].

There is now substantial literature dealing with the incidence of skin tumours in groups of PUVA-treated patients. Although certain studies have failed to show a clear relationship between PUVA and tumour development [4–6], long-term follow-up of a large US cohort has provided conclusive evidence for the carcinogenicity of PUVA [7]. In this study, an initial cohort of 1380 PUVA patients was followed up for a mean of 13.2 years. Squamous cell carcinoma (SCC) developed in one-quarter of patients exposed to high doses of PUVA, giving a relative risk of SCC of 5.9-fold on comparison with patients receiving low-dose PUVA. High-dose PUVA was regarded as a total of over 299 treatments, low-dose less than 160 [7]. Precise UVA doses were not given, but taking an average dose of 11 J/cm^2 after clearing, the high-dose group can be estimated to have had more than approximately 3200 J and the low-dose group less than 1760 J. The latter figure may therefore be taken as a cumulative dose, which should ideally not be exceeded. However, a study in Northern Ireland, where there is a high population of sun-sensitive Celtic subjects, indicated increased risk for non-melanoma skin cancer (including particularly basal cell carcinoma) with cumulative UVA doses above only 250 J/cm^2 [8]. Therefore, far more conservative UVA limits may be needed with certain populations, and safety limits may be better expressed as numbers of treatments rather than cumulative UVA doses. In the Northern Ireland study, a cumulative UVA dosage of 250 J/cm^2 equated with approximately 100 treatments. The US study showed that fair-skinned persons (skin types I or II; Table 35.2) had an approximately twofold higher risk of SCC than those with skin types III or IV. Overall, there was no substantial increase in the risk of basal cell carcinoma with high-dose PUVA in the US study [7]. Metastatic SCC was seen in seven patients, but two of these were elderly and had had little PUVA. Four were younger (41–57 years) and had had moderate- to high-dose PUVA, although methotrexate or ionizing radiation may have played an additional part [7].

The substantially increased risk of SCC with high-dose PUVA therapy has been supported by a large Swedish study [9]. The male genitalia appear particularly to be at risk [10–12]. In a prospective cohort study [7,12] of 892 men first exposed to PUVA in 1975–76, 24 (2.7%) had developed a total of 51 genital neoplasms. It appears that increased risk is associated with high-dose PUVA in association with UVB and coal tar. Shielding of the genitalia during PUVA therapy reduces the risk.

PUVA lentigines may exhibit cytologically atypical melanocytes [13]. There is an increased risk (8.4-fold) of malignant melanoma in patients who have received PUVA—the 1380 patient cohort study of patients who first received PUVA in 1975–76 calculated that high-dose PUVA (more than 250 treatments) and passage of time were contributing factors [14,15]. PUVA is best avoided in those predisposed to malignant melanoma (e.g. those with numerous melanocytic naevi or atypical moles) and a family history of melanoma.

There is no evidence of any internal carcinoma hazard, but acute leukaemia [16,17] and a preleukaemic state [18] have been reported. In addition, a patient transformed from myelodysplasia to fatal acute myeloid leukaemia after 4 months of PUVA [19].

PUVA using other psoralens

There has been interest in 5-MOP as a substitute for the standard 8-MOP in PUVA therapy. The two forms have been compared [1], and it has been reported that 0.6 mg/kg 5-MOP is as effective as the same dose of 8-MOP [2]. Higher doses of 1.2 mg/kg were more effective, but produced more erythema [2]. The main advantage of 5-MOP lies in better gastrointestinal tolerance, nausea occurring only rarely [1,2]. It has also been shown that therapeutic doses of 5-MOP are associated with a lower incidence of phototoxic reactions than 8-MOP [3]. It may therefore be preferable to 8-MOP in PUVA therapy, particularly in light-sensitive patients and subjects with 8-MOP intolerance. There is no evidence that 5-MOP is less photocarcinogenic than 8-MOP [4].

Trimethylpsoralen has been used to good effect in PUVA baths (see below). Use of 3-carbethoxypsoralen has been advocated because it is non-carcinogenic in mice [5].

PUVA therapy with topically applied psoralens

A desire to avoid some of the side effects of oral treatment, especially in patients with localized forms of psoriasis, reactivated interest in the use of 8-MOP topically. A lotion or emulsion containing 0.1–1% 8-MOP has been used, and the time interval before UV irradiation seems to be relatively unimportant, periods as short as 5 min giving results as good as those with a delay of up to 2 h [1]. If extensive areas of skin are treated with topical 8-MOP in an oil-in-water emulsion, blood levels comparable to those achieved during oral therapy are found [2], so that the usual precautions to protect the eyes must be taken and little advantage is incurred. Local treatment can be given two to five times weekly, the dose of UVA being slowly increased according to response.

Trimethylpsoralen (TMP) has also been used topically to the whole body in a bath, combined with UVA, initially mainly in Finland and Sweden [3–5]. TMP is used at a concentration of 0.33 mg/L [6]. Comparisons of TMP baths with oral 8-MOP PUVA have shown that the response and relapse rates are similar. Nausea and headache occurred in the group using systemic treatment but not in the bath group, but short-term local cutaneous side effects, such as pruritus, were more common in the bath group [7,8]. Benefits have also been claimed for a combination of TMP bath PUVA with oral etretinate [9] and acitretin [10]. One report has suggested that TMP bath PUVA carries a lower risk for skin cancer than oral 8-MOP PUVA, possibly because the doses of UVA are 15–20 times lower with bath PUVA [11]. However, the data are preliminary and may be confounded by the fact that there were fewer high-dose PUVA patients among the bath group, that maintenance treatment was not given and that the face (an important site of SCC in the oral PUVA group) was not treated in the bath PUVA patients. It is prudent to conclude that, as yet, there is insufficient evidence that bath PUVA is safer. While no excess risk of skin cancer has been reported with bath PUVA, both keratoses and lentigines are common [12].

Bath PUVA with 8-MOP, at a concentration of 2.6–3.7 mg/L, has been successful [8,13]. A comparison of 8-MOP bath PUVA and oral PUVA found no difference in efficacy between the two, but bath delivery required 50% less UVA [13]. Although plasma levels of psoralen have been reported as either undetectable or very low after bath PUVA, a relationship between plasma 8-MOP levels and severity of psoriasis has been found, raising the possibility of adverse systemic reactions in patients with extensive disease [14]. The practice of not using UVA-screening spectacles following bath PUVA [13] may therefore need to be reassessed in such patients. Bath temperature should remain constant from treatment to treatment, 37°C seems optimal with a bath time of 15 min—followed immediately by UVA; local head and foot treatment may require up to 40 min before UVA. Guidelines issued by the British Photodermatology Group provide protocols for delivery of bath PUVA [6].

Psoriasis of the fingernails has been successfully treated with topical 1% 8-MOP solution and UVA two to three times weekly [15].

Systemic therapy

For practical purposes, the alternatives are corticosteroids, antimetabolites, retinoids, ciclosporin and the new biological therapies. Photochemotherapy is discussed above.

Methotrexate

The beneficial effect of aminopterin on psoriasis was first observed in 1951 [1]. Safe regimens were soon developed [2], and aminopterin was replaced by its more stable analogue, methotrexate, which may be given orally, intramuscularly or intravenously. In cancer patients, absorption of an oral dose was found to be complete [3], but variable degrees of malabsorption are found in psoriatics even with small doses, 32–98% of the oral dose being absorbed, and the degree of absorption correlating well with D-xylose absorption [4]. Excretion is largely (95%) by the kidney, but there is extensive enterohepatic cycling [5,6]. The drug is 50–70% bound to plasma albumin [3,7]. Methotrexate inhibits DNA synthesis by competitive inhibition of dihydrofolate reductase [8], and may thus exert an antimitotic action on the epidermis. Recently, *in vitro* studies showed that methotrexate was 10–100 times more effective at inhibiting the proliferation of lymphoid cell lines than cultured keratinocytes, suggesting that lymphoid cells may be a more important cellular target than epithelial cells in psoriasis [9]. In regimens for psoriasis, methotrexate also inhibits polymorphonuclear leukocyte chemotaxis [10]. These actions may explain its clinical effects.

Controlled trials have suggested that topical methotrexate is ineffective in psoriasis [11,12] in spite of evidence for local absorption [13]. In contrast, significant improvement was subsequently noted following the use of a topical methotrexate gel containing the penetration enhancer, laurocapram. It was therefore suggested that topical methotrexate may be effective in psoriasis if adequate percutaneous absorption is provided for a sufficient period [14].

Oral therapy is given once weekly, occasionally fortnightly. Daily regimens are dangerous and have been abandoned. For a 70-kg adult, an initial test dose of 5–10 mg is given to avoid early toxicity. Maintenance doses should be achieved by gradual increases of 2.5–5 mg/week, and usually range between 7.5 and 30 mg/week. Methotrexate may be given as a single weekly oral dose, or divided into three parts given 12 h apart over 24 h [15]. Parenteral therapy is equally safe, similar doses being given intramuscularly or intravenously every 7–14 days. In the elderly, the effective dosage of methotrexate is below the above range, and toxicity may be more readily encountered with higher dosage, probably owing to reduced renal clearance. Patients over 80 years have been adequately treated with as little methotrexate as 2.5 mg/week [16].

Before treatment, renal, hepatic and marrow function must be shown to be normal. If renal function is impaired, a reduced dosage of methotrexate may be given with extreme care and regular monitoring. Routine liver-function tests should be supplemented by a liver biopsy, which may be delayed for 2–4 months until it is established that methotrexate is effective and tolerated, and that long-term treatment will be carried out. Many centres are now starting to use an assay of serum levels of the aminopropeptide of type III procollagen (PIIINP) as an alternative to liver biopsy (see below) [17,18]. Anaemia, thrombocytopenia and leukopenia are contraindications to therapy, as are active infection, peptic ulceration, ulcerative colitis past or present, alcoholism, immunodeficiency, pregnancy, lactation and an unreliable patient [15].

Initial dosage should always be cautious (at the lower end of the therapeutic range). Note should always be taken of concurrent therapy with drugs that may displace methotrexate from plasma albumin, such as aspirin, NSAIDs and sulphonamides, including co-trimoxazole [19], as has been reviewed [15]. In addition to the drugs

reviewed, frusemide (furosemide) has induced severe toxicity in one patient [20] and a profound fatal leukopenia in another (D.H. Jones, personal communication), probably by interfering with tubular secretion of the drug. Diuretic therapy should be avoided if possible, and used only with great caution if cardiac failure threatens. Special caution is needed if corticosteroids are being given orally, because the toxic effects of the two drugs on the intestinal tract and defence against infection may be additive [21].

Clinical response is usually evident in 7–14 days, but maximal response may take 4–8 weeks. Generalized pustular psoriasis (if acute) may respond within 48 h. As soon as acceptable control is achieved it may be possible to lower the dosage or to extend the interval between doses. It is prudent to accept less than 100% control; quite small doses (e.g. 7.5–10 mg or less weekly) may afford adequate control, especially in the elderly patient. Subsequent minor fluctuation in activity can be treated by other means. In the treatment of erythrodermic or pustular psoriasis where gross oedema, especially of the legs, is common, the temptation to use diuretics, especially frusemide (furosemide) [20] should be resisted. As the psoriatic inflammation is controlled, a spontaneous diuresis will follow.

Laboratory control of treatment is essential. Initially, the haemoglobin, leukocyte and platelet counts should be shown to be within normal limits; weekly, but later less frequent counts, say monthly or even less often, are adequate. Maximal myelosuppression occurs 7–10 days after an oral dose. The liver enzymes give the simplest guide to hepatic function, and serum albumin, liver-function tests and blood urea or creatinine levels should be checked every 3–4 months during maintenance therapy, although the value of liver enzyme measurements in predicting significant hepatotoxicity is controversial [22]. Liver biopsy should usually be undertaken not less frequently than after every 1.5 g of cumulative methotrexate dosage [15,22]. However, the need for repeated follow-up liver biopsies in carefully selected and monitored patients who have no other risk factors for hepatotoxicity has been questioned, especially in view of the morbidity and cost associated with liver biopsy, and the low yield of pathological findings leading to discontinuation of methotrexate [23].

Numerous toxic effects of methotrexate therapy are recognized. In one long-term study, 73% of patients had side effects, most frequently abnormal liver-function tests, nausea and upper gastrointestinal symptoms [24]. Oral regimens commonly provoke transient anorexia, nausea and dyspeptic pain. Many patients feel slightly unwell for 24 h or so after each dose. Bursting headaches, lasting a day or so, may follow large parenteral doses. Burning sensations in the psoriatic plaques, lasting several days, are not uncommon after full doses, and herald rapid resolution of lesions. Toxic effects on the marrow include leukopenia, thrombocytopenia and, rarely, folate-deficient megaloblastic anaemia. Folic acid given regularly during treatment with methotrexate can prevent nausea and reduce the chances of bone marrow suppression. A recent UK audit [25] of folic acid prescribing during methotrexate therapy indicated the preferred regimen to be 5 mg/day every day including the day of methotrexate dosing. Modest thrombocytopenia ($100–125 \times 10^9$/L) and low to normal white cell counts ($3.5–4.5 \times 10^9$/L) do not necessarily preclude safe long-term treatment if the counts remain stable.

It is now established beyond all doubt that methotrexate is hepatotoxic, causing fibrosis and cirrhosis, the incidence of which has varied in different series [15,26,27]. One report described cirrhosis and liver failure leading to liver transplantation in three patients receiving largely unsupervised methotrexate treatment for psoriasis, although no information was given about other potential aetiological factors [28]. In general, the incidence of cirrhosis is low with total dosage of less than 1.5 g. Higher incidences of fibrosis and cirrhosis have been reported by Danish authors in patients receiving higher cumulative dosage or longer exposure, findings that have conflicted with the data of others [15]. These higher incidences in Denmark may possibly be explained by a higher average age and previous intake of hepatotoxins, such as arsenic, vitamin A and alcohol [29].

Pre-existing liver disease adds to the risk from the drug, and both functional and structural abnormalities have been demonstrated frequently in severe psoriatics being assessed prior to methotrexate therapy. In one series, premethotrexate liver biopsies showed that steatosis, periportal inflammation and focal necrosis were all found with a statistically significant higher grading among psoriatic patients than controls [26]. Other risk factors include impaired renal function, diabetes, obesity and increasing age [11,15,29–31]. The presence of chronic hepatitis B or C infection is also likely to be a risk, and should be excluded prior to methotrexate therapy.

The clinical course of cirrhosis induced by methotrexate may, however, not be aggressive, some patients being able to continue on the drug without worsening of liver biopsy findings [27,32]. Generally, it is an indolent, slowly developing process that will be detected by serial liver biopsies, when the hazards of stopping and continuing therapy can be weighed against each other. Fatty change and mild inflammatory infiltrate can be ignored, as can the mildest stage of fibrosis if the need for methotrexate is compelling. Progressively more severe damage in serial biopsies demands withdrawal of the drug, as do the findings of advanced fibrosis or cirrhosis, but the serial biopsies may show apparent reversibility or fluctuation of changes [23]. At present, liver biopsy remains the gold standard for the exclusion of significant hepatotoxicity, as indicated in the guidelines of Roenigk *et al.* [15]. However, there is now compelling evidence that 3-monthly monitoring of serum levels of PIIINP may permit dispensing with liver biopsy

altogether in approximately 70% of patients. Careful work by researchers in Manchester, UK, and Aarhus, Denmark, [17,18,33] has established that serum levels of PIIINP accurately reflect liver pathology. If serum levels of PIIINP remain within the normal range liver histology is normal; there are occasions when high serum levels of PIIINP occur with a normal liver biopsy—in such circumstances patients can continue on methotrexate but hepatoxicity is monitored by regular (1.5 g cumulative dosage of methotrexate) liver biopsy.

Another focus of anxiety has concerned the possible hazard of the development of malignant disease. Metastasizing SCC of the skin has been described in a patient on long-term methotrexate [34]. Furthermore, long-term follow-up of a large cohort of patients on PUVA, and other treatments for psoriasis, has suggested a relative risk of 2 : 1 for SCC of the skin in those who have had high-dose methotrexate exposure (a probable cumulative dosage of more than 3 g over 4 years or more) versus low or no exposure. This risk was independent of PUVA therapy [35]. Careful examination of the skin at intervals would therefore be prudent in any patient on high cumulative dosage of methotrexate.

Anagen alopecia, cutaneous erosions, ulceration and bleeding are rare with weekly dose regimens [36]. Other uncommon side effects include epidermal necrolysis [36], candidiasis [36], folliculitis, ataxia [37], keratoconjunctivitis [38], depression and other psychotic symptoms [21], reactivation of tuberculosis [39] and other pulmonary illnesses [40]. Gastrointestinal bleeding has been reported. Fatal complications of therapy [21] have included rapidly progressive renal failure [41] and septicaemia, as well as the consequences of irreversible marrow or hepatic failure. Death has followed a single intravenous injection in a patient with severe renal failure. The majority of the published deaths are attributable to absolute or relative overdosage [21]. Renal damage is not a recognized hazard of conventional antipsoriatic dosage [41]. Oligospermia is an important hazard in men [42] and may persist long after the drug is withdrawn. Methotrexate osteopathy is a little-recognized complication of long-term low-dose treatment, affected patients presenting with the triad of severe pain localized to the distal tibia, osteoporosis and compression fractures of the distal tibia. The condition is readily confused with psoriatic arthropathy and, as the only treatment is said to be withdrawal of methotrexate, it is important that it should be recognized [43].

Despite these dangers, methotrexate has a secure place in the treatment of severe psoriasis that is physically or socially disabling, and which is resistant to conventional topical therapy and photochemotherapy. It is particularly valuable in the chronic erythrodermic and generalized pustular forms, where it may be life-saving, and for weaning such patients off systemic steroids. It is useful in intractable non-pustular forms of psoriasis of the hands and feet. Nevertheless, it has long-term hazards and it should never be used as an easy substitute for topical therapy. It should rarely be used in the first half of life, but this is sometimes inevitable, and the use of methotrexate (0.2–0.4 mg/kg/week) in children with severe psoriasis has been reported [44]. It is abortifacient and teratogenic in early pregnancy [45] and fertile patients should take contraceptive precautions. Conception should not be allowed within 3 months of stopping treatment, but is probably safe after that time [46].

In the event of accidental overdosage or unexpected acute toxicity, folinic acid should be given intramuscularly in full dosage (10 mg/m^2) and repeated every 6 h orally or parenterally as tolerated by the patient [15]. After the first dose, subsequent administration of folinic acid should ideally be governed by the serum methotrexate level [15]. Its effectiveness in counteracting the haematological toxicity of methotrexate diminishes with increasing delay.

Methotrexate has been combined successfully with various other therapies such as UVB phototherapy [47–49], PUVA [50] and etretinate [51], in the hope of reducing dosage and therefore toxicity of each modality, while maintaining efficacy. Methotrexate and etretinate should only be used with caution because of the risk of hepatitis. Combining methotrexate with ciclosporin [52] appears to be effective in patients (particularly those with psoriatic arthritis) in whom either drug as monotherapy is poorly tolerated and/or ineffective. This combination approach is analogous to that practised by rheumatologists. Reactivation of UV-induced erythema by methotrexate [47–49] ('erythema recall') may be a problem. Colchicine and methotrexate together have been used in generalized pustular psoriasis [53], and methotrexate can be used to maintain clearance induced by PUVA or a dithranol regimen [54]. However, in view of a report of possible cancer induction, care should be exercised in using PUVA and methotrexate concomitantly [55].

Hydroxyurea

Hydroxyurea is an antimetabolite that has been used principally for the treatment of malignant disease, particularly chronic myeloid leukaemia. The active drug, which is converted *in vivo* from its parent, blocks the conversion of ribonucleotides to deoxyribonucleotides by interfering with the enzyme ribonucleoside diphosphate reductase, thereby inhibiting DNA synthesis in proliferating cells [1,2]. Hydroxyurea was first recommended for psoriasis by Yarbro in 1969 [3,4]. It is quickly and well absorbed and excreted by the kidney. Bone marrow suppression is a common side effect of treatment with hydroxyurea, leukopenia is seen in most treated patients. Profound anaemia and thrombocytopenia occur less frequently, although a fall in haemoglobin to 110 g/dL is common [5–8]. Macrocytosis is almost universal. Irreversible bone marrow failure and death have not been reported. Because it is teratogenic, hydroxyurea must be avoided during pregnancy. Compared with methotrexate, it has the virtue of being a less frequent cause of anorexia, nausea and hepatoxicity. In the three largest case series of patients with

psoriasis treated with hydroxyurea [1,9,10], the reported satisfactory response rates have ranged from 45 to 80%. Clinical response is slow, and may become evident only over several weeks [4]. A therapeutic trial should therefore last at least 2 months. It is only modestly effective in palmoplantar pustulosis [11], and is less effective than methotrexate overall. That it may be a valuable reserve drug for patients needing systemic treatment and who are resistant to methotrexate or develop side effects, has been confirmed by a report of its use in 85 patients [1]. Hydroxyurea may be effective when other systemic drugs have failed, but is a less potent antipsoriatic agent. Its use has been advocated in combination with methotrexate [12], ciclosporin [13] and acitretin [14].

Regimens should rarely exceed 0.5 g three times daily, and sometimes 0.5 g once or twice daily long-term suffices for therapy [1,2]. A cutaneous vasculitis resulting from the drug has been reported [9,15]. Other recently recorded side effects include diffuse hyperpigmentation, actinic psoriasis, alopecia and psychological effects [1].

Retinoids

Vitamin A has long been recognized to have profound effects on epithelial differentiation, and the toxicity of hypervitaminosis A is well known. Deficiency causes cutaneous hyperkeratosis and squamous metaplasia of mucous membranes. This knowledge stimulated development of synthetic derivatives, and the term 'retinoid' has been applied to a family of natural and synthetic analogues of vitamin A [1,2].

Etretinate [3–6]

This analogue was first reported in 1975 by Ott and Bollag [7] to have antipsoriatic efficacy, and many subsequent reports have confirmed this [8–13]. In a dosage of 1 mg/kg/day, resolution of psoriasis vulgaris [9,10], pustular [10,14] and erythrodermic psoriasis [14] has been demonstrated. The usual initial dosage is between 0.5 and 1 mg/kg/day, and daily doses of 0.75–1 mg/kg/day are generally required for exfoliative and plaque psoriasis [3]. With the higher dosage level, side effects are inevitable (see below) [10,12,14]. Fortunately, response to higher dosage (1 mg/kg/day) is often rapid in generalized pustular psoriasis, beginning within days [14], and lower dosage of between 0.5 and 0.75 mg/kg/day may be sufficient to maintain control [3]. It has been regarded as the treatment of choice for generalized pustular psoriasis of the Zumbusch type, and need not necessarily be given continuously to maintain disease clearance [15]. Psoriasis vulgaris may be less responsive, and is often best treated by a combination of etretinate with another modality [3], allowing lower dosage of the retinoid or greater therapeutic effectiveness. Thus, corticosteroid cream [13,16], dithranol [17,18], tar [14], selective UVB phototherapy [11,19] and PUVA [20–22] all appear to have been successfully combined with etretinate, allowing maintenance dosage of 0.3–0.6 mg/kg/day or even lower. However, a randomized double-blind comparison of PUVA–etretinate and PUVA–placebo in chronic plaque psoriasis failed to show significant differences between the two regimens [23], although this could have been because of the small number of patients studied [24,25]. A subsequent randomized double-blind multicentre study showed that patients receiving PUVA–etretinate appear to undergo an additional response when compared with the PUVA–placebo group, but again this did not reach statistical significance [26], possibly for the reason given above [24,25]. A proportion of patients with palmoplantar pustulosis will improve with full dosage [10] or in combination with PUVA [27,28].

The combination of long-term methotrexate and etretinate has been reported to be useful in difficult cases, and the short-term use of this combination has been reviewed [29]. During a switch from methotrexate to etretinate, combination treatment may be justified for up to 8 weeks while the therapeutic effects of etretinate become established [6]. However, extreme caution should be exercised in view of the potential for toxic hepatitis and increased blood levels of methotrexate [6].

Etretinate has been used with success in children with generalized pustular psoriasis or psoriatic erythroderma [30,31]. The potential skeletal toxicity of retinoids in

childhood has been reviewed [30,31], and includes premature epiphyseal closure, growth retardation and hyperostosis during prolonged high-dose treatment, although this appears to be less common with etretinate than with isotretinoin treatment [31]. It has been argued that etretinate may be effective in childhood generalized pustular psoriasis if given in short intermittent courses (unlike the prolonged high dosage needed for keratinizing disorders), and that under these circumstances it may not be associated with skeletal changes and may be the treatment of choice if the only alternatives are methotrexate and systemic steroids [30]. However, retinoids should not be given to children except in compelling circumstances.

Side effects of etretinate are usually inevitable, but are often a nuisance rather than a real danger. The drug is lipophilic and progressively accumulates in the subcutis. After withdrawal, it disappears from the epidermis within 1 week, but remains in the subcutis for months and it is detectable in the plasma for up to 140 days after cessation of treatment [32]. Etretinate is teratogenic [17] and is strictly contraindicated in pregnancy. Fertile women must be warned of the teratogenicity and must maintain effective contraception during treatment and, in view of its lipophilicity, for 2 years after cessation of treatment [6]. There is no evidence for carcinogenicity or mutagenicity [14,17,33]. Effects on serum lipids are well known. The serum triglyceride level becomes elevated in approximately 75% of patients, and serum cholesterol in approximately 25%, although high-density lipoprotein cholesterol is unchanged [14]. The lipid abnormalities induced by etretinate, particularly the hypertriglyceridaemia, may be alleviated by concomitant administration of fish oils [34,35]. Minor elevations in serum levels of enzymes reflecting liver function occur in a minority of patients, but are often not of importance, and return to normal when the retinoid is withdrawn [14]. However, in one follow-up study of patients on long-term etretinate, clinically evident hepatitis and cirrhosis each occurred in 1% of patients [36]. In contrast, in a prospective study of patients receiving long-term etretinate, serial liver biopsies failed to show any significant pathology during treatment [37]. Prolonged retinoid treatment has been associated with radiographical spinal changes, including anterior spinal ligament calcification, osteophytes, bony bridges and disc abnormalities, resembling diffuse idiopathic skeletal hyperostosis (DISH). These changes may be asymptomatic or associated with back or neck stiffness [38]. Prior and periodic repeat spinal radiographical assessment should therefore be considered if long-term treatment is to be carried out. Other musculoskeletal changes are well recognized, and include arthralgia, objective arthritis, stiffness and myalgia, which can affect 25% of patients [6].

Additional clinical side effects are frequent and dose related [14,16]. Dryness of the lips, nose, eyes, mouth, throat or vagina is common, and full dosage may induce painful exfoliative cheilitis, urethritis, balanitis, gingivitis, peeling of the fingertips and corneal ulceration. Rhagades, palmoplantar desquamation, burning sensations in the skin, especially of the face, pruritus, skin atrophy, increased hair loss, epistaxis, increased bruising and widespread erythema are all very well recognized. Paronychia may be severe and purulent [10,16], forcing withdrawal of therapy. Rare complaints are of lethargy, headache, loss of taste and smell, nail plate thinning, increased sweating and generalized oedema [39,40]. Dark adaptation failure may cause night blindness.

To summarize, despite the high incidence of nuisance side effects, etretinate has been a valuable addition to the antipsoriatic weaponry, especially in generalized pustular psoriasis. The drug should not be used in children except in compelling circumstances nor in young women unless essential. Active liver disease and pre-existing hyperlipidaemia are contraindications to treatment. Etretinate has now been superceded in many countries by acitretin, which has a shorter half-life.

Isotretinoin (13-cis-retinoic acid)

Isotretinoin was reported to improve generalized pustular psoriasis, but additional therapy was required to produce satisfactory control during maintenance treatment. Isotretinoin was also found to be less effective than etretinate in the treatment of chronic plaque psoriasis [1]. However, it may have a place in the management of psoriasis in fertile females who urgently need treatment, in view of its short half-life [2], and has been advocated in combination with PUVA in this patient group [3].

Acitretin

This is the main active metabolite of etretinate. Being a free acid as opposed to an ester as in the case of etretinate, acitretin has the great advantage of decreased lipophilicity. It is therefore not sequestered in the adipose tissue, and has an elimination half-life of approximately 50 h compared to more than 80 days for etretinate [4,5]. Several clinical trials showed that the clinical efficacy and side effects of acitretin are similar to those of etretinate [6–11]. The greatly reduced half-life of acitretin compared with etretinate suggested that it would have clinical advantages over the latter, especially for women of child-bearing potential. Accordingly, marketing of etretinate ceased in the UK in 1993 and acitretin took its place. However, in an unpredictable number of patients, reversed metabolism of acitretin to etretinate has been found to occur [12]. It has therefore been essential for women on acitretin to avoid pregnancy during and for 2 years after the course, as in the case of etretinate. A further comparative study [13] confirmed the equal efficacy of etretinate and acitretin in psoriasis, but in this study etretinate was better tolerated both objectively and subjectively, and to an extent that was statistically significant. Limited recent experience also indicates that the occasional patient previously controlled on etretinate may not do well on acitretin but benefits from transfer back to etretinate once again [14]. Thus, the great advantages initially perceived for acitretin have not been realized in practice. If reversed metabolism to etretinate only occurs in 50% of subjects, albeit unpredictably [12], and the levels of etretinate thus obtained are low, this may confer a theoretically lower risk of fetal abnormalities in women becoming pregnant inadvertently before expiry of the 2-year period. The use of acitretin in fertile women therefore has a theoretical advantage, but it seems to have no major advantages over etretinate in other patients. In combination with PUVA, acitretin has been shown to be therapeutically superior to PUVA with placebo. Acitretin in a regimen of 50 mg/day for 2 weeks followed by up to 10 weeks of 25 mg/day combined with PUVA significantly reduced the number of PUVA treatments required for clearance and the cumulative dosage of UVA (by 40%) [15]. These results were confirmed by Tanew [16], in that acitretin at 1 mg/kg/day in addition to PUVA reduced the total UVA dosage and time to clearance. Similarly, acitretin enhances the efficacy of broad-band UVB in that the number of subjects who improve or clear with the combination therapy is significantly greater than with UVB alone: 60 versus 24% in one study [17] and 74 and 35%, respectively, in another [18]. Acitretin may also reduce the photo-ageing effects of

phototherapy and act as a chemopreventive against the development of cutaneous malignancy. This benefit has not been proven, but extrapolates from the known effects of retinoids on photo-aged skin and as chemopreventive agents in kidney transplant recipients [19,20]. A review of acitretin combination therapy with UVB or PUVA has recently been published [21].

The side effect profile of acitretin is generally similar to that of etretinate [5–10,22–24]. Although apparently 1.5% of patients on acitretin may develop a toxic hepatitis, there is no histological evidence of hepatoxicity on liver biopsy [25]. The starting daily dosage in adults is usually 25 mg, the optimum being about 50 mg (0.66 mg/kg/day) depending on therapeutic response and side effects.

Ciclosporin

The antilymphocytic effects of ciclosporin, a cyclic undecapeptide derived from the fungus *Tolypocladium inflatum* Gams, were first described in 1976 [1]. The ability of ciclosporin to clear the skin lesions of psoriasis was first noted in four patients in 1979, as an incidental finding during a trial of this drug in inflammatory arthritis [2].

This information appears to have been somewhat disregarded until 1984, when the dramatic therapeutic effect of ciclosporin was again noted in a single patient with otherwise unresponsive psoriasis [3]. Subsequently, several case reports appeared [4–10], followed by unequivocal evidence for therapeutic efficacy in the form of double-blind placebo-controlled trials with both high [11] and lower [12,13] dosage. The mechanism of action of ciclosporin in psoriasis is not entirely certain, but is likely to be related to its inhibitory effects on T-cell activation [14], a possibility that has substantially affected attitudes towards pathogenic mechanisms in psoriasis.

Ciclosporin is highly lipophilic, but is active orally and metabolized in the liver by the cytochrome P-450 system. A series of consensus conferences on its use in psoriasis have been held and the proceedings published [15–17]. Briefly, a twice daily oral regimen is recommended. The side effects associated with ciclosporin (see below) demand that it should be given only to patients with sufficiently severe disease, in whom less toxic forms of treatment have been unsuccessful. Such treatment should include conventional topical therapy, if possible carried out in an in-patient department or day-treatment centre on at least one occasion, UVB, PUVA and possibly a retinoid. However, the prolonged use of high-dose PUVA may predispose certain patients to skin malignancy, and constitute a relative contraindication to ciclosporin. The choice between ciclosporin and methotrexate is not straightforward, the latter being thoroughly tried, relatively safe in the right hands and much cheaper, but currently requiring repeated invasive investigation in the form of liver biopsies. There has, to date, been no published head-to-head comparison of the two drugs in the treatment of psoriasis. Ciclosporin should not be given to unreliable patients or if regular

monitoring for side effects is not possible. Other major exclusion criteria include renal dysfunction, uncontrolled hypertension, past or present malignancy, history of epilepsy, acute infections, other immunosuppressive therapy, concomitant therapy with nephrotoxins, previous serious side effects from ciclosporin and known hypersensitivity. Minor exclusion criteria include abnormal liver function, previous therapy that may predispose to skin malignancy, malabsorption, drug or alcohol abuse, and concomitant treatment with drugs that affect the metabolism of ciclosporin. NSAIDs are often used by patients with psoriatic arthropathy, and may enhance the nephrotoxicity of ciclosporin (see below). Other drugs interacting with ciclosporin are described in a consensus report [17] and elsewhere [14], and include anticonvulsants which induce hepatic cytochrome P-450 and thus enhance metabolism of ciclosporin, which may never reach therapeutic blood levels [18].

An initial daily oral regimen of 2.5 mg/kg equally divided in two doses has been recommended. Improvement may be seen within days, but if this does not occur within 2 weeks, the dosage may be increased gradually to a maximum of 5 mg/kg/day [14,17]. Maintenance dosage should be reduced to the minimum that allows adequate control and, as for methotrexate, the aim should not be to achieve complete clearance. Withdrawal of ciclosporin in patients with severe psoriasis is usually associated with relapse within weeks but, with few exceptions [19], has not been associated with the severe rebound phenomenon seen following withdrawal of systemic steroids. In patients with moderately severe chronic psoriasis, the relapse rate (41% at 6 months) following cessation of ciclosporin therapy (5 mg/kg/day) was no greater than that seen with dithranol or PUVA [20]. A systematic review of therapies for severe psoriasis [21] concluded that 'ciclosporin is a well-tested treatment for severe psoriasis and in the short term is probably more effective than other forms of systemic therapy'. Ideally, ciclosporin should be used for short courses of 3–4 months' maximum duration [22,23]. Only in exceptional circumstances should ciclosporin be used as continuous therapy for periods exceeding 6 months. The accepted modern regimen (intermittent short courses of ciclosporin) is effective for at least 2 years—most patients require less than four courses of treatment over this time with good control of the disease and no significant side effects [23]. A Japanese study that compared intermittent with continuous ciclosporin for psoriasis showed that an intermittent regimen was probably safer [24].

The most important side effects associated with ciclosporin are dose-related hypertension and nephrotoxicity. The blood pressure may rise sharply within weeks of starting treatment, and plasma creatinine levels may increase or glomerular filtration rates decrease within the same period [14]. Immunosuppression associated with the long-term use of ciclosporin may increase the risk of cutaneous malignancy, especially in patients who have previously had high-dose UV irradiation, PUVA, Goeckerman regimens or arsenic. SCCs of the skin have been reported in patients receiving ciclosporin for psoriasis [14]. A prospective 5-year survey of 1252 European patients with psoriasis who had on average received ciclosporin for 1.9 years [25] found that ciclosporin produced a sixfold increase in risk for developing non-melanoma skin cancer (mainly SCC). The risk was compounded by contributions from PUVA and other immunosuppressants such as methotrexate. There was no increase in non-cutaneous malignancies. Lymphoproliferative disorders are an important risk of high-dose immunosuppressive treatment in transplant recipients, although these diseases were not more common in transplant recipients receiving ciclosporin than in those not receiving it [14]. Eight malignant lymphomas developed in more than 6000 patients receiving ciclosporin for autoimmune disorders, although a causal relationship was not proved [14]. Overall, there is no clear association between ciclosporin treatment and a risk of other internal malignancies, although cases have been reported [26,27] and vigilance is essential. The finding of cervical intraepithelial neoplasia associated with possible human papillomavirus infection underlines the need for cervical smears in female patients on ciclosporin, perhaps every 6 months [14,27]. Human papillomavirus-associated penile carcinoma has also been reported [28]. Other side effects include elevated serum potassium and uric acid levels, decreased serum magnesium, mild normochromic normocytic anaemia, gum hyperplasia, hypertrichosis, acral paraesthesia or hyperaesthesia, tremor, altered liver-function tests and gastrointestinal intolerance [14]. Gum hyperplasia is associated with poor dental hygiene and regular dental check-ups are recommended. The hyperplasia may respond to treatment with azithromycin [29].

Regular monitoring is therefore essential during ciclosporin therapy, and has been reviewed [14,17]. It was recommended in an earlier review that ciclosporin should be used only in patients with normal glomerular filtration rates, and that this investigation should be repeated every few months [14]. However, the last consensus conference [17] recommended serum creatinine measurements every 2 weeks for the first 6 weeks, then monthly for the duration of ciclosporin treatment. Great care should be exercised in preventing sustained rises in serum creatinine to more than 30% above baseline, even if the level remains within the normal range. Should this rise occur, an estimation of serum creatinine should be repeated within 2 weeks, and the dosage of ciclosporin reduced if the elevation is sustained. Ciclosporin treatment may be continued if the serum creatinine then falls to within the 30% range, but if not, treatment should be stopped. It appears that rigorous adherence to the above protocol should prevent

significant renal injury. Irreversible renal structural changes may occur but will be minor and of no functional significance, and there have been no cases of progressive deterioration of renal function after stopping ciclosporin if these guidelines are followed. Inherent in the protocol is the need to establish a stable pretreatment serum creatinine, by carrying out at least two independent estimations. Persistent diastolic blood pressure above 95 mmHg is an indication for dosage reduction or, if this precipitates a relapse, treatment with a calcium-channel antagonist such as nifedipine is the preferred option [30]. Diltiazem and verapamil are not recommended as they inhibit the metabolism of ciclosporin [17]. Potassium-sparing diuretics are also best avoided as ciclosporin may raise serum potassium levels [17]. The occurrence of malignancy would usually lead to withdrawal of ciclosporin, but this may not be an absolute rule if, for example, a cutaneous basal cell carcinoma is easily treated and the need for ciclosporin is compelling. There is no evidence that monitoring of serum trough levels of ciclosporin is indicated during treatment of psoriasis unless there is doubt about compliance and/or absorption of the drug [31].

Ciclosporin is now marketed in a new microemulsion formulation (Neoral®), which provides more predictable absorbance following oral administration, better bioavailability and improved therapeutic efficacy in severe psoriasis [32]. This is now the formulation of choice.

Systemic glucocorticosteroids [1]

The glucocorticosteroids (steroids) have shown themselves to be double-edged weapons. The fluorinated forms such as triamcinolone and betamethasone have more effect on psoriasis than prednisolone [2,3]. When triamcinolone, 12–20 mg/day, is given for the first time, clearance of the psoriasis is rapid but the disease usually eventually 'breaks through', necessitating progressive increases in dosage and incidence of side effects [4]. If withdrawal is attempted, the psoriasis tends to relapse often promptly [4] and may 'rebound'. 'Rebound' may take the form of widespread small-patterned eruptive psoriasis often involving the face and backs of hands. Erythrodermic or generalized pustular phases may be precipitated [1,5]. Systemic steroids should not be used in the routine care of psoriasis. They do have a role in the management of persistent, otherwise uncontrollable erythroderma that is causing metabolic complications and in fulminating generalized pustular psoriasis of the von Zumbusch type [6] if other drugs are contraindicated or ineffective. Associated

psoriatic arthropathy is not an indication *per se*, but steroids may occasionally be needed, and in high dosage (prednisolone 40 mg/day initially), to control hyperacute polyarthritis that is threatening severe irreversible joint damage. Patients with psoriasis who have concomitant psoriatic arthritis controlled with low-dose steroids often have active labile skin disease that is difficult to control [7].

Psoriasis may remain labile and treatment resistant for many months after the withdrawal of systemic corticosteroids [8].

6-Thioguanine

6-Thioguanine is closely related to 6-mercaptopurine. The observations of one group [9] led to studies confirming that thioguanine appears to be effective in psoriasis [10]. Further experience in 81 patients was reported [11]. This drug may prove to be a useful alternative when other forms of treatment have failed. In 21 patients with severe psoriasis that had failed to respond to other systemic therapies, 14 of 18 had greater than 90% improvement in psoriasis [12]. Treatment was for an average of 15 months and regimens ranged from 20 mg twice weekly to 120 mg/day. Bone marrow toxicity is common, and is usually inevitable if an effect on psoriasis is to be seen. Increased liver enzymes are also seen and veno-occlusive disease of the liver may be a consequence of therapy [13], but preliminary evidence suggests that 6-thioguanine does not induce hepatic fibrosis [11]. Clearance of psoriasis correlates with depletion of T cells in the skin [14].

Fumaric acid esters (fumarates)

For more than 20 years fumarates have been used extensively in northern Europe, particularly German-speaking countries, for the treatment of moderate to severe psoriasis [15,16]. The commercially available preparation of fumarates, Fumaderm, comprises a mixture of dimethylfumarate and the calcium magnesium and zinc salts of monoethylfumaric acid. After ingestion, dimethylfumarate is hydrolysed to monomethylfumarate—the main active metabolite. Clinical trials [17–19] attest to the efficacy of fumarates. The drug is introduced gradually, starting at 30 mg/day, building up over several weeks to a maximum dosage of 240 mg three times daily. It is estimated that if they tolerate the drug then approximately 57% of patients will achieve a 70% reduction in severity of psoriasis. Two-thirds of treated patients develop gastrointestinal symptoms such as dyspepsia and diarrhoea; one-third of patients develop flushing. In most patients these side effects settle down over time. Lymphocyte counts fall in nearly all treated patients, sometimes by 50% [17,19]. Renal function and liver function should be monitored but impairment is unusual. The mechanism of action of fumarates appears to be an ability to promote the secretion of Th2 cytokines [20], such as IL-10, which are beneficial in psoriasis.

Miscellaneous therapies

Sulfasalazine

Sulfasalazine (sulphasalazine) is an anti-inflammatory agent, 5-{[*p*-(2-pyridylsulfamoyl)phenyl]azo}salicylic acid, commonly used in the treatment of inflammatory bowel disease. One open study and one randomized controlled trial provide evidence that sulfasalazine for 8 weeks at 3–4 g/day can produce marked improvement in about

one-third of patients [1,2]. Approximately 25% of patients find the side effects of headache, nausea and vomiting disabling. Oligospermia, pruritus and haemolytic anaemia may occur. Sulfasalazine is a useful alternative systemic therapy for psoriasis.

Azathioprine

This is a synthetic purine analogue synthesized by attaching 6-mercaptopurine to an imidazole ring—*in vivo* it is converted to its active metabolite 6-mercaptopurine by hepatic xanthine oxidase. Several uncontrolled or case studies [3–5] describe efficacy in psoriasis but, in the absence of data from controlled trials, it is best to conclude that there is no good evidence that azathioprine is an effective treatment for psoriasis. The most important side effect is bone marrow suppression.

Mycophenolate mofetil

Following ingestion, mycophenolate mofetil (MMF) is hydrolysed to its active metabolite—mycophenolic acid. Mycophenolic acid inhibits inosine 5′-monophosphate dehydrogenase, a key enzyme in *de novo* purine synthesis —this results in blockade of T- and B-cell proliferation. Dosage is 1–2 g/day increased to a maximum of 4 g/day. MMF is only moderately effective as monotherapy for psoriasis [6–8], but its place in the therapy of severe psoriasis is probably in combination with ciclosporin as a ciclosporin-sparing agent [9,10], used at an average dosage of 1–2 g/day. Side effects include gastrointestinal symptoms and bone marrow suppression.

Tacrolimus and pimecrolimus

Despite the undoubted efficacy of ciclosporin in the treatment of psoriasis, its long-term use is limited by nephrotoxicity and hypertension. In an effort to find drugs that have a similar mechanism of action, namely blockade of calcineurin phosphatase and consequent inhibition of T-cell activation, a number of drugs structurally dissimilar to ciclosporin, but with a similar mechanism of action, have been investigated.

Tacrolimus and pimecrolimus, both of which are derived from species of the soil fungus *Streptomyces*, have been trialled for the treatment of severe psoriasis. Oral tacrolimus at a dosage of 0.05–0.15 mg/kg/day can significantly improve severe psoriasis in the short term (10 weeks) [11,12]. Side effects include paraesthesia, headache and minor elevations in serum creatinine and blood pressure. Tacrolimus is rarely used for the treatment of psoriasis, but is a useful alternative.

Oral pimecrolimus is under clinical trial development for the treatment of severe psoriasis following the highly promising results of a 4-week trial [13]. Side effects were minimal, with no effect on either blood pressure or serum creatinine.

Biological therapies

Biological therapies directed at selected targets integral to the pathogenesis of psoriasis are the logical progression of the biotechnological revolution. This arises from a more detailed knowledge of the roles of T cells, pro-inflammatory cytokines and Th1 cytokines in psoriasis. Several of these therapies are under active development for psoriasis and two, alefacept and efalizumab, are already approved for this indication in the USA. Furthermore, the use of these selective therapies allows detailed investigation of the immune processes involved in psoriasis. Two main approaches are under development: (i) targeting of T cells; and (ii) cytokine modulation [14].

T-cell targeting

Case reports of the efficacy of monoclonal antibodies to CD4 (expressed by T cells) as therapy for psoriasis provided initial encouragement that a T-cell targeted approach would be effective in the management of psoriasis [15,16]. An IL-2 diphtheria fusion toxin (Denileukin diftitox) that specifically targets and lyses cells which express the high affinity IL-2 receptor—predominantly T cells—can significantly and rapidly improve psoriasis. Side effects including coagulopathy have hindered its development as a therapy for psoriasis, but its demonstrable efficacy further underlined the key role that T cells have in psoriasis [17].

Most investigational approaches involve blockade of T-cell binding to antigen-presenting cells, a process mediated by co-stimulatory molecules, thereby inhibiting T-cell activation. Alefacept, a lymphocyte function-associated molecule-3 (LFA-3)–IgG1 fusion protein, blocks CD2–LFA-3 binding, and also apoptoses peripheral lymphocytes belonging to the $CD45RO^+$ memory effector subset. Controlled trials indicate that alefacept, whether delivered by intravenous or intramuscular route once weekly over a 12-week course, significantly improves psoriasis in approximately 30% of subjects [18,19]. A small proportion of patients may go into long-term remission. In the short to medium term, alefacept appears to be safe; it was the first biological agent to be licensed for the treatment of psoriasis.

Efalizumab is a humanized monoclonal antibody to CD11a (LFA-1). CD11a is expressed on leukocytes. Efalizumab blocks T-cell binding to ICAM-1 on antigen-presenting cells and endothelium, thereby inhibiting T-cell activation and T-cell trafficking from peripheral blood into the skin. It is administered once weekly subcutaneously. Results are similar to those reported for alefacept in that 30% of patients show significant clinical improvement, but it has a faster onset of action [20].

Daclizumab, a humanized monoclonal antibody to the α subunit of CD25, blocks binding of IL-2 to activated T cells. Early trials indicate a moderate beneficial effect on psoriasis [21]. Basiliximab is a chimeric human–mouse antibody to CD25. This is already licensed for the treatment of acute solid organ graft rejection, where it is used in combination with ciclosporin. This same combination is effective in severe psoriasis, but seemingly only in those cases where disease is rapidly progressive, such as generalized pustulosis [22,23].

Not all biological therapies are effective, despite good scientific rationale for use. For instance, T-cell adherence to endothelium via cutaneous lymphocyte-associated antigen (CLA)–E-selectin binding is considered a critical step in skin inflammation. However, a placebo-controlled trial of a humanized antibody to E-selectin in psoriasis was unable to demonstrate any efficacy despite adequate blood levels [24].

Cytokine blockers

TNF-α is a ubiquitous pro-inflammatory cytokine involved in inflammation. Anti-TNF-α blockers initially developed for therapy of rheumatoid arthritis are in advanced trials for psoriasis. The two main agents are infliximab, a chimeric human–murine IgG antibody to TNF-α; and etanercept, a dimeric fusion protein consisting of the extracellular portion of the human p75 TNF-α receptor linked to the Fc portion of human IgG1. A serendipitous observation of the efficacy of infliximab for psoriasis in a patient with concomitant Crohn's disease and psoriasis [25] led to placebo-controlled trials. These trials show that infliximab delivered intravenously at 5 mg/kg on three occasions at 0, 2 and 6 weeks is a highly effective therapy for severe psoriasis—approximately 85% of treated subjects achieve significant clinical improvement [26,27]. In the management of rheumatoid arthritis, infliximab is combined with methotrexate—this combination is also effective for psoriasis [28] and may reduce the occurrence of infusion reactions. Infliximab can be associated with reactivation of pulmonary tuberculosis.

Etanercept is less effective than infliximab and is given twice weekly by self-administered subcutaneous injection —approximately 30% of patients achieve significant benefit from 12 weeks treatment [29,30]. It is approved for use in psoriatic arthritis.

Cytokines

Plaques of psoriasis contain a predominance of Th1 cytokines such as IL-2, IL-12 and IFN-γ. Systemic administration of Th2 cytokines such as IL-4 or IL-10 appears to neutralize the Th1 bias and improve psoriasis. IL-10 was the first Th2 cytokine to be used for treatment of psoriasis. Phase II trials show that subcutaneous injections of recombinant IL-10 given either daily or three times weekly produce a mean reduction in psoriasis severity of 50% [31,32]. This response is associated with a Th2 cytokine shift and, when used as maintenance therapy, length of remission correlates with T-cell production of IL-4 [33]. Recently, systemic administration of IL-4, in an open study, has demonstrated very significant reduction in clinical severity of psoriasis [34].

Zidovudine (azidothymidine, AZT)

The skin lesions of patients with therapy-resistant AIDS-associated psoriasis have been reported to clear with oral zidovudine [35,36]. This drug may be the treatment of choice for retinoid-resistant AIDS-associated psoriasis, as therapies such as methotrexate, ciclosporin and PUVA may be contraindicated.

Somatostatin

Following uncontrolled reports of the efficacy of somatostatin in psoriasis, a double-blind placebo-controlled study of intravenous somatostatin suggested benefit in recalcitrant psoriasis [37].

Liarozole

Liarozole, a member of the imidazole family and an inhibitor of retinoic acid 4-hydroxylase, belongs to a new class of drugs, the retinoic acid metabolism blockers. It delivers a retinoid-like effect by increasing endogenous levels of naturally occurring all-*trans*-retinoic acid and other retinoids upstream of retinoic acid 4-hydroxylase. The advantage of liarozole over acitretin is that the raised levels of retinoic acid return to normal within a few days of cessation of therapy. Early trials [38,39] indicate that liarozole is effective for chronic plaque psoriasis. Side effects are 'retinoid' in nature (teratogenicity, hyperlipidaemia and mucocutaneous symptoms).

Troglitazone

The thiazolidinediones are ligands of the nuclear hormone receptor peroxisome proliferator activated receptor-γ (PPARγ). Troglitazone, a member of this family, is used to treat diabetes mellitus. A small open study established that oral troglitazone therapy improved psoriasis accompanied by normalization of the histological features of psoriasis [40]. Hepatotoxicity enforced the withdrawal of troglitazone but further studies in psoriasis are being performed with rosiglitazone.

Gluten-free diet

Studies, primarily from Sweden [41,42], have established

that approximately 16% of patients with psoriasis have IgA and IgG antibodies to gliadin. In a further study [43], 33 psoriasis patients with IgA antibodies to gliadin (15 of whom had evidence of a lymphocytic infiltrate in the duodenal epithelium) were placed on a gluten-free diet for 3 months. All 33 patients had significant improvement in psoriasis severity while on the diet. These fascinating results indicate that in a very few patients a gluten-free diet may be worth trying if antigliadin antibodies are present.

Photodynamic therapy

Photodynamic therapy has been investigated for the treatment of small plaques of psoriasis. Using 5-aminolaevulinic acid as the topical photosensitizer has produced improvement in the treated plaques, but use is limited by local pain at the site of treatment [44,45]. Further work is required to ascertain the value of photodynamic therapy for treatment of psoriasis—if larger plaques could be treated in a relatively painless manner then this would be an advance.

Lasers

Recalcitrant plaques of psoriasis have been treated with lasers. Local destruction of psoriatic epidermis using CO_2 laser resurfacing gave mixed results [46,47]; further investigation is required. Pulsed dye laser (585 nm) therapy appears to be more effective than the CO_2 laser; indeed some plaques treated with pulsed dye laser remain in remission for a year or more [48,49].

Excimer laser-generated 308-nm UVB radiation is the laser source most likely to be used for routine management of psoriasis. The UVB source is handheld and delivers high-intensity UVB selectively directed to plaques, thereby sparing uninvolved skin. Controlled trials show it to be safe and effective for localized plaques, and it requires fewer treatments than conventional phototherapy [50,51].

Dialysis and related therapies [1,2]

The clearing of incidental psoriasis during haemodialysis for uraemia was reported in 1976 [3]. Others then recorded similar experiences with both haemodialysis and peritoneal dialysis [4–6]. It soon became clear that dialysis could favourably influence psoriasis in patients with normal renal function [1,6–9] and that peritoneal dialysis is more effective than haemodialysis [1,9,10], possibly because substances of higher molecular weight can be removed in larger quantities [2].

Success rates with dialysis have been variable. Although some patients clear completely, others do not improve, and successfully treated patients may relapse quickly afterwards [4,8]. Not all have achieved success [11] and, confusingly, there are several reports of psoriasis worsening or appearing *de novo* during chronic haemodialysis for renal disease [12–14].

Plasmapheresis and leukapheresis were ineffective, findings that led to the suggestion that there is no pathogenic circulating factor or leukocyte abnormality in psoriasis [15,16].

Pustular forms of psoriasis

Neutrophilic accumulation in the epidermis is a characteristic histological feature of all types and patterns of psoriasis, but in clinical practice the term 'pustular psoriasis' is reserved for those forms of the disease in which macroscopic pustules appear.

It is convenient to separate two main types of pustular psoriasis: localized and generalized. In the localized forms, the disease is confined to the hands and feet and tends to be chronic. In the generalized forms, the whole body may be involved and the course is subacute, acute or even fulminating and life-threatening.

A convenient classification is as follows.

1 Localized pustular psoriasis:
  (a) chronic palmoplantar
  (b) acrodermatitis continua
2 Generalized pustular psoriasis:
  (a) acute
  (b) of pregnancy
  (c) infantile and juvenile
  (d) circinate
  (e) localized (not hands and feet).

Localized pustular psoriasis

Palmoplantar pustulosis

SYN. CHRONIC PALMOPLANTAR PUSTULAR PSORIASIS; PUSTULOSIS PALMARIS ET PLANTARIS; PERSISTENT PALMOPLANTAR PUSTULOSIS

Definition. A common condition in which erythematous and scaly plaques studded with sterile pustules persist on the palms or soles. The disease is chronic and very resistant to treatment.

Pathogenesis. The relationship of palmoplantar pustulosis (PPP) to psoriasis vulgaris is controversial [1,2]. Sometimes the presence of typical psoriasis elsewhere, or a personal or strong family history of psoriasis, or the future development of psoriasis vulgaris, establishes the relationship. However, typical PPP often occurs in the absence of such evidence [1–3]. This, and the absence of immunogenetic associations characteristic of psoriasis (see below) in such patients, suggest that some forms of PPP may represent a separate and distinct entity. Furthermore, PPP is more common in females, unlike psoriasis vulgaris there is no seasonal variation, and it tends to start at a later age [2].

HLA antigens. HLA-B13 and -B17 are not associated with PPP [4–6]. Three potential candidate genes for psoriasis susceptibility reside within *PSORS1* locus on chromosome 6, HLA-Cw6, *HCR WWCC* and the *CD5N5*. A recent immunogenetic study demonstrated categorically that PPP is not associated with any of the three candidate genes —indicating that it is a distinct disorder [7]. Combining the results of these and other studies, it may be concluded that there is no predominant HLA locus associated with PPP [2].

Provocative factors. PPP usually starts without obvious provocation. Septic foci have been blamed [1,8,9] but their removal may not cure the eruption [8]. The disease has appeared for the first time after several months of treatment with lithium [10]. Japanese otolaryngologists remain interested in the tonsils as a site of relevant focal infection [11]. Smoking has also been reported as a possible provoking factor [12]. An immunohistochemical study of biopsies of palmar skin revealed an altered staining pattern for nicotinic acetylcholine receptors in PPP—the authors suggested that an abnormal response to nicotine in patients with PPP resulted in inflammation [13].

Clinical features [1–3]. PPP is a disease of adults and is rare in children. It usually starts in the fifth or sixth decade, although sometimes earlier. In most series, there has been a preponderance of women [4]. The disease presents with one or more well-defined plaques. On the hands, the thenar eminence is the most common site. Less commonly, the hypothenar eminence or the central palm or the distal palm are involved. On the feet, the instep, the medial or lateral border of the foot at the level of the instep, or the sides or back of the heel are involved. Less frequently, the distal sole or the whole sole is implicated. Digital lesions are uncommon. A striking symmetry of the lesions on the hands or feet is common, but sometimes a solitary lesion persists for weeks or months before others appear.

The affected area is dusky red and often scaly. Removal of scale (e.g. by treatment) leaves a glazed dull-red surface. Within this plaque, numerous pustules are present, usually 2–5 mm in diameter. Fresh pustules are yellow; older ones are yellow-brown or dark brown as the pustule dries. Eventually, the desiccated pustule is exfoliated. Normally, pustules in all stages of evolution are seen (Fig. 35.23). Itching is variable; more often the patient complains of 'burning' discomfort in the lesions.

Associations. A significant incidence of hyper- and hypothyroidism and the presence of thyroid antibodies has been found in association with PPP [5–7]. A greater tendency to develop diabetes was found in a Japanese study [8]. Various arthropathies are also associated [9], including chronic recurrent multifocal osteomyelitis [10,11], sternoclavicular involvement [12,13], pustular arthro-osteitis, axial and peripheral arthritis [9,14]. The association of some of these conditions with PPP may represent part of the spectrum of SAPHO syndrome [15]. More than

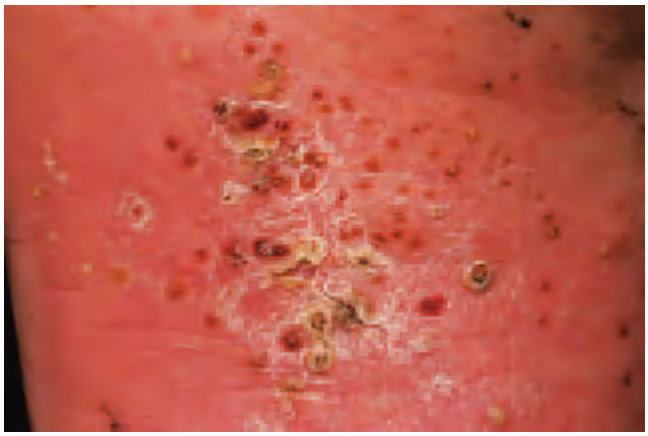

Fig. 35.23 Palmoplantar pustulosis. Note pustules in different stages of evolution. (Courtesy of St John's Institute of Dermatology, London, UK.)

90% of patients with PPP are current or previous smokers [5,16]. Some patients have antigliadin antibodies [5].

Differential diagnosis. Tinea and eczema are the most common alternatives. Tinea is usually asymmetrical or unilateral. The toe clefts may be involved. Acute vesiculopustular tinea is more common in hot weather. Microscopy and culture confirm the diagnosis. Secondary infection of eczema may be pustular but is more painful, and Gram stains and culture of pustule contents will establish the diagnosis. Chronic allergic contact dermatitis caused by rubber in footwear should not cause difficulties. Typically, the insteps are spared. The chronic acropustulosis seen in black infants does not occur in adults, and affects the digits and dorsal aspects of the extremities as well as the palms and soles [17,18].

Prognosis. The usual course is prolonged. Sometimes spontaneous remission does occur but is more often temporary than permanent. Slow spread or extension may be refractory to all treatment.

Pustular bacterid

This term was first used [19] to describe an acute monomorphic eruption of sterile pustules occurring on the hands and feet (Fig. 35.24). Whether it is a distinct entity or merely an acute variant of PPP is unclear. The term 'bacterid' implies that the eruption is provoked by a remote bacterial infection.

Fig. 35.25 Acrodermatitis continua with destruction of nail plate. (Courtesy of St John's Institute of Dermatology, London, UK.)

Acrodermatitis continua

SYN. ACROPUSTULOSIS; PUSTULAR ACRODERMATITIS; ACRODERMATITIS PERSTANS; DERMATITIS REPENS; ACRODERMATITIS CONTINUA OF HALLOPEAU

Definition. A chronic, sterile, pustular eruption affecting initially the tips of fingers or toes that tends slowly to extend locally but which, in adults, may evolve into generalized pustular psoriasis.

Clinical features. Whereas PPP is a disease of middle life, acrodermatitis may be seen in children. It is rare in young adults and, unlike PPP, not infrequently begins in old age. It is more common in females.

The first lesion starts on a finger or thumb more often than on a toe. Onset is often related by the patient to minor trauma, or infection at the tip of the digit. The skin over the distal phalanx becomes red and scaly, and pustules develop. The nail folds and nail bed may be involved, leading to nail dystrophy. The proximal edge of the lesion is bordered by a fringe of undermined epidermis, irregular, often sodden and sometimes preceded by a line of vesiculopustules. Removal of scale or desiccation of pustules may leave a brighter red, glazed, very sore and painful digit. Slow proximal extension is the rule but this may be spread over years. Eventually, other digits may be involved. The nail plate may be completely destroyed (Fig. 35.25). Bony changes can occur with osteolysis of the tuft of the distal phalanx [1]. The free end of the digit may become wasted and tapered, mimicking scleroderma. In such digits, the circulation may be secondarily affected so that discomfort is greatest in cold weather.

Acrodermatitis continua may evolve into generalized pustular psoriasis, especially in the elderly [2]. The tongue may become involved with fissuring or the annulus migrans of pustular psoriasis [3].

Differential diagnosis. In the earliest stage, staphylococcal infection, pulp infection, herpetic whitlow, tinea or contact dermatitis may be suspected. Candidiasis is only likely to be a problem in the immunocompromised. Parakeratosis pustulosa [4] should be considered in children.

4 Hjorth N, Thomsen K. Parakeratosis pustulosa. *Br J Dermatol* 1967; **79**: 527–32.

Histopathology

The changes are essentially psoriatic, but the central feature is a fully developed, large pustule within the epidermis, unilocular and full of neutrophils (Fig. 35.26). Spongiform pustules may be found in the wall of the larger unilocular pustule. There is some overlying parakeratosis. The acrosyringium is involved in the inflammation, and there are at times large numbers of eosinophils and mast cells present [1].

Management

Effective therapy is elusive and treatment is often as disappointing for the physician as for the patient. In view of the finding that PPP is an immunogenetically distinct dis-

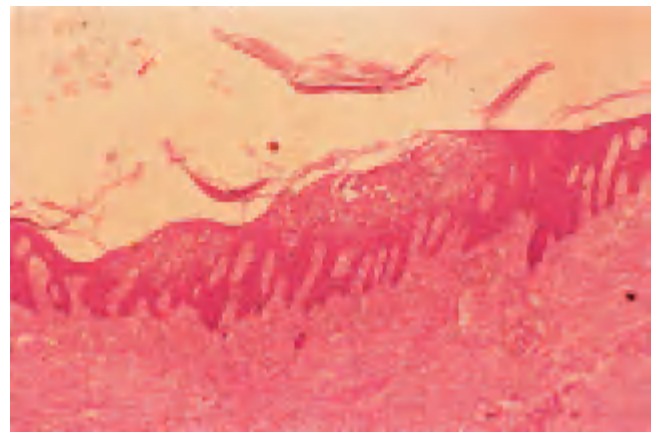

Fig. 35.26 Pustular psoriasis: intraepidermal pustule packed with neutrophils. (Courtesy of St John's Institute of Dermatology, London, UK.)

ease from psoriasis vulgaris [2], it is perhaps unsurprising that using traditional therapies for the treatment of PPP is not ideal. The choice of treatment is influenced by its side effect profile. It is usual to start with topical therapy but topical treatments alone tend to be ineffective for PPP [3]. Superpotent topical corticosteroids may be beneficial in the short term. Hydrocolloid gel occlusion can enhance efficacy of moderate potency steroid cream, which is applied every third day up to a maximum of 4 weeks [4,5]. Atrophy, particularly of the skin around the medial longitudinal arch, is a significant risk. There are no published controlled trials to support efficacy of coal tar or dithranol [3]. Tar-impregnated occlusive bandages may be helpful for acrodermatitis continua. Neither calcipotriol nor tazarotene have been formally evaluated for the treatment of PPP. Studies of topical psoralens in either soak, paint or gel form have failed to demonstrate superiority over placebo [6]. Open studies, particularly for 8-MOP soaks, indicate efficacy; in one study the majority of patients achieved remission [7].

Systemic therapies offer the best opportunity for remission. Oral retinoids either alone or in combination with oral PUVA are the best of the second-line therapies [8–11]. Etretinate at a dosage of 0.6 mg/kg/day produces objective improvement [8,9] in at least two-thirds of PPP patients—an efficacy that is matched by acitretin [10]. Liarozole—an imidazole derivative that blocks metabolism of all-*trans*-retinoic acid and thus boosts endogeneous levels of retinoids, may be effective—as shown in a small placebo-controlled study [12]. Oral PUVA is effective [9,13] and the response is enhanced by combination with etretinate (Re–PUVA) [13–15]. Various other forms of oral therapy have been used. Placebo-controlled trials of clomocycline 170 mg three times daily [16] or tetracycline 250 mg twice daily [17] have demonstrated efficacy in PPP. Ciclosporin at the low dosage of 2.5 mg/kg/day significantly improved PPP in most patients [18]—this placebo-controlled trial confirmed observations made in earlier open trials [19,20]. Dosage as low as 1 mg/kg/day may be effective [21]. Colchicine, known to influence neutrophil function, has been claimed to be effective [22] but randomized controlled trials have not confirmed this [23,24]. Methotrexate is occasionally beneficial, but an open study refutes this claim [25]. Anecdotal evidence exists for dapsone [26] and clofazimine [27], and grenz ray therapy may be a useful adjunct [28]. Oral corticosteroids should be used with extreme caution; triamcinolone in a dosage of 6 mg/day or less initially and 2–4 mg as maintenance may be effective.

Oral tetracycline and topical betamethasone valerate [29], and a combination of oral propylthiouracil and methotrexate [30], have been advocated for treatment of acrodermatitis continua, as has low-dose ciclosporin [31].

Remission of pustulosis in three obese patients after jejuno-ileal shunt operations leading to marked weight reduction awaits confirmation [32].

Generalized pustular psoriasis

Definition. Generalized pustular psoriasis (GPP) is an uncommon variant of psoriasis in which an acute, subacute or occasionally chronic eruption has sterile pustulosis as its central feature.

Relationship to psoriasis vulgaris. GPP is an extreme form of psoriasis in which all the main pathological features of the disease are accentuated. Its relationship to psoriasis vulgaris is clear, because patients may have phases of ordinary psoriasis before or after the GPP [1]. Family data are similar to those found in psoriasis vulgaris [2,3]. In addition, methotrexate, etretinate, PUVA and ciclosporin A are effective in both psoriasis vulgaris and GPP.

Provocative factors. Provocation is most obvious in the acute forms. Von Zumbusch's original patient [4] was provoked by irritating topical therapy. Coal tar [5] and dithranol [2] may provoke pustulation if injudiciously continued when the psoriasis is intolerant. Other documented factors have been infection [2,6], pregnancy (see below) and hypocalcaemia associated with hypoparathyroidism [7–9]. Drugs implicated have included salicylates [10], iodide [11], lithium [12], phenylbutazone and oxyphenbutazone [13] and progesterone [14], terbinafine [15–17] and amfebutamone (bupropion) prescribed to assist with cessation of smoking [18]. The most important drug provocation is by corticosteroids. There is substantial evidence that withdrawal of systemic steroid therapy can precipitate GPP [1,2]. Intensive topical therapy with strong corticosteroids under occlusion has also been implicated [2,19,20]. Withdrawal of ciclosporin therapy has also been documented to induce GPP [21,22]. Chronic, previously stable acrodermatitis continua has been converted to GPP by high-dose oral prednisolone followed by sudden withdrawal [23].

HLA antigens. There is a strong positive correlation of GPP with HLA-B27 [1,2]. The association of GPP with polyarthritis [1,2] may partly explain this finding. A Japanese study has reported an association between HLA CW1 and HLADQβ*0303 and GPP [3].

Histopathology [2,4]. In acute GPP, there is intense inflammation. The earliest infiltrate is lymphocytic. Intense papillary and epidermal oedema cause spongiosis. The arrival of masses of neutrophils leads to spongiform pustule formation (Kogoj) and abscesses that quickly become macroscopic. There is acanthosis with elongation of rete ridges [2]. The stratum corneum soon becomes parakeratotic and the subcorneal pustule is shed as epidermal turnover is accelerated. Essentially, the same features are seen in subacute as in chronic patterns but in a less intense form.

Acute generalized pustular psoriasis (von Zumbusch)

Clinical features [1–3]. Two main groups have been distinguished [1]. In the first, typical psoriasis of early onset develops into pustular psoriasis after some years, often after provocation by steroid withdrawal or other extraneous factors. In the second, the onset of psoriasis is later in life and usually atypical, acral [4] or flexural [2,4] in distribution. A rapid and apparently spontaneous progression to the generalized pustular form follows.

The eruption may be ushered in by a sensation of burning. The skin becomes dry and tender. These warning signs—not always present—are followed by an abrupt onset of high fever and severe malaise. Pre-existing lesions become fiery and develop pinpoint pustules (Fig. 35.27). Sheets of erythema and pustulation spread to involve previously unaffected skin, the flexures and genital regions being particularly involved. Any configuration or variety of pustular exanthems may occur—isolated pustules, lakes of pus, circinate lesions, plaques of erythema with pustular collarettes or a generalized erythroderma. Waves of pustulation may succeed each other, subsiding into exfoliation of the dried pustules.

Fig. 35.27 Acute generalized pustular psoriasis. (Courtesy of St John's Dermatology Centre, London, UK.)

The nails become thickened or separated by subungual lakes of pus. The buccal mucosa and tongue may be involved, the lesions on the latter being clinically and histologically indistinguishable from 'geographic' tongue [1,5,6]. Persistent fissured tongue has also been associated with GPP and geographic tongue [7]. If the patient does not die of exhaustion, toxicity or infection, a remission may occur within days or weeks, the psoriasis returning to its normal state, or erythroderma develops. Relapses are common.

Complications. In the absence of effective treatment, death can occur in the acute stage. Hypoalbuminaemia may be profound, perhaps because of a sudden loss of plasma protein into the tissues [8]. In one patient, albumin half-life was shortened to 4 days (normal 11–12 days) [8]. Hypocalcaemia may be a consequence of the hypoalbuminaemia [1,9]. The consequent oligaemia can cause acute and fatal renal tubular necrosis [10]. There may be evidence of liver damage or even jaundice, perhaps caused by a combination of oligaemia, general toxicity and drugs [10,11]. Cholestatic jaundice of uncertain pathogenesis, closely related to acute episodes of GPP, has been described [12]. Deep-vein thrombosis in a leg can cause fatal pulmonary embolism. Staphylococcal infection may complicate GPP, usually because of hospital ward cross-infection. *Staphylococcus aureus* may be grown from pustules and rarely from blood cultures. However, claims that most GPP is caused by staphylococcal bacteraemia [13] were not substantiated [14].

Inflammatory polyarthritis is common. In one large series, one-third of patients were eventually affected [1]. Malabsorption may be a feature of the acute episode [9,15] and may further contribute to hypocalcaemia [9]. The absorption of therapeutic drugs may be impaired. Amyloidosis is a rare complication [16,17]. The obstetric complications of GPP in pregnancy are discussed below.

If GPP lasts more than a few days, gross hair loss may follow from all areas of the body. Occasionally, a telogen effluvium follows 2–3 months after the height of the illness.

Laboratory findings. There may be an absolute lymphopenia at the onset of GPP [18]. A polymorphonuclear leukocytosis quickly follows [1,18]. Plasma albumin, zinc [19] and calcium may be abnormally low. The ESR is usually raised. Malabsorption partially explains these findings. Hyperlactataemia is probably secondary to hyperproliferation [20].

Generalized pustular psoriasis of pregnancy [1–4]

SYN. IMPETIGO HERPETIFORMIS

Definition. A rare eruption, occurring especially in pregnancy, with the features of generalized pustular psoriasis, but with a tendency to be symmetrical and grouped, and often starting in the flexures. Constitutional disturbance may be severe.

Pathogenesis. The worsening of pustular psoriasis just before menstruation is well recognized [5,6] and challenge with progesterone [7] or clomifene (clomiphene) [5] has produced pustular exacerbations in such patients. The syndrome was first described by Hebra [8] and an endocrine cause is suspected. The claims that impetigo herpetiformis stands as an entity separate from GPP have been restated [3,9].

Clinical features. The disease is rare; by 1982 less than 200 cases were documented [2]. Onset is usually in the last trimester of pregnancy, but may be earlier, and has been recorded in the first month of pregnancy [6] and in the first day of the puerperium [10]. The disease tends to persist until the child is born, and occasionally long afterwards [6]. There is one report of familial disease [11]. Essentially, the features are of a GPP, usually of flexural onset and with a marked tendency to symmetry, and sometimes grouping of areas of pustulation. Constitutional disturbance is characteristically severe with fever, and death may occur, attributable to cardiac or renal failure. Delirium, diarrhoea, vomiting and tetany have been described. The eruption usually starts in the inguinogenital region and other flexures, with minute pustules arising on an acutely inflamed area of skin. These extend centrifugally, drying in the centre, or form plaques in which eroded greenish yellow pustules become fetid, crusted or vegetating. Condyloma-like lesions may form in the flexures [12]. The eruptions may become widespread. As individual areas heal, they leave a reddish brown pigmentation. The tongue, buccal mucosa and even the oesophagus may be involved, with circinate or erosive lesions following short-lived pustules.

The more severe and long-standing the disease, the greater are the risks of placental insufficiency leading to stillbirth, neonatal death or fetal abnormalities [3,9,13].

Prognosis. Characteristically, the disease recurs in subsequent pregnancies [2,14]. Recurrence has been described in up to nine pregnancies, and on subsequent use of oral contraceptives [2,3]. In one case, the disease continued unabated despite termination of the pregnancy [6].

Laboratory findings. Hypocalcaemia has often been reported [1,6]. Lowered levels of serum vitamin D have been found, probably attributable to its malabsorption [2].

Treatment. This is discussed with that of other forms of GPP (see below). In one case, where termination failed to halt the disease, a mestranol–ethynodiol combination orally was effective when other measures had failed [6].

Infantile and juvenile pustular psoriasis

All forms of pustular psoriasis are rare in childhood. Five cases were seen in one series of 479 children with psoriasis [1], and one case of GPP in another series of 112 [2]. In a series of 104 cases of GPP in patients of all ages, there were only five children [3]. Although GPP can begin at any age in childhood, in over 25% of certain series onset has been in the first year [4,5]. The disease may begin in the first few weeks of life and two cases of congenital GPP have been described [5].

In contrast to psoriasis vulgaris in childhood [6] and GPP in adults [3], a male preponderance is seen in GPP of childhood (about 3 : 2) [4,5]. Infantile cases are usually benign. Systemic symptoms are often absent and spontaneous remissions occur [4,5]. In at least one-third of infantile cases, a history of an eruption diagnosed as seborrhoeic dermatitis [7], napkin dermatitis or sudden-onset napkin psoriasis [8] is obtained [4,9]. More severe forms with fever and toxicity do occur, necessitating active treatment. Rarely, pustulosis has supervened on a congenital erythroderma [4,10].

The majority of children are aged 2–10 years at onset. The disease may be of Zumbusch pattern, but annular and circinate forms are the most common [4,9,11]. Onset of Zumbusch-type psoriasis may be abrupt with toxicity, and an erythrodermic background can become generalized rapidly (Fig. 35.28). Attacks often settle within a few days, but repeated waves of inflammation may follow [4]. Systemic steroid therapy carries the hazard of disseminated infections with varicella and other viruses [9]. In older children, the disease resembles that in the adult and may be of any of the recognized patterns.

The prognosis may be variable [3] but has been generally good in two series [9,12]. Treatment is discussed below.

Circinate, annular and linear pustular psoriasis

Annular and other patterned lesions may be seen in acute GPP, but are more characteristic of the subacute or chronic forms of widespread pustular psoriasis [1,2]. Lesions begin as discrete areas of erythema, which become raised and oedematous. Slow centrifugal spread may mimic erythema annulare centrifugum [3,4]. Pustules appear peripherally on the crest of the advancing edge, become desiccated and leave a trailing fringe of scale as the lesion slowly advances.

Some authors have separated a related pattern, well described by Lapière as recurrent circinate erythematous

psoriasis [5,6]. It was originally described in 1907 as 'recurrent circinate erythema'. It may occur alone (in the complete absence at any stage of recognizable psoriasis) or as a phase in what is clearly generalized pustular psoriasis.

Linear forms of pustular psoriasis are occasionally observed within the context of more generalized pustulosis [7,8].

Localized forms of GPP

These must be distinguished from PPP or acropustulosis. The term 'psoriasis with pustules' is perhaps more appropriate. One or more plaques of psoriasis vulgaris may develop pustules (e.g. after excessively irritant topical therapy).

Differential diagnosis. Subcorneal pustular dermatosis of Sneddon and Wilkinson remains a controversial entity [1,2]. Acute generalized exanthematous pustulosis (AGEP) is perhaps the most important differential, occurring as an acute, spontaneously healing reaction to drugs, usually antibiotics [3]. It is probable that some cases previously reported as drug-induced GPP (see above) may in fact have been AGEP. In infantile acropustulosis, the process does not become generalized and is not associated with constitutional disturbance [4,5]. The distinction between GPP and pustular lesions in Reiter's disease is probably academic. Acute pemphigus foliaceus can mimic subacute GPP, but histological and immunofluorescence testing will distinguish the two. The wasting, glossitis and anaemia associated with the migratory necrolytic eruption of glucagonoma should allow easy differentiation. Occasionally, the bowel bypass syndrome [6,7], Sweet's syndrome [8] and Behçet's syndrome will cause difficulty. Staphyloderma, rampant impetigo or candidiasis in the immunosuppressed or pustular drug eruption (e.g. caused by halides) should be remembered.

Management [1]. The treatment of acute GPP requires admission to hospital, removal of possible provocative factors, general support measures and topical and usually systemic drug therapy.

Withdrawal of provocative factors. Tar or dithranol can be withdrawn abruptly, but massive overdosage with potent topical corticosteroids requires more care. The application of serially diluted topical steroids over several days may be the safest course, and is preferable to substitution of oral or parenteral corticosteroid, however temporary. Infection, where present, should be treated rigorously with the appropriate antibiotic, usually erythromycin or flucloxacillin. Rarely, when GPP in pregnancy is threatening maternal life, termination or early delivery may be indicated.

General measures. If there is no immediate metabolic threat in acute GPP, and generally in subacute forms, initial treatment should be conservative [2]. This is particularly so in infancy and childhood [3]. Bed rest in hospital, mild sedation, bland local applications with fluid and protein replacement may promote spontaneous reversion to a quieter erythrodermic psoriasis or even psoriasis vulgaris [2]. This approach is particularly apt if a provocative factor has been at play [2]. However, such a course has to be weighed against the risk of repeated waves of pustulation that may exhaust the patient, and the hypostatic and thrombotic hazards of prolonged bed rest, particularly in the elderly patient. Excessive heat loss must be prevented by maintaining an adequate ambient temperature, avoiding cool draughts of air. A low-reading thermometer is essential. Fluid intake should be increased so that the daily urine volume remains adequate.

Topical therapy. Often, completely bland creams or lotions are best. Weak corticosteroid creams may be helpful in subacute forms. Tar [4] and dithranol are contraindicated.

Systemic therapy. Most cases of GPP require systemic therapy. Retinoids are probably the treatment of choice. A

recent survey of 385 Japanese patients with GPP [5] reported that acitretin was effective in more than 80% of cases. Response to high doses of acitretin (1 mg/kg/day) may be rapid [6] and lower doses of 0.5–0.75 mg/kg/day may be sufficient to maintain control [7]. Disease control can sometimes be achieved with intermittent therapy [8]. Combination of etretinate with PUVA is beneficial [9].

PUVA therapy is effective in acute and subacute GPP [9–12]. Very ill patients may have to be treated in the horizontal position. Small doses of UVA should be given initially three or four times weekly; the dose of UVA is slowly increased.

Methotrexate is probably as effective as acitretin but no comparative studies are available [2]. In fulminating GPP, small (7.5–10.0 mg) intravenous doses, repeated every 5–7 days may be safest. The intramuscular route can be used, but the intravenous or intramuscular dosage should rarely exceed 0.3 mg/kg/week. Oral therapy is less predictable, because of variable absorption. Sudden unexpected toxicity from repeated methotrexate doses may follow, because of improved absorption of the drug as the GPP subsides. Orally, dosage of 0.2–0.4 mg/kg/week should suffice, starting at the lower end of the range. If the patient is very ill, renal function may have to be monitored daily if methotrexate overdosage is to be avoided. Methotrexate has been used with success in children with GPP [13].

Control of GPP has been achieved with very high dosage of ciclosporin alone (9–12 mg/kg/day), but toxicity prevented prolonged treatment at these dose levels. With lower dosage, the addition of topical steroids allowed adequate control [14]. However, ciclosporin (5–7 mg/kg/day) failed to alleviate GPP in a renal transplant recipient during periods of prednisolone withdrawal [15]. In contrast, a case of GPP was reported to respond rapidly to ciclosporin 7.5 mg/kg/day, and was successfully maintained in remission at 3.5 mg/kg/day [16]. Three patients, including two children, were successfully treated with low-dose (1–2 mg/kg/day) ciclosporin; the lesions cleared within 4 weeks of starting therapy [17].

Razoxane has been effective in acute GPP [18] but is rarely used now. Hydroxyurea is less effective [19]. Colchicine has been used either alone [20,21] or in combination [22] with methotrexate. 6-Thioguanine has also been used successfully [23].

In the subacute and chronic forms of GPP, the use of dapsone (50–200 mg/day) [24–26] can be considered, and may be particularly valuable in atypical variants and children [2,27]. Oral or parenteral corticosteroid should be used only when urgent control of metabolic complications is needed [2]. The short-term effects of prednisolone (30–40 mg/day) are excellent [2,28], but serious relapses are liable to occur as the dosage is reduced unless another form of therapy (e.g. methotrexate or acitretin) is given simultaneously [2].

Biological agents have been used occasionally and to excellent effect. It appears that these therapies are perhaps well-suited to rapid control of GPP. The TNF-α blockers, infliximab and etanercept, and basiliximab, an antibody directed at the IL-2 receptor, have all been reported to rapidly control acute GPP [29–32]. It is likely that these therapies will become the treatment of choice in cases of fulminant disease.

Cytotoxic drugs, etretinate and PUVA cannot be used in GPP of pregnancy unless termination has become inevitable. Fulminating disease in pregnancy is best treated with prednisolone, the drug that carries the least hazard for the fetus, but ciclosporin has been used safely for treatment of impetigo herpetiformis [33]. Methotrexate, retinoids, PUVA or combination therapy may be needed after delivery to allow weaning off the steroid or ciclosporin [34].

Prognosis. There is a paucity of data on the long-term prognosis of GPP. Von Zumbusch's patient [1] survived many acute episodes over a number of years, and perhaps had the good fortune to live before potent (and dangerous) remedies were available. Ryan and Baker [2,3] reported on the prognosis in 155 patients with all types of GPP. Thirty-four of 106 patients followed up had died, and 26 of these deaths were attributable to the disease or its treatment. GPP developing from acropustulosis (acrodermatitis continua) had the worst prognosis, seven out of 11 patients having died and a further one remaining severely disabled. To some extent, this particularly poor outlook reflected the age at onset of these patients, who were predominantly elderly. However, death was a direct result of GPP in all of these cases, resulting from cardiac failure or respiratory infection during uncontrolled pustular psoriasis. In general, patients with preceding ordinary psoriasis had a better prognosis than those with atypical prepustular psoriasis [2,3].

The better prognosis of GPP of pregnancy reflects the abrupt removal of the main provocative factor by childbirth or, *in extremis*, termination of the pregnancy [4,5]. GPP of childhood also carries a more benign prognosis [6], providing oral corticosteroids and methotrexate can be avoided [7]. Khan *et al*. [7] stressed the hazard of fatal virus infections in corticosteroid-treated children and advocated bland topical therapy, if necessary in hospital, for up to 3 months in anticipation of spontaneous remission. In their patients, where oral corticosteroids were avoided, growth and development progressed unimpaired despite GPP [7].

Psoriatic arthritis

Definition. An inflammatory arthritis associated with psoriasis of the skin and/or nails, with usually a negative serological test for rheumatoid factor and the absence of rheumatoid nodules [1].

Epidemiology. Like psoriasis of the skin, good population studies remain to be performed and thus estimation of population prevalence is difficult and highly variable, depending on the study. Historically, arthritis prevalence amongst psoriasis patients has been estimated at 2.6–7% [2,3]. However, more recent large questionnaire-based studies have indicated that the real prevalence may be much higher. Thus, a Scandinavian study revealed arthritis in 30% [4] of psoriatics and in the USA, 23% (www.npf.org). In general, it appears that the more severe the skin disease, the greater the prevalence of arthritis [5,6]. Further, nail disease is more frequent in cases with arthritis. A review of population-based studies estimated the population prevalence of psoriatic arthritis at 0.02–0.1% [7]. There appears to be a stronger association with generalized pustular psoriasis [6] or erythrodermic psoriasis [8] and arthritis.

The age of onset for psoriatic arthritis is, in general, later than for the skin disease, with peak age of onset being the fourth decade. Biodi-Oriente *et al*. [9] reported psoriasis predating arthritis in 68% of cases occurring at the same time in 11%, and following it in 21%. There is a rare but well-recognized juvenile-onset form of psoriatic arthritis [10], with age of onset between 9 and 12 years. Psoriatic arthritis appears more common in individuals with type 1 early-onset psoriasis vulgaris.

In contrast to rheumatoid arthritis, where females predominate 3 : 1, in psoriatic arthritis the sexes appear equally affected.

Aetiology and pathogenesis

Genetics. Familial clustering of psoriatic arthritis has been reported [1] although much less frequently than for cutaneous psoriasis. There is no evidence that psoriatic arthritis follows Mendelian patterns of inheritance. A large number of HLA association studies have been performed [2]. In general, results concur with studies of cutaneous disease, with HLA Cw6, B13, B17 and DR3 occurring most frequently. A specific association with psoriatic arthritis, not seen in the cutaneous form, is HLA-B27, seen particularly in spondyloarthritis (see below). Genome scans have recently been reported with evidence for a susceptibility locus on chromosome 16q [3]. *CARD15*, a molecule involved in macrophage–monocyte cell signalling, has been implicated as a candidate gene at least in some patients [4]. This molecule has also been implicated in Crohn's disease but not in cutaneous psoriasis.

Environmental factors. Studies of families in which psoriatic arthritis aggregates suggest an important environmental component to disease pathogenesis [5]. Increased immunoreactivity to streptococcal antigens has been reported in sera of patients [6], but establishing a pathogenic link has proved elusive and appears much more tenuous than for the skin disease. An increased prevalence of psoriatic arthritis has been reported in HIV [7] and hepatitis C infection [8], and antibodies to enterobacterial antigens are also recorded [9].

Trauma as a precipitating event has also been noted. Interestingly, trauma appears to be more important in psoriatic compared to rheumatoid and other inflammatory forms of arthritis [10]. Neuropeptides and the nervous system have been implicated in these events [11].

Pathogenetic mechanisms. As for cutaneous psoriasis, T cells probably have a key role in arthritis pathogenesis. Those implicated possess activation and memory surface markers but, unlike skin, do not express the skin homing molecule CLA [12]. Thus, when skin and joint manifestations coexist, different populations of T cells mediate disease at different sites. Intra-articular clonal expansion of CD8-expressing T cells have been observed, but putative antigens remain elusive. As observed in the skin, the morphology of blood vessels in psoriatic arthritis is altered with the presence of dilated tortuous vessels and evidence of angiogenesis [13]. Interestingly, these features are different from that seen in rheumatoid arthritis.

Clinical features. In one series of 180 patients, the mode of onset was studied, and skin lesions were found to precede arthritis in 65%, arthritis antedated skin lesions in 19%, and in 16% skin and joint involvement occurred almost simultaneously. The peak age of onset of arthritis in this series was 40–60 years [1].

Clinical subgroups. Psoriatic arthritis is not accompanied by rheumatoid-type nodules. The Moll and Wright

classification includes five clinical groups, which often overlap [2,3].

1 Predominantly peripheral mono- or asymmetrical oligoarthritis is the most common form, and often overlooked. An appearance similar to low-grade gout, as well as sausage-like swelling of one or more digits (dactylitis) resulting from terminal and proximal interphalangeal joint involvement and flexor sheath synovitis are recognized (Fig. 35.29).

2 Predominantly distal interphalangeal arthritis, the well-recognized classical form, but less common than previously emphasized.

3 Predominantly symmetrical, rheumatoid-like, rheumatoid factor-negative polyarthritis, usually less severe than rheumatoid arthritis.

4 'Arthritis mutilans', a relatively uncommon, severely deforming arthritis involving fingers and toes predominantly. Gross osteolysis may cause digital foreshortening and ankylosis (Figs 35.30–35.32).

5 Predominantly axial arthritis: psoriatic spondylitis and/or sacroiliitis, with or without variable peripheral arthropathy. Spinal involvement may be clinically silent, but radiological examination suggests that it may affect about one-third of all cases of psoriatic arthritis. Clinically, this form may involve: (i) both spine and sacroiliac joints, as in idiopathic ankylosing spondylitis; (ii) sacroiliac joints alone; and (iii) spine alone. It may be less disabling than the idiopathic form [3,4].

Several more recent clinical studies have indicated a need to reclassify psoriatic arthritis. In two studies, each involving 100 patients, three subgroups were proposed, any of which may include the classical features of psoriatic arthritis, such as distal interphalangeal joint involvement, dactylitis or spondylitis [5,6].

1 Asymmetrical arthritis usually, but not always, involving a small number of joints with few erosions, infrequent deformity and good preservation of function.

Fig. 35.32 Arthritis mutilans: gross osteolysis of metatarsal heads and phalanges. Note pencil-in-cup changes at metatarsophalangeal joints. (Courtesy of Royal London Hospital, London, UK.)

2 Symmetrical polyarthritis, frequently erosive, deforming and functionally disabling, but distinguished from rheumatoid arthritis by association with distal interphalangeal joint involvement, spondylitis and negative rheumatoid factor (titre less than 1 : 80).
3 Predominant spondylitis, similar to ankylosing spondylitis, possibly accompanied by peripheral arthritis but behaving independently of it [6].

Cervical spinal involvement is well recognized [7,8] and may be primarily ankylosing in nature or inflammatory and rheumatoid-like [9]. Both forms may be associated with cord or nerve-root compression related to intervertebral subluxation and/or fusion, and neurological deterioration may require surgical stabilization [8,10–13].

Temporomandibular joint involvement may manifest as local pain, often aggravated by eating [14,15] and may progress to ankylosis requiring surgical management [16]. Orthopantomographical examination showed that 31% of patients with psoriatic arthritis had radiographical changes in the condyle of the temporomandibular joint, as compared with 13% of controls [17]. Computed tomography may reveal changes not visible on conventional radiography [18].

Sternal joint involvement is becoming increasingly recognized but is unusual as an initial manifestation [19,20].

Nail involvement. Psoriasis of the nails occurs in about three-quarters of psoriatic patients with arthritis, but only in about one-third of those with skin lesions alone [1,21,22]. The distal and mutilating forms of arthritis are particularly associated with severe nail dystrophy, and the distal joints and nails affected are often but not necessarily correlated in the same digits [22]. All types of nail involvement may occur [23].

Extra-articular features. These occur less frequently than in rheumatoid arthritis. Subcutaneous nodules are not seen, and tendon sheath effusions are uncommon. In contrast, inflammatory eye lesions are common, conjunctivitis being reported to occur in 20%, uveitis in 10%, and episcleritis and keratoconjunctivitis sicca in about 2 and 3%, respectively [24]. Cardiac involvement similar to that seen in ankylosing spondylitis has been reported [25].

Laboratory findings. The most important serological feature is the negative test for rheumatoid factor, particularly in patients with distal and mutilating arthritis. In patients with psoriatic arthritis of the rheumatoid type, about one-quarter had a positive test or a test that fluctuated between positive and negative [1]. Some of these patients probably represent the coincidental association of psoriasis and rheumatoid arthritis, but a weakly or intermittently positive rheumatoid factor occurs in approximately 5% of the normal population [2] and should not necessarily lead to the diagnosis of rheumatoid arthritis. Other reported laboratory abnormalities, such as anaemia, raised ESR and C-reactive protein, transient leukocytosis, and raised immunoglobulin levels, most consistently IgA, have been reviewed [3,4]. It has been concluded that none of these is sufficiently specific to contribute to diagnosis, management or prognostic evaluation [4]. The conflicting reports of the association between hyperuricaemia and psoriasis are outlined above. Antinuclear antibodies have been reported as both positive and negative [3], but in an American study of 1285 patients they were found to have little predictive value [5].

Histopathology. The histopathologies of psoriatic and rheumatoid arthritis appear to be similar, except that characteristic rheumatoid granulomas have not been found and there may be more fibrosis [6,7] and vascular changes [8] in the psoriatics. In spite of these possible differences, synovial biopsy usually has no place in the routine clinical management of psoriatic arthritis [4].

Radiological changes [1–3]. The changes may be indistinguishable from those of rheumatoid arthritis: local demineralization, narrowing of joint spaces, articular erosion of varying degree and soft-tissue swellings. Atypical features include destructive changes in the terminal interphalangeal joints, a tendency to hypertrophic changes and absence of generalized demineralization.

In the distal type of psoriatic arthropathy, early changes may consist only of minimal 'fluffiness' and osteoporosis of the distal phalanx, but gross destruction eventually occurs. Four characteristic signs of psoriatic arthropathy, seen in one controlled series [1], were:

1 A destructive distal interphalangeal arthropathy—bony ankylosis of the interphalangeal joints
2 Destruction of the interphalangeal joints with abnormally wide joint spaces and sharply demarcated adjacent bony surfaces
3 Destruction of the interphalangeal joint of the great toe with bony proliferation of the distal phalanx
4 Resorption of tufts of the distal phalanges of hands and feet (uncommon).

In arthritis mutilans, the joint changes are widespread. The 'opera-glass hand', in which the fingers can be pulled in and out, results from gross destruction and absorption of the bones. The heads of metacarpals and metatarsals may completely disappear, leaving a tapered bone looking like a sharpened pencil. Such gross osteolysis may be followed by bony fusion (Figs 35.31 & 35.32).

Intermittent hydrarthrosis may occur. Sacroiliac changes similar to those of ankylosing spondylitis are common [4–6]. Syndesmophytes and calcification of the interspinous ligaments are also seen [6]. Cervical changes including apophyseal sclerosis or joint narrowing, and calcification of the anterior ligament, are common [7], and there is a tendency to posterior fusion of the cervical vertebrae [3]. Paravertebral ossification of the lumbar and thoracic regions may occur more laterally in psoriasis than in spondylitis [8].

Differential diagnosis. This has been reviewed in detail elsewhere [1]. One of the subgroups of psoriatic arthritis may be clinically indistinguishable from rheumatoid arthritis. As a weakly or intermittently positive rheumatoid factor occurs in 5% of the normal population [2], this should not necessarily lead to the diagnosis of rheumatoid arthritis. Gout may be simulated, especially if the onset is acute and monoarticular, or if widespread psoriasis is associated with hyperuricaemia. Ankylosing spondylitis may be similar, but the onset tends to be later, peripheral

involvement is more common, and the arthritis does not necessarily begin in the spine. The acute Heberden's node of osteoarthritis may cause confusion, and distinction from Reiter's disease may be difficult or impossible.

Treatment. Treatment follows the general lines of management of inflammatory polyarthritis, and is best supervised by a rheumatologist. Assessment of efficacy of therapies for psoriatic arthritis is hindered by inexact definition of the condition, the variable clinical presentation and lack of validated outcome measures. The treatment of psoriatic arthritis has been recently reviewed [1].

Symptomatic treatment. Mild arthritis can usually be controlled with NSAIDs. There is concern that NSAIDs may exacerbate the skin lesions of psoriasis [2,3], although a randomized controlled trial showed no worsening of psoriasis in patients treated with the NSAID nimesulide [4]. Cyclo-oxygenase-2 (COX-2) selective inhibitors are effective but, as with traditional NSAIDs, caution should be exercised in the elderly and those with impaired renal function.

Systemic glucocorticosteroids are not recommended for the long-term treatment of psoriatic arthritis not only because of the well-recognized side effects but also because chronic glucocorticosteroid use can make psoriasis more labile and withdrawal can on occasion lead to a rebound pustular flare [2,5]. Intra-articular injections of glucocorticosteroid are used to treat monoarthritis [6].

Disease-modifying antirheumatic drugs (DMARDs). Ascertaining effectiveness of DMARDs in the management of psoriatic arthritis is complex [1]. The clinical subgroups respond differently, for instance axal involvement associated with HLA-B27 has a relatively poor response to treatment [7]. The most commonly used DMARDs for psoriatic arthritis are methotrexate, ciclosporin and sulfasalazine although there are few randomized controlled trials.

Methotrexate is the most widely used of the DMARDs for psoriatic arthritis—particularly as it is effective for the skin lesions, and is amenable to combination with other DMARDs to enhance efficacy. Only two randomized controlled trials provide evidence [8,9], one [8] used parenteral injections of high-dose methotrexate (1–3 mg/kg)—a dose probably too toxic. A second study [9] showed that methotrexate 7.5–15 mg/week was superior to placebo only in physician assessment of arthritis. Thus, the data imply that methotrexate is beneficial for synovitis but there is no evidence of benefit for axial disease.

Ciclosporin is probably less effective than methotrexate for the treatment of psoriatic arthritis but evidence is mainly accrued from open studies. In an 18-week open study [10], ciclosporin 4.8 mg/kg/day benefited psoriatic arthritis but the effect was less marked than for the skin lesions. In a trial comparing methotrexate to ciclosporin [11], ciclosporin 3–5 mg/kg/day produced significant improvement in clinical and serological measures of severity of psoriatic arthritis. An Italian study [12] found that ciclosporin was more effective than either sulfasalazine or placebo in reducing a variety of clinical measures of severity. Long-term use of ciclosporin may control progression of radiological damage in peripheral joints [13].

Sulfasalazine has been subject to more open trials and randomized controlled trials than either methotrexate or ciclosporin for the treatment of psoriatic arthritis. Despite encouraging results from open studies and one short (8-week) study [14], this promise has not been substantiated by most randomized controlled trials [1,15,16]. Overall, the evidence suggests that sulfasalazine has a small beneficial effect on peripheral synovitis, particularly pain [17], but whether efficacy is enhanced by increasing the daily dosage above 3 g is unclear [1,18]. Axial disease is not benefited [1].

Gold salts (oral auranofin) and intramuscular sodium thiomalate are used to treat psoriatic arthritis [19,20]—on the evidence sodium thiomalate appears to be the better of the two, but less effective than methotrexate [21,22]. Occasional exacerbation of the skin lesions of psoriasis by gold salts can occur [23].

A variety of other DMARDs have been investigated and advocated for the treatment of psoriatic arthritis, none of which has been subject to good randomized controlled trials. Leflunomide (a pyrimidine synthesis inhibitor effective for rheumatoid arthritis) appeared to have some benefit in psoriatic arthritis in both the short term (3 months) and long term (2 years) in a longitudinal study of eight patients [24].

Antimalarials, particularly chloroquine [25], may be of limited benefit, but this class of drug can, on occasion, exacerbate psoriasis. Mycophenolate mofetil has shown some initial promise [26], but the efficacy of colchicines is variable; however, one randomized controlled trial has demonstrated benefit [27]. Open studies suggesting that etretinate is effective have been reviewed [28], but a randomized controlled trial demonstrated only a modest effect [28]. PUVA, oral and extracorporeal, was reported to improve peripheral joint arthritis [29,30], but had no effect on axial disease [30]. A limited randomized controlled trial of azathioprine versus placebo showed benefit [31]. Success has been reported for other drugs including 6-mercaptopurine [32], D-penicillamine [33], systemic 1,23-dihydroxyvitamin D_3 [34] and 2-chlorodeoxyadenosine [35].

Biological agents. The introduction of biological agents into the therapy of rheumatoid arthritis has revolutionized the management of that disease. Unsurprisingly, the same agents have been trialled, and in one case approved for the treatment of psoriatic arthritis. The main biological agents

to have been trialled in psoriatic arthritis are blockers of TNF-α and of T-cell activation. The two main anti-TNF-α blockers are infliximab, a chimeric human–murine anti-TNF-α IgG1 antibody, and etanercept, a dimeric fusion protein consisting of the extracellular portion of the human p75 TNF-α receptor linked to IgG1. Infliximab significantly improved psoriatic arthritis in small open studies either as monotherapy [36] or in combination with methotrexate [1]. Etanercept has been subject to good randomized controlled trials [37]; 25 mg administered subcutaneously twice weekly over 12 weeks produced significant improvement in 87 and 23% of patients treated with etanercept and placebo, respectively. An open trial has reported that axial arthritis is also improved by etanercept [38]. Blockade of T-cell activation by inhibition of co-stimulatory molecule binding is under rigorous investigation in psoriasis. Alefacept (licensed for treatment of psoriasis) is an LFA-3 IgG1 fusion protein that blocks LFA-3–CD2 binding and apoptosis circulating $CD45RO^+$ memory effector T cells. A small study of 11 patients demonstrated clinical improvement in 64% of patients [39]. It is highly likely that more biological agents, particularly blockers of pro-inflammatory cytokines, will be approved for treatment of psoriatic arthritis.

Surgery. The place of surgery has been reviewed [40,41]. In spite of past reluctance to perform elective surgical procedures in view of perceived risks of infection, a review of 41 orthopaedic operative procedures and 54 other surgical procedures in patients with psoriasis and arthritis revealed a low prevalence of wound sepsis and other complications. It was therefore suggested that elective surgery should not be withheld from these patients [40]. Such procedures might include joint prosthesis and cervical spine stabilization, and the use of digital distraction lengthening and bone grafting for severe arthritis mutilans has also been described [41].

Prognosis. A 10-year follow-up study suggested that psoriatic arthritis produced less pain and disability than rheumatoid disease [42]. Excluding the arthritis mutilans group, in this study 30% lost no time off work, only 3% had more than a total of 1 year off work in 10 years, and many patients showed little or no radiological deterioration. Thus, it is usually perceived that psoriatic arthritis may be a mild disease, and that the descriptions of mutilating digital disease and occasional severe spondylitis may give a false impression of the usual prognosis in these patients. However, in a Canadian study of 220 patients with psoriatic arthritis, deforming erosive arthropathy was found in 40% of cases. The concept that psoriatic arthritis is often a benign arthropathy was therefore challenged [43]. Indicators of poor prognosis include younger age at onset, extensive skin involvement, polyarticular synovitis, HIV infection, high ESR at presentation, large numbers of effusions and association with HLA B27, B39 and DLW3 [1,44].

Chapter 36

Non-Melanoma Skin Cancer and Other Epidermal Skin Tumours

R.M. MacKie & A.G. Quinn

Introduction

The complexity of the cellular composition of the skin means that the range of tumours that can arise within the skin is very wide. This chapter deals chiefly with the benign and malignant tumours arising from epidermal keratinocytes. Non-melanoma skin cancers and related premalignant lesions are dealt with in a separate section in view of their clinical importance and the overlap in the epidemiology, pathogenesis and management of these tumours. Chapter 37 is devoted to appendage tumours, Chapter 38 to tumours arising from the melanocyte and Chapter 53 to soft-tissue tumours.

A *tumour* is an abnormal mass of tissue, the growth of which exceeds and is uncoordinated with that of normal tissues. Although most tumours retain a resemblance to the normal tissue from which they arise, they can show an extraordinary variation in their structure and it is this variation that causes difficulties in some cases in establishing a definitive pathological diagnosis. Most of the keratinocyte-derived tumours described in this chapter are *benign*, which is the term used to describe tumours where the cells remain at their site of origin forming a single mass of tumour cells. *Hamartomas* are difficult to distinguish from true benign tumours clinically. They are not true tumours and best considered as a localized overproduction of one or more elements of a tissue but without the progressive growth characteristics of a tumour. *Malignant* tumours are composed of cells that have acquired the ability to invade through a basement membrane and this is associated with the capacity to metastasize to other organs by the lymphatics and blood vessels. In addition, malignant tumours frequently show more rapid growth and less differentiation than benign tumours, which is reflected histologically by higher mitotic rates, cellular and nuclear pleomorphism and abnormal mitoses. Differentiation between benign and malignant tumours is one of the major responsibilities of a dermatopathologist. The distinction, however, can be

difficult with small tissue samples and is not absolute, which means that it is vital that there is good communication between the clinician and pathologist, particularly when the pathology report suggests biological behaviour that is not in keeping with the clinical impression.

Non-melanoma skin cancer and related premalignant lesions

Non-melanoma skin cancer (NMSC) is the most common human cancer. The term encompasses basal cell carcinoma (BCC) and squamous cell carcinoma (SCC) of the skin, which are both derived from epidermal keratinocytes. Although these tumours are clinically and pathologically distinctive, they share some characteristics and are frequently classified under the term non-melanoma skin cancer for health care planning, cancer registry reporting and epidemiological purposes. In contrast to other common epithelial cancers, NMSCs rarely metastasize, which means that the case fatality rate for these cancers is low. This low mortality from NMSC has contributed to the widespread underreporting of this cancer to disease registries in many countries and makes it impossible at present to quantify accurately the morbidity and health care costs associated with this disease. Nevertheless, given the high prevalence of NMSC and the frequent occurrence of multiple primary tumours in affected individuals, there is little disagreement amongst dermatologists that NMSC is an important and frequently underestimated public health problem.

Patients at risk for development of NMSC are also predisposed to the development of actinic keratoses (AK) and Bowen's disease, which are premalignant lesions that show some of the histological characteristics of SCC. The prevalence of AK and the multiplicity of lesions within individual subjects is considerably greater than that for NMSC. While there is some controversy about the premalignant potential of AK and Bowen's disease and their relationship to SCC, these lesions are in themselves an important clinical problem for two reasons. First, they need to be distinguished from SCC and, secondly, the scaling and inflammation associated with these lesions means that they are the cause of some morbidity in their own right.

Epidemiology and risk factors for non-melanoma skin cancer development

Epidemiological surveys have a key role in the generation of incidence and prevalence data for NMSC in populations, quantification of the clinical impression of increasing skin cancer incidence and identification of environmental and host factors important in NMSC development.

Incidence and mortality

Up-to-date accurate incidence figures for NMSC in different geographical regions are difficult to obtain as there are relatively few population-based studies. Giles *et al*. [1], in an Australian postal survey of 31 000 individuals, conducted in 1985, reported 652 BCCs and 160 SCCs and an increased incidence of SCCs from 166 to 250 per 100 000 over the 5-year period, and an 11% increase in the incidence of BCCs [2]. In the USA, a population-based study [3] quotes an incidence of 38 SCCs per 100 000 population, with a 3 : 1 male : female preponderance. Miller and Weinstock [4] have estimated that in 1994 there were 1 million new cases of NMSC in the USA. Mortality from NMSC in the USA is estimated at $0.44/10^5$ per year [5], with the main cause of death being metastases from SCC. There are a few recorded deaths from BCC, most of these being related to refusal of surgical treatment. The annual cost of treating NMSC in the USA has been estimated at over $500 million [6].

The incidence of NMSC has increased dramatically over the last 30–40 years in many populations worldwide. In addition to the study by Giles in Australia showing a 50% increase in the incidence of SCC and an 11% increase in the incidence of BCCs between 1985 and 1990 [2], Miller and Weinstock have reported a threefold increase in NMSC incidence in the USA over the past two decades with a continuing rise at a rate of 8% per year [4]. Increases in NMSC incidence have also been reported in Europe. In Wales, a population-based study has shown that the crude incidence for NMSC has increased from 173.5 to 265.4 per 100 000 population per annum between 1988 and 1998 [7]. Although differences in the methodologies between reported population-based studies make it difficult to directly compare NMSC incidence in different countries, comparison of age-specific incidence rates of BCCs in two studies from Sweden and Australia indicate that the rate in northern Europe is approximately 3–4 times less than that seen in the Australian population [1,7,8].

Most studies indicate that BCCs account for more than 70% of the cases of NMSC in areas with both high and low ambient sun exposure. Although a ratio of 4 : 1 BCC : SCC has been described as a relatively consistent finding in studies of NMSC incidence in non-immunosuppressed white-skinned individuals, closer examination of the available information shows that that this ratio differs between countries with low and high ambient sun exposure, which reflects a disproportionate increase in SCC relative to BCC with increasing sun exposure. In some groups such as white Maryland fisherman with very high occupational ultraviolet radiation (UVR) exposure, the ratio of BCC : SCC is almost 1 : 1 [9].

Environmental risk factors

Ultraviolet radiation

UVR is now recognized as by far the most important and best understood risk factor for NMSC development. An association between sun exposure and NMSC was first suggested by Thiersch and Unna at the end of the 19th century and substantiated by the work of Hyde [1] and Dubreuilh independently at the beginning of the 20th century [2]. Since then, a large body of information from epidemiological, clinical and experimental observations has been generated to substantiate the proposed causal link between the sun and NMSC development. This evidence includes the increased frequency of NMSC in areas of high ambient sun exposure; the latitude gradient in the annual age-adjusted incidence in the USA for cutaneous SCCs, with an increasing incidence the nearer one gets to the equator because of greater levels of the UVB component of terrestrial sunlight [3]; the increased incidence of NMSC in sun-sensitive people, which is dramatically highlighted by the differences in NMSC risk between albinos and non-albinos in countries such as Tanzania with high ambient sun exposure [4]; the association between NMSC and 'benign' sun-related conditions such as photoageing and solar telangiectasia; and the marked increase in NMSC incidence with increasing age resulting from cumulative sun exposure, which reflects both the intensity and duration of this exposure [3,5]. The strength of the evidence led the International Agency for Research on Cancer to conclude in 1992 that sun exposure was carcinogenic in humans and that it has a causal role in NMSC development [6].

The increasing incidence of NMSC over the last 30 years is largely the result of increased recreational sun exposure and there are many parallels between the changing epidemiology of NMSC with that other well-known 20th century epidemic, smoking-related lung cancer. Sunbathing, like cigarette smoking, became popular in the early half of the century with the popularization of the bronzed look by Coco Chanel in the 1930s. Although the development of sunbathing as a popular leisure pursuit has lagged behind cigarette smoking, changes in attitudes about the desirability of a tan, coupled with increased leisure time, the introduction of paid holidays and the development of cheap package holidays have seen a marked increase in the level of individual sun exposure in the latter half of the 20th century. In parallel with smoking-related lung cancer, the incidence rate for NMSC has lagged behind the changes in carcinogen exposure, which means that the current clinical impression of increasing NMSC incidence is likely to be a prelude to reporting on a more substantial scale over the next 30–40 years.

The relationship between exposure to UVR and skin cancer development is complex. Epidemiological studies have had an important role in the identification of differences between BCC and SCC with respect to age and pattern of sun exposure. Migrant studies have established that high sun exposure in childhood is especially important in determining NMSC risk and that that there is a sharp change in relative risk of NMSC between arrival before and after 10 years of age [7]. Although the basis for this age effect is still unclear, an important consideration is the possibility that the skin is more susceptible to the carcinogenic effects of UVR in childhood. The concept that the response of the skin with respect to cancer susceptibility may be qualitatively different in early life is supported by the observation that susceptibility to melanocytic naevus formation is also greatest during this period [8]. Although both BCC and SCC increase with increasing ambient sun exposure, there is a proportionately greater effect of increasing sun exposure on SCC risk [9]. Other observations that suggest that the relationship between sun exposure is not the same for BCC and SCC include the greater preponderance of BCCs on intermittently sun-exposed areas, the plateauing of BCC but not SCC risk after moderate solar exposure, and the finding that for occupational sun exposure SCC but not BCC risk is related to hours of exposure, whereas BCC risk but not SCC risk is increased by sun exposure occurring during holidays [6,10].

UVR comprises a broad band of energy extending from 200 nm to visible light in the lower 400 nm range (see Chapter 24). The UV part of the solar electromagnetic spectrum is subdivided into three broad regions: UVA, UVB and UVC. Although UVB is the main wave-band responsible for skin cancer induction, there is increasing interest in the carcinogenic potential of UVA. Exposure to UVA has increased considerably over the last 20 years for two reasons. First, UVB blocking sunscreens have allowed sunbathers to spend longer in the sun and, secondly, the desire to achieve a tan has led to the growth in popularity

of UVA sunbeds. Experimental evidence suggests that UVA is carcinogenic [11] but it has been difficult to assess the risk of NMSC development from commercial tanning equipment, as people who tend to use sunbeds also tend to have greater levels of exposure to natural sunlight. Support for a role for UVA in NMSC induction in humans comes from recent reports of both precancerous lesions and NMSC in some individuals in areas of skin exposed almost exclusively to artificial UVA sources [12,13].

Photochemotherapy (PUVA) and UVB phototherapy

PUVA and UVB phototherapy are widely used by dermatologists and are recognized as highly effective treatments for a variety of skin diseases. On theoretical grounds, repeated exposure of the skin to artificial UVR or PUVA would be expected to result in cumulative actinic damage and an increased risk of NMSC. Although a recent meta-analysis has estimated excess skin cancer incidence in patients treated with UVB phototherapy between −0.6 and 2 extra skin cancers per 100 patients treated per year [1], this in itself is insufficient evidence to definitively establish that phototherapy for psoriasis and other dermatological problems increases skin cancer risk. Given the links between sun exposure and NMSC, however, it is prudent to ensure monitoring and accurate record keeping of cumulative doses of UV, particularly with the newer phototherapeutic modalities such as narrow-band UVB lamp (TL01) and high-dose UVA1 regimens while this uncertainty remains.

In marked contrast to the lack of clinical evidence of carcinogenicity of UVB phototherapy, there is strong evidence that PUVA increases the risk of developing SCC. The carcinogenic potential of PUVA in humans was first described in 1979 [2] and there is now a substantial amount of information documenting the long-term clinical effects of PUVA [3,4]. NMSC risk in PUVA-treated patients is correlated with cumulative UVA dose and, although earlier data suggested that PUVA may increase susceptibility to both BCCs and SCCs, more recent studies indicate that the increased skin cancer risk is almost exclusively a result of increased SCC risk. Although at a population level it is clear that high-dose PUVA (defined as more than 200 treatments or 2000 J/cm^2) is associated with a 14-fold (95% CI 8.3–24.1) increase in NMSC incidence rate compared to low-dose patients [4], there is evidence that the risk is not uniformly distributed in high-exposure patients, which suggests that other factors may have an important role in modifying risk [5]. In this study, clinical review of patients exposed to more than 2000 J/cm^2 revealed that only 50% of patients had SCCs or premalignant lesions. Interestingly, none of the 13% of patients in this study without PUVA lentigines had dysplastic lesions, which suggests that the absence of lentigines may be helpful in the identification of patients at low risk of PUVA malignancy.

Chemical carcinogens

The importance of exogenous carcinogens in human skin carcinogenesis was first suggested by Sir Percival Potts, based on observations of an increased incidence of scrotal cancers in chimney sweeps [1]. This hypothesis was supported by observations made by Volkmann in 1874 of a high incidence of NMSC in workers exposed to tar and mineral oil. These observations, and the occurrence of NMSC in other occupational groups exposed to aromatic hydrocarbons at work, served as a stimulus for the large body of experimental studies with chemical carcinogens in animals, which have provided considerable insight into the biology of cancer. The epidemiology of skin cancers

resulting from the occupational environment has been extensively reviewed [2]. Many aspects of occupational skin cancers parallel observations made in animal chemical carcinogenesis models. The prevalence of industrial skin cancer is determined by the potency of the carcinogens and by the thoroughness of the measures used to protect workers from them. The likelihood of an individual developing tumours is influenced by the duration of the exposure. An inverse relationship has been established between the age at first exposure and the length of the latent period following exposure to cutting oils and some other industrial carcinogens [3]. The long latent period between exposure and NMSC development and the observation that cancers can develop without a requirement for ongoing exposure means that it is likely that many cases of occupational-induced skin cancers are not recognized and therefore, by implication, the published figures are likely to reflect a lowest approximation of the true incidence.

Arsenic is another important chemical carcinogen implicated in NMSC development. The association between arsenic administration and the subsequent development of both cutaneous and systemic malignancies was first recognized in 1887 by Sir Jonathan Hutchinson. Unlike aromatic hydrocarbons where exposure was frequently occupationally related, arsenic exposure in the first half of the 20th century was more often caused by the ingestion of medical arsenic in the form of potassium arsenite (Fowler's solution) used to treat asthma and psoriasis [4]. Today, arsenic exposure most frequently occurs because of high arsenic levels in well water from either natural sources or as a result of contamination from mining waste [5].

X-rays and thermal radiation

Physical agents other than solar radiation are less frequent causes of NMSC but are an important aetiological factor in some subject groups. The carcinogenic effects of X-rays on the skin were first recognized by Frieben in 1902. NMSCs resulting from X-rays still occur in some at-risk occupational groups such as dentists, radiographers, physicians and engineers. Other at-risk groups include patients treated with Grenz rays for other dermatological conditions such as scalp ringworm, and patients who have received radiotherapy for the treatment of ankylosing spondylitis [1], lymphomas and other malignancies. Exposure to X-rays in childhood appears to be an important risk factor for BCC development [2]. The long latent period between exposure to ionizing radiation and NMSC development means that cases of radiation-induced NMSC may be overlooked if a careful history is not taken, particularly if they occur on sun-exposed sites. Patients who develop large numbers of BCCs within an irradiated field should be examined for signs of the naevoid basal cell carcinoma syndrome (Gorlin's syndrome) as some patients with this syndrome show a marked increase in susceptibility to ionizing radiation-induced BCCs [3,4].

Chronic exposure to thermal radiation is also recognized as a risk factor for NMSC development. Most of the evidence comes from studies of different cultural groups where an increased incidence of NMSC has been linked to common practices within these groups. Examples include Kangri cancer in the people of the Kashmir, resulting from repeated contact of abdominal skin with an earthenware brazier containing burning charcoal [5]. Additional clinical signs implicating thermal radiation include erythema ab igne and/or thermal keratoses, which frequently co-localize with thermal-induced cutaneous SCCs [6,7].

Human papillomavirus

The association between human papillomavirus (HPV) and squamous cell neoplasia is best established for cervical and anogential cancers, which have served as a useful paradigm for unravelling the complex relationship between HPV and cancer development. HPV infection of mucosal keratinocytes is common and the prevalence is increased in woman at high risk of cervical cancer. Epidemiological HPV typing studies had a key role in defining two distinct groups of genital HPV types that show marked differences in their strength of association with cancer development. 'High-risk' types (HPV16, 18, 31, 33 and 35) were found to be strongly associated with cancer

development while 'low-risk' types (HPV6, 11, 42, 43 and 44) were not [1]. HPV typing studies to date have not generated convincing evidence that implicates high-risk genital HPV types with the development of most cutaneous squamous cell neoplasms. An association has been identified between HPV16 and two unusual clinically distinctive cutaneous squamous cell neoplasms, periungal SCC and palmoplantar Bowen's, and it is likely in these tumours that the oncogenic effects are mediated by mechanisms similar to those operating in mucosal keratinocytes [2].

In spite of the absence of a link between high-risk genital HPV types and NMSC, there is compelling evidence of a link between cutaneous viral warts and NMSC. This association was recognized from observational studies of patients with the rare inherited condition epidermodysplasia verricuformis (EV) many years before the epidemiological studies linking HPV infection to cervical cancer [3]. Patients with EV develop extensive cutaneous plane and common warts at an early age and in later life frequently develop SCCs on sun-exposed areas. Although the genetic basis for EV is still unclear, HPV typing suggests that there may be an aetiological link between HPV and skin cancer development as over 90% of the EV-associated skin cancers contain HPV types 5 and 8. The clinical similarities between EV and the skin phenotype seen in immunosuppressed organ transplant recipients has led to speculation that HPV may contribute to the increased risk of NMSC development in these patients. The development of new approaches that allow detection of a wide range of HPV types has provided some new insights into the potential role of HPV in NMSC development. In a recent study, HPV DNA was detected in more than 80% of NMSC from immunosuppressed patients [4]. In contrast, less than 40% of NMSC from immunocompetent individuals contain HPV DNA. In this study, HPV DNA was detected in SCCs, BCCs and premalignant lesions in both immunocompetent and immunosuppressed patients and the most common HPV types identified were of the EV type. Cutaneous HPV types were more common in tumours from immunosuppressed patients compared to immunocompetent patients, and in the immunosuppressed patients the cutaneous HPV types were frequently found as mixed infections with EV-type papillomaviruses.

Host susceptibility factors

Familial cancer syndromes

Interindividual differences in the susceptibility to NMSC development have been recognized for many years and epidemiological studies have identified a number of phenotypic features, such as hair colour, skin colour, freckling tendency and ability to tan, which show a consistent correlation with NMSC risk. Genes that determine inherited susceptibility to NMSC development can be divided broadly into two main types. The first type are genes associated with rare, highly penetrant cancer predisposition syndromes and includes conditions such as the naevoid basal cell carcinoma syndrome (NBCCS), Gorlin's syndrome (MIM 109400), Bazex's syndrome (MIM 301845) and xeroderma pigmentosum. The second type are multiple low-penetrant genetic loci that may contribute to susceptibility in the general population. Evidence for the importance of these latter genes has come from quantitative trait loci mapping of other cancers in murine models. Although mapping of similar loci in humans is difficult, association studies provide some evidence to support a role for high-frequency low-penetrant traits such as DNA damage repair capacity and xenobiotic metabolism in BCC susceptibility.

Naevoid basal cell carcinoma syndrome [1,2]

SYN. BASAL CELL NAEVUS SYNDROME; GORLIN'S SYNDROME

Definition. An autosomal dominant familial cancer syndrome in which affected individuals are predisposed to the development of multiple BCCs at an early age and a variable combination of other phenotypic abnormalities including a highly characteristic facies (with large forehead), bifid or otherwise misshapen ribs, vertebral and other skeletal anomalies, pits of the skin of the palms and soles, dysgenesis of the corpus callosum, calcification of the falx cerebri (at an earlier age than is seen in non-affected individuals) and macrocephaly.

Aetiology and incidence. Population-based studies suggest that the prevalence of this disorder in the UK is approximately 1 in 56 000 of the population [3]. The high rate of new mutations and the variable expressivity of the condition, however, makes full ascertainment difficult, particularly in mildly affected individuals where there is no family history of the condition. Although NBCCS differs from other autosomal dominant cancer syndromes in that many of the associated features are developmental abnormalities, the presence of multiple BCCs at an early age is consistent with the 'two hit model' for inherited cancers first proposed by Knudson. The gene for this syndrome maps to chromosome 9q22.3–3.1 and the frequent

loss of heterozygosity of this region in DNA from both sporadic and familial BCCs indicates that the gene is a tumour-suppressor gene [4]. The NBCCS gene was identified in 1996 with the identification of mutations in the *PATCHED* (*PTCH1*) gene in the germ line of NBCCS patients and in sporadic BCC tumour samples [5]. *PTCH1* is the human homologue of PTC, which was first identified as a key regulator of the evolutionarily conserved Hedgehog (Hh) signalling pathway in elegant genetic studies of embryonic segmentation and imaginal disc specification in *Drosophila*. This finding was the first reported example of a link between genes important in development and cancer, and provided a completely new insight into the molecular pathways important in the development of this common skin cancer. The importance of Hedgehog signalling during normal development explains many of the other phenotypic abnormalities seen in patients with NBCCS and these features are consistent with findings from studies of heterozygote *PTCH1* knock-out mice [6].

Clinical features [7]. The skin manifestations of the syndrome are varied and include BCCs, skin tags, palmoplantar pits, milia, epidermoid cysts and lesions that clinically resemble dermal naevi. Skin lesions including BCCs may be present at birth or develop in infancy but more frequently develop between puberty and 35 years of age. The number and type of skin lesions is very variable both within and between families and there is a marked difference between white people and African Americans in the number of BCCs [8]. It is not uncommon to find affected individuals with several hundred lesions. With the exception of the pits that are localized only on the palms and soles, skin lesions can occur in any region. The eyelids, nose, cheeks and forehead are the usual sites, but the neck, trunk and axillae are quite frequently involved. The scalp and limbs are usually spared.

The individual lesions are smooth surfaced, rounded, elevated papules, flesh-coloured or pigmented, varying in size from 1 to 15 mm in diameter. The lesions tend to increase in size and number up to late adolescence. There may be fine telangiectasia and milium-like bodies just below the surface. Tumours of the axillae, neck and eyelids tend to be pedunculated. Most lesions appear to behave in a relatively benign fashion with barely discernible growth and/or evidence of clinical progression. As is the case for patients with sporadic BCCs, some patients with NBCCS develop more aggressive tumours, which can be more difficult to treat and may cause significant morbidity or, rarely, death resulting from extensive invasion and/or recurrence following treatment. The proportion of NBCCS patients who develop very aggressive tumours and the risk factors for this have not been established. Aggressive tumours appear to occur more frequently on the eyelids or nose, and can cause gross destruction. In one study, four of five cases with aggressive BCCs in a series of 36 NBCCS patients received radiotherapy as the initial therapy, which suggests that radiotherapy may be a contributing factor to tumour aggressiveness in some NBCCS patients [9]. A variety of other skin manifestations have also been described, including multiple epidermoid cysts, milia and palmoplantar pits. The pits are a useful diagnostic feature that occur in about 65% of adults with NBCCS but are relatively rare in children. They are characterized by small, more or less circular pits, which may have an erythematous base and are usually 1–2 mm deep.

Other diagnostically useful phenotypic abnormalities in NBCCS patients include jaw cysts, a highly characteristic facies (broad nasal root, hypertelorism, frontal bossing), bifid or otherwise misshapen ribs, vertebral and other skeletal anomalies, dysgenesis of the corpus callosum, calcification of the falx cerebri (at an earlier age than is seen in non-NBCCS individuals) and macrocephaly [2]. The dental cysts are usually multiple, occurring in one or or both jaws, and are odontogenic keratocysts [10]. Skeletal abnormalities include spina bifida occulta, bifid or splayed ribs, scoliosis or kyphosis, and occur with one-third of the frequency of the cysts or the basal cell naevi [11]. Less common associated anomalies include syndactyly, shortened metacarpals, cleft lip and palate, bicornuate uterus, hypogonadism in males, lymphatic cysts of the mesentery, ocular abnormalities including dystopia canthorum, cataracts and congenital blindness, and a variety of neurological disorders [12–17]. In addition to BCCs, the syndrome is associated with an increased susceptibility to other neoplasms including rhabdomyosarcoma, ovarian and cardiac fibromas and, in particular, medulloblastoma. Approximately 3% of NBCCS patients develop medulloblastomas, and approximately 3% of patients with medulloblastomas have NBCCS [18].

Pathology [19]. The histopathological appearance of BCCs from patients with NBCCS are indistinguishable from those seen in sporadic BCCs. The tumours induce a fibrous stroma as occurs with trichoepithelioma or nodular BCC, and the lesions may become papular or pedunculated. Deeper penetration, ulceration and invasion can occur, with lymphocytic infiltration. There may be pigmentation in and around the masses. The presence of calcification and the general architecture can resemble trichoepithelioma. Palmoplantar pits show focal absence of the stratum corneum with vacuolization of the spinous layer. At an ultrastructural level, pits show evidence of premature desquamation with a reduction in desmosomes and tonofibrils resulting from delay in maturation of the epidermal basal cells [20,21]. BCC has developed in palmar pits [22–24].

Diagnosis. In many cases, the skin lesions resemble melanocytic naevi, von Recklinghausen's neurofibromatosis or skin tags rather than BCC, and their true nature

may be suspected only because of associated features or family history. The correlation between the clinical and pathological features of the range of skin lesions seen in NBCCS patients is still poorly understood, which makes it difficult to draw firm conclusions about the natural history of the different skin lesions in these patients.

Treatment. The large number of lesions in patients with NBCCS means that primary excision of all lesions is not always practicable. Radiotherapy is contraindicated as many patients show an accelerated rate of development of new BCCs within an irradiated field, and where recurrences do occur they frequently are more aggressive and difficult to manage than the initial primary tumour. Surveillance of NBCCs patients who have developed BCCs can be useful for the early detection and treatment of new lesions. Although no controlled trials have established that reduced sun-exposure can reduce the rate of BCC development in NBCCs patients, the reduced prevalence of BCCs in African Americans with this syndrome suggests that advice on reducing sun exposure is important [8].

Treatment of individual lesions should be guided by anatomical location, tumour size, clinical appearance and histology, with primary excision the treatment of choice for BCCs on the central face near critical structures. For superficial BCC on the trunk, approaches such as curettage and cautery or cryotherapy are useful. While the recurrence rate is potentially greater with these therapies, they are an effective, convenient alternative for small or superficial BCCs distant from critical sites in patients with large numbers of lesions. Where the presence of large numbers of superficial lesions limits the acceptability of conventional therapies, then photodynamic therapy with a systemic or topical photosensitizer and an appropriate laser or non-laser light source can be a useful and effective treatment option. Other non-surgical approaches that can be useful in the management of superficial lesions at non-critical sites include topical 5-fluorouracil and imiquimod formulations. These approaches have been shown to induce histological clearing of some BCCs and can reduce but not replace the need for more conventional therapies in patients with large numbers of lesions [24,25]. The value of systemic chemoprevention strategies in the management of patients with NBCCs is still unclear. A few studies suggest that systemic retinoids (isotretinoin (> 4 mg/kg) and etretinate (0.7–1 mg/kg)) may reduce the rate of development of new BCCs [26,27]. The clinical benefits, however, appear small relative to those seen in patients with multiple cutaneous SCCs.

Follicular atrophoderma and basal cell carcinoma

SYN. BAZEX–DUPRÉ–CHRISTOL SYNDROME

This syndrome is a rare genodermatosis that also

predisposes affected individuals to multiple BCCs [1,2]. Additional clinical features that allow distinction from NBCCS include follicular atrophoderma, hypotrichosis and hypohidrosis. Follicular atrophoderma is present at birth or in early childhood, and shows as 'ice-pick marks', enlarged follicular ostia on the dorsa of hands, elbows, feet and face. The follicular changes are not caused by injury or inflammation but there may be facial eczema soon after birth. There may be anhidrosis of the face and head, and hypotrichosis. The BCCs appear on the face in the second or third decade and resemble cellular naevi [3].The absence of male–male transmission is suggestive of X-linked inheritance, and this has been confirmed by linkage analysis, which has mapped the gene to Xq24–q27 [4]. The association between BCCs and clinical abnormalities of the hair follicle is of interest as BCCs have the same cytokeratin profile as a subpopulation of follicular keratinocytes [5]. The importance of the Hedgehog signalling pathway in BCC development in patients from affected families with this disorder is not yet known.

Rombo syndrome

Rombo syndrome is a very rare autosomal dominant syndrome first described in 1981 (MIM 180730). Affected individuals develop vermiculate atrophoderma, milia, hypotrichosis, trichoepitheliomas and peripheral vasodilation in addition to BCCs [1,2]. Although there are some similarities with Bazex's syndrome (follicular atrophoderma and milia), there are a number of distinctive features including cyanotic discoloration of the hands and lips in childhood, and telangiectasia. The genetic locus for Rombo syndrome has not yet been mapped.

Self-healing epitheliomas

SYN. MULTIPLE SELF-HEALING EPITHELIOMA OF FERGUSON-SMITH

This condition is an autosomal dominant condition first described by Ferguson-Smith in the 1930s, characterized by the intermittent development of spontaneously regressing skin tumours histologically identical to well-differentiated SCCs.

Incidence and aetiology. The incidence is unknown but the condition is very rare. Two large Scottish kindred are well described in the literature [1–3], and accurate genetic pedigree analysis has suggested that the condition may have arisen in these two families from a single mutation around 1790. The gene has been mapped to chromosome 9q22–q31 in these families but has not yet been identified [4]. Other sporadic cases have been reported. The lesions develop most frequently on light-exposed skin and it is postulated that UVR is an important co-factor in the development of these tumours.

Clinical features [5]. Patients usually develop their first lesions in the second decade, and each patient tends to have a fairly specific pattern of development, duration and evolution. Knowledge of the 'normal' pattern for the patient is of great value in the management of individual lesions.

The lesions develop predominantly on exposed skin and may cluster around the nose or ears. In the majority of reported cases, one or more lesions have been present in the scalp, a site rarely affected by keratoacanthoma. A small, raised, red nodule is the first sign of a new lesion. This may grow over 2–4 weeks to a diameter of 2–3 cm and may become crusted or ulcerated. The lesion then may remain unchanged for 1–2 months, and then gradually shrink, leaving behind a very characteristic and unsightly crenellated scar (Fig. 36.1).

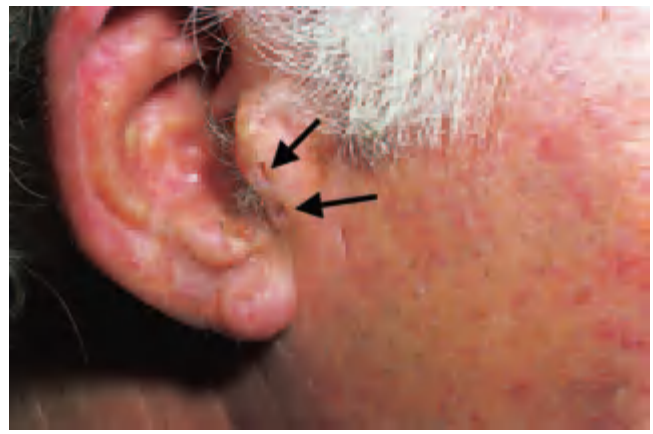

Fig. 36.1 Scarring seen in patient with multiple self-healing squamous epitheliomas of Ferguson-Smith.

Lesions develop singly or in crops. In one case they were strikingly confined to half of the body [6].

Pathology. The lesions have features that are indistinguishable from invasive SCCs, but are quite distinct in most cases from multiple keratoacanthoma with which they should not be confused. The epidermis may be ulcerated, and demonstrates marked cellular atypia and loss of polarity. Invasive tongues of epithelial cells will be seen at the base of the lesion and isolated invasive clumps of cells may be seen detached from the main tumour mass, which is still adherent to the epidermis. There is no marked 'shouldering' of the lesion by normal keratinocytes as is seen in keratoacanthoma, and the leukocyte abscesses characteristic of the older keratoacanthoma are absent.

Management. Although spontaneous involution does occur, the resultant scar is unsightly and the end results of shaving or curetting the lesions at an early stage in their development are more acceptable. Cryotherapy of a lesion in the early stages produces an excellent result.

Xeroderma pigmentosum

This is a rare autosomal recessive disorder characterized by extreme sun sensitivity, which is associated with a marked increase in skin cancer susceptibility, with affected individuals developing multiple precancerous lesions and skin cancers at an early age (see Chapter 12). From a historical perspective this condition is important as it is one of the key pieces of evidence that highlighted the carcinogenic potential of UVR and was the first model in humans that supported the somatic mutation theory of the initiation of cancer. Recent evidence from studies of other genetic sun-sensitive syndromes in humans has challenged the original assumption that the increased cancer susceptibility in xeroderma pigmentosum (XP) patients is exclusively the result of persistent DNA lesions caused by defective DNA repair following exposure to UVR. The new data have come from elegant studies of patients with trichothiodystrophy (TTD) who show photosensitivity and defective nucleotide excision repair that resembles that seen in XP patients [1]. In contrast to XP patients where there is a more than 2000-fold increase in skin cancer incidence, TTD does not appear to be associated with skin cancer. Although the basis for the differences in NMSC susceptibility between XP and TTD has not yet been established, a number of XP-specific changes have been identified that are helping to shed new light on the mechanisms of ultraviolet carcinogenesis. These include differences in the repair of some photoproducts, in the nature of DNA damage induced, and in the effects of UVR on the immune response to tumour cells.

Muir–Torre syndrome

SYN. HEREDITARY NON-POLYPOSIS COLORECTAL CANCER

This autosomal dominant syndrome originally described in 1967 is characterized by the presence of one or more sebaceous neoplasms in association with internal malignancies, most frequently carcinoma of the colon. The clinical and pathological features overlap with hereditary non-polyposis colorectal cancer (HNPCC) syndromes and these disorders have now both been shown to be caused by germ-line mutations in genes involved in DNA mismatch repair [1]. Tumours in patients with Muir–Torre syndrome are characterized by alterations in the length of DNA sequences called microsatellites and this microsatellite instability has been identified in sebaceous neoplasms from patients with Muir–Torre syndrome [2]. A number of other skin tumours including SCC, BCC, keratoacanthoma and AK have also been described in patients with this syndrome but the significance of these findings has been difficult to establish as the high frequency of undiagnosed NMSC in the population make it hard to differentiate a real increase from an increase resulting from ascertainment bias. The recent identification of microsatellite instability in skin tumours other than sebaceous neoplasms indicate that the NMSC noted in previous clinical studies of Muir–Torre kindreds are more likely to reflect a true increased susceptibility and not simply a result of ascertainment bias [3,4].

Other cancer susceptibility modifying genes

In addition to the rare, highly penetrant skin cancer predisposition syndromes described above, there is increasing evidence that other genetic loci can contribute to sporadic NMSC risk. The importance of these so-called modifying genes has been highlighted in studies using mouse cancer models in which genes have been identified that markedly reduce the rate of cancer development in mice carrying germ-line mutations in known tumour-suppressor genes [1,2]. It is likely that similar, as yet unidentified genes in humans account for the marked variations in the susceptibility to BCC development seen both within and between families with NBCCS. At present, identification of these high-frequency low-penetrant genes in humans is based on educated guesswork based on consideration of factors that might contribute to NMSC development. Epidemiological studies have already identified a number of complex phenotypic traits such as skin colour, ethnicity and freckling tendency, which are associated with an increased risk of NMSC development [3]. In addition to the well-recognized importance of differences in skin pigmentation, variations in UVR, DNA repair capacity and xenobiotic metabolism have been implicated as important modifiers of sporadic NMSC risk [4]. The complexity of this area is well illustrated in a recent population-based case–control study of the *XRCC1* arginine to glutamine (arg399gln) polymorphism [5]. The *XRCC1* gene is important in base excision and single-strandbreak repair and the arg399gln polymorphism is associated with decreased DNA repair capacity. For NMSC, the overall effect of the polymorphism is a reduction of NMSC risk. This contrasts with the findings in many other cancers where the polymorphism is associated with an increased cancer susceptibility. Comparison of subjects, however, with marked differences in sun exposure in the same study has revealed that the impact of the polymorphism on NMSC risk is dependent on sun exposure and that it is associated with an increased risk in subjects with high exposure and a reduced risk in subjects with low exposure. While the basis for this differential effect is still unclear, it may reflect differences in the apoptotic capacity of keratinocytes in these different patient groups. A delay of repair in keratinocytes capable of apoptosis may increase the likelihood of elimination of abnormal cells, whereas a delay of repair in apopototic-deficient keratinocytes may favour persistence of abnormal cells and the development of further genetic changes.

Chronic injury and scarring

It has been recognized for many years that NMSC can arise at sites of chronic inflammation and/or scarring. Although there is a substantial literature on this subject, it is difficult to assess the risk as there are no prospective studies of patients with conditions recognized as being associated with NMSC development. Conditions linked to NMSC development include burns [1,2], discoid lupus erythematosus [3], necrobiosis lipoidica [4,5], lupus vulgaris and skin fistulae resulting from discharging sinuses. A particularly strong clinical association has been identified between patients with recessive dystrophic Epstein–Barr virus (EBV) and SCC development [6,7]. The basis for the association between deficiency in type VII collagen resulting from germ-line gene mutations and SCC risk in dystrophic EBV patients is not known. In contrast to other forms of EBV, fibroblast collagenase is increased in dystrophic EBV and this has recently been shown to be associated with marked elevation of urinary excretion of basic fibroblast growth factor [8]. Further studies of SCC development in patients with dystrophic EBV may provide new insight into the long-recognized association between wounding and SCC development.

Immunosuppression

Immunosuppressed patients show a marked increase in susceptibility to NMSC development, with an earlier age of onset and a higher incidence of multiple primary tumours relative to immunocompetent patients. This marked increase in NMSC incidence in these patients is powerful evidence of the importance of the immune system in limiting NMSC development in humans. The cumulative incidence for NMSC uncorrected for age has been shown to vary between 27 and 40% after 20–25 years of immunosuppression in different populations within Europe [1,2]. In Australia, the cumulative incidence appears to be significantly higher after only 10 years of immunosuppression, highlighting the importance of UVR as a co-factor for cancer development in these patients [3]. The risk of NMSC development in renal transplant recipients, which is the best-studied group of immunosuppressed patients, is very variable between different centres as a result of differences between populations including the age distribution of the transplanted patients, the duration of transplantation and the ambient sun exposure of the country. In the UK, a 50-fold increase in the risk of developing SCCs and a fivefold increase in BCC risk has been described in renal allograft recipients [1]. Even greater increases in risk have been described in another European study with a 250-fold increase in SCC incidence and a 10-fold increase in the incidence of BCCs [4]. Epidemiological studies have established that in immunosuppressed patients there is a close association between the development of NMSC and premalignant lesions and the presence of viral warts [5]. The viral warts and skin cancers both preferentially co-localize to areas of sun-exposed skin, although there are some interesting differences between immunocompetent and immunosuppressed patients in SCC distribution with a greater proportion on the hands and forearms in immunosuppressed patients [6].

The molecular and cellular biology of non-melanoma skin cancer

NMSC is unique among human cancers in that the main aetiological factors have been identified and the accessibility of the skin has facilitated analysis of the clinical, pathological and molecular characteristics of these tumours. Advances in molecular and cell biology over the last 10 years has seen an enormous growth in the amount of descriptive data cataloguing changes at the DNA, RNA and protein level in NMSC [1]. While this information in itself has provided an insight into the basis for some of the clinicopathological differences between BCCs, SCCs and related premalignant lesions, a fuller understanding of the biology of NMSC will be critically dependent on approaches that integrate emerging molecular data with the clinical and epidemiological aspects of this important disease. This section outlines current concepts and summarizes some of the more important advances in the biology of NMSC, which have important clinical implications. Topics discussed include cancer genetics, multistage carcinogenesis, UV carcinogenesis and the role of HPV infection in NMSC development.

Cancer as a genetic disease

Cancers are, with few exceptions, clonal; they are derived from a single somatic cell and have accumulated a series of changes that lead to complex and persistent changes in gene expression and cell behaviour. Although it has long been thought that these phenotypic changes require the stepwise accumulation of growth-advantageous heritable changes, direct evidence of the importance of genetic alterations in tumorigenesis has only come within the last decade [2]. Genes important in cancer development can be broadly divided into three categories:

1 Proto-oncogenes that encode for proteins that regulate cellular proliferation and differentiation. These genes are inappropriately activated in cancer cells by point mutations, gene amplification or chromosome translocation.

2 Tumour suppressor genes that maintain a normal phenotype by limiting growth, invasiveness and other features of malignant cells. Mutations are recessive at the cellular level, which means that the effects of alterations in these genes are only seen when both copies are inactivated.

3 Mutator genes that encode for proteins that play a critical part in maintaining genomic integrity. The importance of this class of genes in determining cancer susceptibility was first recognized in studies of patients with rare autosomal cancer susceptibility syndromes such as XP, Bloom's syndrome and ataxia telangiectasia where there

are abnormalities in the recognition, response and/or repair of DNA damage [3]. Further evidence of the importance of 'mutator' genes has come with the demonstration of instability of dinucleotide repeats in a number of common cancers that are caused by either germ-line or somatic mutations in enzymes important in mismatch repair [4]. More recently, a number of groups have shown that genetic factors also influence genetic stability at a chromosome level and there is increasing evidence that the destabilizing of the genome by mutations in genes that normally maintain chromosomal stability plays an important part in the development of some cancers [5].

Molecular genetic analysis of human NMSC have to date focused on four main areas: the role of genes identified in other human cancers; the mapping of chromosome losses; the mapping and positional cloning of familial NMSC susceptibility genes; and comparisons of genetic changes in SCCs with AK and Bowen's disease [1]. As has been the case for other epithelial cancers such as breast and colon cancer, most of the genes implicated to date in NMSC development are tumour-suppressor genes. DNA sequencing has identified mutations in the *p16* and *p53* tumour-suppressor genes. Comparison of the mutational spectra of these genes in NMSC and internal malignancies has confirmed the importance of UVR-induced mutagenesis in NMSC development [6]. Although the *p53* gene has been linked to genetic instability in other cancers, the mutation frequency in BCC and SCC appears broadly similar, which raises interesting questions about the functional effects of *p53* mutations in keratinocytes. Loss of heterozygosity studies have revealed that BCCs and SCCs show marked differences in the pattern and extent of chromosome loss. BCCs differ from SCCs and other epithelial neoplasms in that chromosome losses are largely confined to a single chromosome arm, 9q. Subsequent studies have confirmed that the gene for the NBCCS maps to chromosome 9q and that the high frequency of loss in sporadic BCC reflects the importance of the *PATCHED1* tumour-suppressor gene in BCC development. SCCs show more widespread losses with frequent loss of 9p, 13q, 17p, 17q and 3p [1]. Although the high frequency of allelic loss on these chromosome arms suggests that these regions may contain one or more genes important in the development of cutaneous SCCs, with the exception of *p16* on 9p and *p53* on 17p chromosome, the identities of the candidate tumour-suppressor genes on these chromosome arms are unknown.

Multistage carcinogenesis in the murine skin model

Mouse skin has, for more than 50 years, played a critical part in the development of the concept of multistage carcinogenesis that has underpinned studies of the biology and molecular genetics of the carcinogenic process. While there are important differences between murine and human skin in the response to both chemical carcinogens and UVR, many of the basic concepts identified using this system have been shown to be generally applicable to many human cancers including NMSC. Observational studies of skin tumour induction by chemical carcinogens led to the concept of 'initiation', 'promotion' and 'progression', which represent different stages of the carcinogenic process [7]. 'Initiation' is characterized by the acquisition of an irreversible change in a cell that in the presence of appropriate growth selection pressures ('promotion') can clonally expand to form a benign tumour (papilloma). The probability of papilloma formation within a given mouse strain is dependent on the nature of the carcinogen, the dose applied and the time course over which the mouse is observed. In the murine two-stage skin carcinogenesis model, 'initiation' is accompanied by mutations in the H-*ras* proto-oncogene and the position and type of mutation within this gene is carcinogen-specific. Dimethylbenzanthracene (DMBA)-induced skin tumours predominately have a mutation at the middle adenosine of Ha-*ras* codon 61 (C<u>A</u>A → C<u>T</u>A)s, whereas methylnitrosurea (MNU)-induced tumours have a G → A transition at codon 12 [8]. This concept of a 'signature' mutation in critical target genes identified in the murine model has underpinned the studies of mutation spectra in the *p53* tumour-suppressor gene and other genes in UVR-induced human NMSC.

The latency period for tumour formation following the application of an initiator is significantly reduced by the application of 'promoters' such as 12-*O*-tetradecanoylphorbol-13-acetate (TPA) and other phorbol esters. In contrast to an 'initiator', a 'promoter' generally has to be applied repeatedly and the frequent visible consequences of promoter application, such as hyperkeratosis and scaling of the skin, subside if the application is discontinued. The observation of latency has parallels with the recent observations in humans that clones of *p53* mutant keratinocyte exist within the normal sun-exposed epidermis many years before clinical lesions become detectable [9].

Initiation and promotion, for example using DMBA and TPA, result in the development of multiple papillomas, which rarely progress to invasive carcinoma. The rate of progression of papilloma to carcinoma can be increased by application of the initiator to a papilloma after it has developed or by repeated application of the initiator to 'normal' skin before promotion. Progression is distinct from promotion in that it is considered to reflect accumulation of additional genetic changes and is generally regarded as irreversible. Support for this concept comes from studies of mouse skin tumours, which have established that the transition from benign papilloma to carcinoma is accompanied by an increase in the number of genetic abnormalities in the tumours. This requirement to accumulate additional genetic changes to facilitate tumour progression can occur without further application

of an initiator in tumour cells that show 'genetic instability' as this increases the probability of additional genetic changes, which allow histological progression, invasion and metastasis.

Differences between mouse strains and between species in both their susceptibility to cancer induction and the types of tumours induced by identical regimens highlight the importance of other genetic factors in determining cancer susceptibility. The well-defined mouse model system has allowed mapping of these 'modifier' genes and it has now been established that these genes frequently exert their effect by acting in combination and that the same allele can exert opposite effects in different strains of mice [10]. These observations highlight the difficulties in interpreting results from cancer gene association studies in humans.

Ultraviolet radiation mutagenesis and DNA repair

The overwhelming evidence from clinical and epidemiological studies implicating UVR as the most important skin carcinogen makes it easy for us to answer the question, 'Does the sun cause skin cancer?' Answering the question, 'How does the sun cause skin cancer?' is much more challenging and from the information available at present it is still unclear which one or combination of the multitude of effects that UVR has on the skin is critical for all of its carcinogenic properties.

The UV part of the solar electromagnetic spectrum is subdivided into three broad regions:

- UVC (200–280 nm)
- UVB (280–315 nm)
- UVA (315–400 nm).

UVC is widely used in *in vitro* studies of the effects of UVR but is not relevant to human skin cancer as it is efficiently attenuated by the Earth's atmosphere. Although it accounts for less than 10% of the spectral energy of sunlight, UVB is the main waveband responsible for sunburn and skin cancer induction. UVA differs from UVB in a number of ways. It is the main (more than 90%) component of terrestrial sunlight but is less biologically active than UVB. Both UVB and UVA are complete carcinogens in that they are both capable of inducing benign papillomas and SCCs in murine skin.

The effects of UVR on the skin are complex and it is likely that a number of these effects contribute to its initiating and promoting properties. Exposure to both UVB and UVA cause genetic changes in many biological systems [11]. Dose for dose, UVB is a much more efficient mutagen than UVA and the types of mutations induced by these different wavebands are distinct. The action spectra for DNA damage and skin cancer induction are very similar for UVB and closely coincide with the absorption spectra of DNA, which suggests that direct DNA damage by UVB is an important contributor to its carcinogenic effect. Cyclobutane or pyrimidine dimers and the 6-4 photoproduct are the predominant photolesions induced by UVB and these are the preferential sites for UVB-induced mutagenesis [12]. For UVA, the spectra for DNA damage diverges from that of DNA absorption and it has been inferred that DNA damage by wavelengths above 347 nm is not caused by direct absorption by DNA but is more likely a consequence of indirect effects caused by the generation of reactive oxygen species [13]. The types of DNA damage associated with exposure to UVA are DNA strand breaks and DNA protein cross-links.

The mutagenic effects of UVR on keratinocytes within the skin are dependent on the amount and wavelength of the exposure, cellular antioxidant defences [14], the effectiveness of DNA repair mechanisms and the characteristics of the target keratinocyte. Studies in *Escherichia coli* have demonstrated that UVB induces a characteristic spectrum of mutations that is sufficiently distinctive to serve as a molecular 'signature' or 'fingerprint' of DNA damage [15]. This 'fingerprint' is characterized by the presence of C → T transitions at dipyrimidine sites, either singly (C → T) or as a tandem double bases substitution (CC → TT). The identification of mutations that show this molecular fingerprint in human NMSC [6] and in mouse skin tumours induced by UV provides important evidence at the molecular level of the importance of UVB as a mutagen in skin carcinogenesis [16]. Considerably less is known about the characteristics of mutations induced by UVA. As the DNA damage with UVA is predominately indirect, it is more difficult to extrapolate findings from *in vitro* studies using bacteria or mammalian cells. *In vivo* studies using a transgenic mouse model have shown a predominance of GC → AT transitions at non-pyrimidine dimer sites, which is consistent with the proposed involvement of oxidative DNA damage [17].

Mutations induced by UVR are a result of persistence of unrepaired photoproducts at the time of DNA replication. During DNA replication, the DNA polymerase complex misreads the photoproduct on the template strand and this leads to the insertion of a default adenine residue at this position. At subsequent cell divisions, this adenine pairs with thymine and the net result is the conversion of a cytosine base to a thymine base on the originally damaged strand. A number of studies have shown that there appears to be a close relationship between photoproduct formation and carcinogenesis in that enzymatic repair of photoproducts by endogenously activated photolysase [18] or by topical application of T_4 endonuclease in liposomes [19] reduces the incidence of tumour formation. Although these studies are consistent with the original XP paradigm, which directly links unrepaired DNA lesions, mutations and cancer, recent observations from studies of patients with TTD indicate that the marked increase in susceptibility to UV carcinogenesis seen in XP patients is a

result of other effects and not simply a reflection of an increased mutation rate [20]. Detailed comparisons between XP and TTD cells have revealed a number of differences in the repair efficiency and mutational spectrum, but it is still unclear which of these underpin the differences in cancer susceptibility between these syndromes [21,22].

Immunological effects of ultraviolet radiation

The importance of the immune system in human skin carcinogenesis is dramatically illustrated by the marked increases in NMSC incidence in immunosuppressed patients. UVR, in addition to its mutagenic and other direct effects on keratinocytes, has been shown in murine models to exert an immunosuppressive effect that interferes with the ability of the immune system to eliminate UV-induced skin tumours. These observations and the importance of immunosuppressants as a risk factor for NMSC development in humans has led to speculation that UV-induced immunological injury may be an important contributor to the carcinogenic effects of UVR. In mice, skin tumours induced by UVR differ from chemical carcinogen-induced skin tumours in that they are highly immunogenic and are rejected when transplanted into genetically identical recipient mice. The importance of UV-induced immunosuppression in UV carcinogenesis was first recognized in the 1970s when Kripke [23] made the seminal observation that irradiation of recipient mice abolished the ability to reject the transplanted tumours. This work and subsequent studies established that immunosuppression could be transferred to unirradiated animals by adoptive transfer of splenic lymphocytes and that UVR exerted similar effects on the normal immunological reactions to sensitizing chemicals such as dinitrochlorobenzene in contact hypersensitivity reactions. Further investigation of the immunological effects of UVR using skin contact hypersensitivity has revealed that there are marked differences between mice strains in their susceptibility to UVR-induced immunosuppression. Genetic studies have demonstrated that the UV-susceptibility phenotype is dominantly inherited and two genetic loci have been identified that are thought to mediate this effect [24].

The significance of UVR-induced immunosuppression in humans is still unclear. There are some similarities with the findings in mice in that UV irradiation decreases the ability to mount a delayed-type hypersensitivity response when the immunization occurs on exposed skin and there appears to be interindividual differences in the susceptibility to this effect [25–27]. One study suggests that the UV-susceptibility phenotype is more common in patients with NMSC and that 50% of such patients develop hapten-specific tolerance using this test system [28]. While these observations raise the possibility that exposure to UVR may interfere with the ability of the immune system to eliminate UV-induced skin tumours in humans, the clinical importance of this effect is unclear. The observation that pharmacological inhibition of the immune system has a profound clinical effect on NMSC development suggests that the impact of UVR-induced immunosuppression on NMSC development may not be as great as that seen in murine models. However, further work is required to better understand the impact and clinical significance of other, more subtle aspects of the effects of UVR on cutaneous immunity and the implications of these effects in determining NMSC susceptibility in humans.

Human papillomaviruses

The subdivision of HPV types, based on clinical biology and epidemiological studies of anogenital cancers, played a critical part in the dissection of the molecular mechanisms of HPV carcinogenesis. This allowed identification of the characteristics specifically associated with the carcinogenic properties of the high-risk HPV types [29]. Cell biology and molecular studies have shown a good correlation between high- and low-risk HPVs and their ability to transform primary human keratinocytes [30]. The major transforming proteins of the high-risk genital HPVs are the E6 and E7 proteins, which target and inactivate tumour-suppressor genes including *p53* and the retinoblastoma gene.

Clinical and epidemiological studies have also provided compelling evidence of a link between cutaneous viral warts and NMSC and recent molecular studies have allowed analysis of HPV types. Although the increased prevalence of HPV infection in NMSC from high-risk organ transplant recipients is less compelling compared to the information from studies of other HPV-associated cancers, there are some other pieces of evidence that point to a possible direct role for HPV in NMSC development. Genetic analysis of squamous cell neoplasms from immunocompetent and immunosuppressed patients has revealed that there are significant differences between these two patient groups, with significantly less chromosome loss in SCCs from immunosuppressed patients [31]. Further support for a causal role for HPV in NMSC development has come from recent molecular studies that have shown that the E6 protein from some cutaneous HPVs blocks the epidermal apoptotic response to UVR by targeting the pro-apoptopic Bak protein for proteolytic degradation [32]. This finding and the demonstration of an inverse correlation between Bak protein levels and HPV positivity in cutaneous SCCs suggests that cutaneous HPV may promote SCC development by blocking the normal epidermal apoptopic response to UVR [33].

General principles in the management of patients with non-melanoma skin cancer

Many aspects of the management of patients with BCC and SCC are common to both tumour types and these general principles are discussed in this section. Tumour-specific issues are discussed in the treatment section for the relevant tumour. Management of patients with NMSC requires early detection and accurate diagnosis, selection of the appropriate treatment modality based on the clinical and/or pathological findings, consideration of patient-specific risk factors and institution of preventative measures if appropriate.

Detection and diagnosis

Early detection of NMSC is critically dependent on a good awareness of risk factors and the characteristics of tumour development in at-risk groups. Although most patients with NMSC initially present with a lesion requiring a therapeutic intervention, the high prevalence of benign skin disease and the increasing use of medical screening examinations means that there are opportunities for identifying at-risk individuals sooner than they might present with an obvious clinical lesion. Superficial BCCs on the back, Bowen's disease on the leg and AK are not uncommonly either not noticed or dismissed as a normal consequence of ageing. Although early detection of such lesions may have little impact on the clinical prognosis of the identified tumour, the ability to identify at-risk individuals means that advice on preventative measures such as sun awareness and protection can be initiated much earlier than otherwise would have been the case.

Selection of appropriate therapeutic modality for tumour treatment

The aims of any treatment directed against an NMSC is the removal or destruction of the primary tumour mass and, in the case of SCC, the prevention of metastasis. A broad range of therapeutic options are available to achieve these aims and while surgical excision is frequently the treatment of choice, there are a number of reasons why an alternative treatment may be preferred on some occasions. Treatment selection is dependent on a good understanding of the clinical and/or pathological aspects

of NMSC that affect prognosis and clinical experience of the pros and cons of the different therapeutic modalities. The different modalities used in current practice include curettage and cautery, cryosurgery, radiotherapy, photodynamic therapy, laser surgery, conventional surgical excision and Mohs' micrographic surgery (described in detail in Chapter 78). Specific issues with respect to these therapies from a NMSC perspective are outlined below.

Cryosurgery. This modality has been recommended for the treatment of AK, Bowen's disease, superficial BCC, small nodular BCC and small well-differentiated SCC. While freezing with liquid nitrogen is a quick and relatively tolerable procedure that does not require anaesthesia, it can be associated with significant morbidity, particularly when tumours selected for treatment require prolonged freeze times to ensure adequate treatment. This form of treatment is considered in more detail in Chapter 77.

Curettage and cautery. This modality can be used for the same spectrum of lesions as cryotherapy. Curettage with traditional curettes is critically dependent on the friable nature of the tumours, which leads to a selective removal of the abnormal tissues. This differential effect on tumour tissue is an effective way of delineating the extent of some tumours and can be useful before standard or Mohs' excision of some BCCs to define more accurately lateral tumour spread within the epidermis [1]. When used therapeutically it is important that the stroma and surrounding dermis are charred with diathermy or cautery to a depth of 1 mm following initial curettage and that this is repeated a further twice with curetting of the charred tumour base. As the procedure does not divide the upper dermis connective tissue network, healing is usually predictable and occurs in most cases with minimal scarring.

Radiotherapy. Most NMSCs are sensitive to ionizing radiation and radiotherapy offers the potential to treat large areas of tumour and a surrounding rim of normal skin with minimal tissue damage. The effectiveness and cosmetic end result of this therapy is critically dependent on the treatment regimen administered. This operator dependence, which makes comparison of published studies difficult, is also an important contributor to the misconceptions that some physicians have about the value of this approach. Radiotherapy can be an effective cosmetically acceptable treatment for NMSC including BCC, SCC and premalignant lesions such as Bowen's disease. Although it is often stated that radiotherapy is best suited for elderly patients, the inconvenience and practical difficulties of frequent outpatient appointments required for a full fractionated course needs to be taken into account when radiotherapy is considered as an alternative to conventional surgical approaches. In addition to a primary therapy, radiotherapy is also an important adjuvant therapy following excisional surgery for the treatment of residual microscopic disease and as a prophylaxis against systemic metastases. Situations where radiotherapy is best avoided include NMSC on the lower limbs, ear and eyelid, recurrent tumours, lesions previously treated with radiotherapy, tumours with poorly defined clinical margins and patients with multiple NMSCs and severe actinic damage. The technical details of radiotherapy are discussed elsewhere.

Photodynamic therapy. The development of topically active photosensitizing agents has led to studies on the role of photodynamic therapy (PDT) for the treatment of NMSC. This therapy appears particularly effective for AK of the face and scalp and for the treatment of Bowen's disease, where advantages have been demonstrated over other therapies with respect to tolerability and cosmesis [2,3]. The value of PDT for the treatment of BCC is still under investigation. Studies of superficial BCC suggest that a 96% complete clearance rate can be achieved with two treatments 7 days apart [4]. As with other destructive therapies, PDT appears less effective for nodular BCC with inconsistent clearance rates. One of the main advantages of PDT over existing therapies is its potential for the treatment of large and/or multiple lesions on challenging anatomical sites such as the scalp [5].

Laser therapy. Like PDT, this therapy is still under investigation to determine optimal methods of use and compare efficacy rates to conventional therapies. The most widely used laser for the treatment of NMSC and related premalignant lesions is the carbon dioxide (CO_2) laser where the principal chromophore is tissue water. One application of the CO_2 laser has been as an alternative to scalpel excision. Although laser excision can seal small blood vessels, lymphatics and nerve endings, which may reduce bleeding, swelling and postoperative pain, the tissue damage induced may interfere with wound healing and hinder the assessment of margins in the excised specimen. Developments in CO_2 laser technology have increased interest in the use of this approach to selectively vaporize tissues and a number of studies have examined the effectiveness of this modality for the treatment of superficial BCCs and premalignant lesions. Although a full assessment of the efficacy of CO_2 lasers for the treatment of NMSC will require studies with longer follow-up than those available at present, clinical studies have demonstrated excellent short-term results and suggest that the tolerability and cosmetic results may be superior to destructive therapies.

Conventional surgical excision. This is regarded by many as the treatment of choice for primary NMSC. Excision with primary closure, local rotational or advancement flaps or full-thickness graft to repair the defect, when carried out by a trained operator, usually produces a good cosmetic

result and provides the pathologist with a specimen that allows confirmation of the completeness of excision and identification of histological factors associated with increased risk of local or systemic recurrence. Although undertreatment because of lateral or deep tumour extension may be identified in conventionally processed surgical specimens, there is potential to miss cases of incomplete excision as only a small proportion of the tumour edge is examined using conventional histopathological techniques [6].

Mohs' micrographic surgery with pathological control of excision margins [7,8]. This integrated surgical and pathological technique allows precise definition and excision of primary tumours growing in continuity. It is now well established that this approach offers advantages over conventional surgical excision in the treatment of both BCC and SCC of the skin in terms of local recurrence and, in the case of SCC, for metastatic disease. While there are at present differences in practice between individual countries in the threshold for recommending Mohs' surgery, current recommendations are that it is the treatment of choice for recurrent NMSC and primary NMSC with high-risk clinical and/or pathological features for tumour recurrence. Other indications include tumours at high-risk sites (central face, eyelids) and tumours at sites where maximal preservation of normal tissue is important. The Mohs' technique is described in detail in Chapter 78.

Selection of the optimal treatment modality

The selection of the most appropriate therapy for a patient is determined by three key factors: tumour size, tumour location and the likely tumour characteristics based on clinical and, where available, pathological assessment. Low-risk NMSC and related premalignant lesions include AK, Bowen's disease and superficial BCC. These lesions can usually be adequately dealt with using curettage and cautery, cryotherapy or PDT. Although the recurrence rate for these types of lesions with these modalities when used appropriately is slightly higher than that achieved with surgical excision, this needs to be balanced against the fact that these less invasive procedures are relatively simple to carry out, often associated with less short-term morbidity and more predictably give a good cosmetic result compared to excision and suturing. Excellent cure rates for curettage and cautery and/or cryotherapy have also been reported for small (less than 1 cm) nodular BCCs and well-differentiated slow-growing SCCs on sun-exposed skin [9,10]. For intermediate-risk NMSC (tumours less than 2 cm, well-defined clinical margins), the location of the tumour is an important determinant of treatment choice. A specific advantage of surgical excision over other destructive therapies is the provision of tissue for histological examination, which provides confirmation of the diagnosis, information on the adequacy of excision and may allow recognition of histological features associated with a high risk of local recurrence and risk of metastasis. For BCC, these features include location on the central face and a morphoeic histological pattern. For SCC, depth of invasion greater than 4 mm or extension into subcutaneous fat, poor differentiation and perineural involvement have all been associated with increased risk of local recurrence and metastatic disease [11]. For high-risk NMSC, the treatment of choice is Mohs' surgery.

For the management of most NMSC a treatment plan can be defined based on a clear understanding of the pros and cons of the different treatment modalities and a careful consideration of the tumour characteristics. In some cases, such as high-risk patients with multiple NMSCs, high-risk tumours, recurrent tumours or incompletely excised NMSC, optimal selection of therapy may be best achieved in the context of a multidisciplinary tumour clinic with input from dermatologists, plastic surgeons, oncologists and radiotherapists.

Chemoprevention and management of high-risk patients

The surgical treatment of high-risk NMSC differs from that of high-risk patients with many other common cancers such as colon, breast and bladder cancer in that it is not possible to completely remove the target organ. While excision or destruction of lesions is well suited for the management of small numbers of NMSCs or related premalignant lesions, these approaches become increasingly impractical and distressing for high-risk NMSC patients with multiple lesions. Examples of patient groups where this problem arises include patients with NBCCS, immunosuppressed organ transplant recipients, high-dose PUVA patients and patients with severe actinic damage. From our current understanding of the epidemiology and biology of NMSC, the number of high-risk patients is likely to increase considerably over the next 25 years as a result of the changing age structure of the population and increased recreational sun exposure. The management of patients with multiple NMSCs is a considerable therapeutic challenge, which is not helped by the limited number of treatment options available and the lack of controlled clinical studies.

Topical 5-fluorouracil is a valuable therapy for the treatment of superficial BCC and for patients with multiple AK. For reasons that are still not understood, 5-fluorouracil acts on both clinically detectable lesions and subclinical lesions, which means that application to a contiguous area of skin may target a greater number of lesions than would be achieved using destructive therapies of visible clinical lesions. Although there is some evidence to suggest that 5-fluorouracil may reduce the rate of development of new AK, there is no conclusive evidence at

present favouring a role for 5-fluorouracil in the prevention of NMSC [12,13].

A number of systemic approaches have been investigated as chemopreventive agents for high-risk skin cancer patients. Oral retinoids are used to treat patients with multiple SCCs where the rate of new SCC development makes management by surgical intervention difficult. Although oral retinoids show clinical efficacy, there are many unanswered questions on their mode of action and long-term effects as there are very few controlled trials on their use. Etretinate has been shown to be superior to placebo in the treatment of high-risk patients with AK, some of whom also had at least one NMSC [14].

Basal cell carcinoma [1–3]

SYN. BASALIOMA; RODENT ULCER

Definition. A malignant tumour that rarely metastasizes, composed of cells similar to those in the basal area of the epidermis and its appendages. The histology of the tumour and the surrounding stroma is characteristic.

Incidence and aetiology. BCC is the most common malignant tumour of the skin and the most common cancer in some countries, including the USA and Australia. Although the prevalence of this tumour increases within a population as exposure to sunlight increases, the distribution of the lesions does not correlate well with the area of maximum exposure to UVR in that BCCs are common on the eyelids, at the inner canthus and behind the ear, but uncommon on the back of the hand and forearm. The palm, sole and vermilion of the lips are rarely, if ever, involved. The basis for the different susceptibility of skin at different sites to BCC development is not known.

BCC is more common in males than females. A population-based incidence study in Minnesota gives annual incidence figures for males and females of 175 and 124 per 100 000, respectively, [4], and a recent Australian survey gives an incidence in that country of 849 and 605 per 100 000 for males and females, respectively, in 1990 [5], while figures from Hawaii show an incidence of 576 per 100 000 for males and 298 in 100 000 for females [6].

A Canadian case–control study has identified outdoor occupations (particularly farming), freckling, and Scottish or Irish descent as particular risk factors [7]. The Australian case–control study by Kricker *et al*. [8,9] of 226 patients with BCC suggests that the tumour is more common in those born in Australia than in immigrants, that southern European ancestry is protective, and that poor tanners are more at risk than those who tan easily. The presence of large numbers of naevi, freckles and solar elastosis all add to the BCC risk, while a past history of acne is protective [8,9]. A large European study of 1549 southern European patients with BCC reports that those with fair or red hair, those who tan poorly and those who have a history of childhood sunburn are at greater risk, and that acute episodes of intense burning sun exposure are a greater risk factor than cumulative lifetime sun exposure [10,11]. The study by Gallagher *et al*. [12] of 226 Canadian males with BCC again finds pale skin, the presence of freckles and childhood exposures to be risk factors.

BCC is extremely uncommon in dark-skinned races, and less common in Chinese, Japanese and other oriental populations than in white populations [13,14]. Although it may occur at any age from childhood, more than three-quarters of patients are over 40 years old. It occurs earlier and multiple tumours are more common in those with a fair freckled complexion. On the lower leg, the incidence in women is three times as great as in men [13]. BCC appears to arise more frequently and at a younger age in patients who are immunosuppressed. These lesions are frequently aggressive [15]. It is occasionally seen adjacent to leg ulcers [16].

BCC may arise in skin damaged by sunlight and ionizing radiation. It may occur in burn scars [17] or vaccination scars [18,19]. Arsenic salts are also a proven cause [20]. BCC has been reported in identical twins [21]. The increased risk of BCC development in naevus sebaceus and other adnexal hamartomas is well recognized [22–24].

The identification of mutations in the *PTCH1* gene has provided a completely new insight into the pathogenesis

Fig. 36.2 Typical early basal cell carcinoma on the nose.

Fig. 36.3 Extensive ignored basal cell carcinoma on the back of the neck in an elderly man presenting to a British hospital in 1988.

of this common skin cancer and points to a key role for the Hedgehog (Hh) signalling pathway in its pathogenesis (see above and [25,26]).

Histogenesis. Theories about the nature and origin of the cells of BCC have been put forward at intervals over the last 80 years or more. The histological variability does not accord with a derivation from any individual epithelial structure, and is now generally considered to stem from the pluripotentiality of immature cells of the epidermis. It is thus capable of maturing towards any of the epithelial structures, and its behaviour is governed, as is the normal immature cell, by the connective tissue in its proximity. Thus, the stroma dependence, the range of histological patterns and the way these merge with the more organized hamartomas are explained. It has been rightly emphasized that the stroma is an essential part of the neoplastic process and it must also be removed in treatment.

Clinical features [27]. The early tumours are commonly small, translucent or pearly, raised and rounded areas covered by thin epidermis through which a few dilated superficial vessels show (Fig. 36.2). Tiny flecks of pigment may be seen with a hand lens. Other modes of presentation are a small pearly erythematous lichenoid papule or plaque, as a keratotic and slightly indurated area, or as a small and superficial ulcer resembling an excoriation by a fingernail. It may occasionally be pedunculated and telangiectatic, resembling a pyogenic granuloma.

The more advanced tumours have as wide a variety of forms as the early lesions and tend to maintain the same pattern of growth throughout their course. One common type grows slowly as a well-marginated expanding nodule or thickened plaque. The thinned epidermis closely covers the tumour and may periodically scale or erode and crust. In this variety, ulceration occurs relatively late, and may re-epithelialize and break down several times before becoming permanent. The surface contour usually becomes more irregular as the lesion grows. The degree of vascularity varies. There may be surface telangiectasia over a flesh-coloured mass or the tumour may be pink or red in colour. Pigment, when present, is usually unevenly distributed through the tumour. Some or all of the component nodules may have cystic centres, which add to the translucent appearance; the cystic parts may be more deeply pigmented than the peripheral parts.

Less commonly, the tumour spreads only superficially. It is bounded by a slightly raised thread-like margin, which is irregular in outline and may be deficient at part of the circumference. The epidermis covering the central zone is usually atrophic and may be scaly. This, combined with an increased vascularity, gives a resemblance to Paget's disease of the nipple. There may be a series of thickened papular islands of growth within the margin, and these may be crusted or eroded. Superficial tumours are often pigmented.

The atypical rodent ulcer has an indurated edge and base, but no thread-like margin. The edge is usually raised above the normal level but in some areas, particularly in the nasolabial furrows, it may be flush with the surface. The floor of the ulcer is depressed below the skin surface, fleshy in appearance and not very vascular. However, there is more or less inflammation around the tumour. Such an ulcerated lesion may have begun as a nodule, but more frequently it is crusted or eroded from an early stage of its evolution. If left, the tumour and its following ulcer may spread deeply and cause great destruction, especially around the eye, nose or ear (Fig. 36.3). There may be wide extension in the periorbital tissues; the bones of the face, the skull and even the meninges may be invaded, and

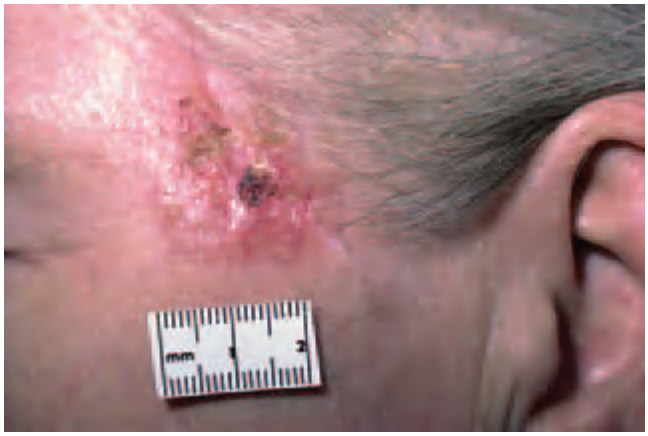

Fig. 36.4 Recurrent basal cell carcinoma that has arisen on the basis of pre-existing morphoeic basal cell carcinoma that was incompletely excised.

advanced cases amply justify the title 'ulcus terebrans' (penetrating ulcer).

The morphoeic or sclerodermiform BCC is uncommon, and is so named because dense fibrosis of the stroma produces a thickened plaque rather than a tumour. The exact margin of the lesion is impossible to define, but palpation reveals a firm skin texture that extends irregularly beyond the visible changes (Fig. 36.4) [28]. The surface is smooth and may be slightly raised above, or sometimes slightly depressed below the normal level. The colour is yellowish and has been compared with old ivory. Ulceration is uncommon and only very superficial when it does occur. Many patients, and doctors, may take little notice of this type of BCC until its slow extension produces a sizeable lesion.

The majority of BCCs arise on the head and neck, with a particular predilection for the upper central part of the face. The morphoeic type occurs almost exclusively on the face. The superficial type, however, is found mainly on the trunk. The palms and soles are rarely affected. BCCs may be multiple.

Post-irradiation tumours of the scalp [29] and those that occur in sun-damaged skin of the face may be multiple and show various stages of development. A few cases of genuine BCCs have been reported to arise from the epidermis over histiocytomas, but the not uncommon basaloid buds seen in sections of histiocytoma are of doubtful significance.

The typical BCC runs a slow progressive course of peripheral extension, which produces the thread-like margin, the nodule with a central depression or the expanding rodent ulcer. Some tumours grow at so slow a rate that they are, for all practical purposes, benign. This is true for many of the superficial lesions and some of the nodular cystic lesions also. There may be spontaneous fluctuation in size, and areas of scarring can be found within many superficial tumours. A patient who has had one BCC treated should always be followed up, not only for local recurrence but also to detect fresh tumours arising elsewhere. There is no recognized premalignant stage of BCC equivalent to solar keratoses or Bowen's disease for SCC.

Rapid growth is so uncommon as to throw doubt on the accuracy of the patient's history. Invasive rodent ulcers, if neglected, may cause death. This is preceded by prolonged mutilation of the face or scalp [30], with destruction of the nose or eye and exposure of the paranasal sinuses or the skull, dura or brain. A few giant exophytic tumours have occurred on the back [31].

In rare cases, the tumour may disseminate [32–37]. When the ulceration involves the airway, fragments of tumour cells and stroma may be inhaled and become implanted in the lungs [35]. Authentic cases of bloodstream metastasis are on record in which, for example, deposits in the viscera or spinal column have caused the presenting symptoms of the terminal illness. Other cases have spread via lymphatics to the regional lymph nodes before disseminating.

Pathology [38,40]. The tumour cells resemble those of the basal layer of the epidermis and the matrix cells of the appendages, in the relatively small amount of cytoplasm they possess and in their ability to interact with the dermis adjacent to them. Their nuclei are compact, rather darkly staining and closely set. Their cytoplasm stains poorly and the cell margins are rather indistinct. Adjacent cells are connected by bridges. The sparsity of keratin fibrils gives these connections a different appearance from the 'prickles' of the Malpighian layer, but the presence of desmosomes and tonofibrils has been shown by electron microscopy. The interaction with the dermis, which is one of the principal functions of the normal epidermal basal cell, produces the characteristic marginal palisade of tumour cells and the well-organized stroma that surrounds it. The dependence of the tumour on its stroma has been shown by transplantation experiments [41]. The cells within the palisade usually show little evidence of organization or differentiation. Mitotic figures may be frequent, and it is speculated that the combination of large numbers of mitoses and a slow growth rate result from a high rate of apoptosis. Data on cell kinetics indicate that a considerable proportion of cells in the tumour die fairly rapidly [42]. Bizarre and atypical cells occur commonly in arsenic-induced tumours [20]. In some tumours, the cells may become acantholytic and amyloid may be identified [38].

In early lesions, the tumour buds can be seen arising from the epidermis. In very small lesions, multiple buds have been seen. These very soon become confluent, and the three-dimensional examination of superficial BCC shows a coherent margin of tumour with a reticular pattern of growth along the interpapillary ridges and larger,

more discrete masses centrally [39]. As the tumour progresses, the masses extend into the dermis, and may separate from each other and from their point of origin. Growth in one area may be accompanied by involution of the tumour in nearby areas leaving an atrophic epidermis. A common site of origin in humans and in the experimental tumours of the rat is the junction between a pilosebaceous duct and the epidermis. From here the tumour may extend along the epidermis and down the duct. It is difficult to prove a purely adnexal origin for BCC, but some lesions behave as though this were so. In all considerations about the origin of the tumour, one must remember that the tumour can either sever its connection with epithelial structures or establish a secondary connection to structures to which it has grown close.

The variability of the natural history of BCCs is reflected in its pattern of growth. Most tumours are composed of rounded expansile islands. These throw out small buds that grow in the same way to produce multilobular masses with thin strands or septa of fibrous tissue penetrating them [39,40]. In some regions, a limited capacity to grow around and enclose adjacent connective tissue may be associated with a reticular or cystic pattern of growth. The capacity to invade in thin strands is often accompanied by an excessive and almost exclusive fibroblastic response, in contrast with the lymphocytic response around the expansile masses. Invasive strands may spread for long distances along nerve sheaths. BCC is truly invasive in only a small proportion of cases. In these, the tumours show no tendency to grow as rounded masses, have no palisade or organized stroma, and penetrate the dermis and deeper structures, destroying them as they go. Such tumours are almost always ulcerated, usually from an early stage. In the less invasive tumour, ulceration occurs when the epidermis is replaced by the tumour. An eroded, vegetating type of growth is rather uncommon.

Most BCCs provoke a round-cell inflammatory reaction of some degree. It increases in extent with ulceration and is often conspicuous in the papillary body, with superficial patterns of growth. Mast cells are often present in numbers among the fibroblasts of the stroma, and Langerhans' cells have been demonstrated within and near the tumour. This infiltrate has recently been correlated with the aggressive nature of the tumour [43].

The diversity of histological patterns of BCC is caused in part by features that have no direct bearing on the clinical course of the tumour. Not infrequently, melanocytes proliferate within the tumour. The melanin they produce causes the tumour to be pigmented, and numerous melanophages collect in the stroma, and sometimes in cystic cavities. Mucin is commonly found in the stroma, particularly at the margin of the tumour, and may be encysted within it. Cystic cavities also form when the centrally placed cells undergo necrosis. There is no evidence that such cavities represent glandular differentiation. Evidence of true sebaceous or sweat gland differentiation has been seen, but is very rare. Within some tumours there are strands of fusiform cells with more abundant eosinophilic cytoplasm, which may form whorls or keratinizing cysts, and which probably represent rudimentary differentiation towards hair roots. Citrulline can be demonstrated as a histochemical confirmation in such cases but does not help in the sometimes difficult separation from trichoepithelioma. Histochemical and electron microscopy investigations show little evidence of differentiation of the tumour cells. However, *in vitro* culture of tumour cells from nodular tumours produces evidence of keratinization after 30 days, suggesting that the cells possess the biochemical mechanisms for keratinization but that some factor, possibly dermal in origin, inhibits them.

Diagnosis. The common nodular type of tumour has a distinctive appearance when it is more than a few millimetres in diameter. In the initial stages it may be hard to separate from a melanocytic naevus (especially when pigmented), molluscum contagiosum or senile sebaceous hyperplasia without the aid of a biopsy. Naevi can be distinguished if hairs grow from the surface, and in molluscum contagiosum and sebaceous hyperplasia there is a central keratin-filled pit. Scaling or crusting on the surface can cause confusion with warts, keratoacanthoma, SCC or molluscum contagiosum. In all cases, the debris should be removed, and this is easily done in BCC. The friable, relatively avascular tissue beneath is characteristic, and if fragments are removed and smeared on a slide the diagnosis can be confirmed by cytology. Darkly pigmented, ulcerated tumours are occasionally confused with malignant melanoma. The margin of BCC is usually rolled, telangiectatic and multinodular, and there is no pigmented halo. The colour tends to be more definitely brown, in contrast with the dusky greyish brown of malignant melanoma.

Perhaps the most difficult problems (although least crucial from the patient's viewpoint) are found with superficial BCCs. Casual inspection may suggest that these are patches of eczema, psoriasis or Bowen's disease. When the scale is removed and the edge stretched, the thread-like margin will reveal the true diagnosis [44]. Careful inspection will almost always rule out eczema or psoriasis, which the patient's history will have also made unlikely. There are some cases, however, where distinction from Bowen's disease can be made only after biopsy. The consistency of a morphoeic BCC may resemble morphoea; the outline is usually less sharp and the evolution more gradual and relentless. A recently described elastotic nodule on the anterior crus of the antihelix of the ear in sun-damaged skin may resemble a nodular BCC on cursory examination.

Clinical diagnostic accuracy in the diagnosis of BCC, widely regarded by most dermatologists as being the

easiest tumour to recognize, is surprisingly poor. One study reported a diagnostic accuracy rate of 70% for academic dermatologists, 65% for dermatologists in private practice and 64% for residents [45].

Treatment. The aims of any therapy selected for the treatment of a BCC is to ensure complete removal and destruction of the primary tumour to prevent local recurrence and the need for further therapeutic intervention. The enormous differences in the natural history and biology of the different subtypes of BCC and the large number of treatment modalities available for the removal and destruction of skin tumours means that it is difficult to draw up rigid guidelines for the management of this common cancer. Successful management of BCC requires a clear understanding of the clinicopathological factors that affect prognosis and a good theoretical and practical knowledge of the strengths and limitations of the many different treatments available for the treatment of BCCs. From published series on treatment outcomes it is clear that successful treatment can be achieved by any one of the large range of therapies, subject to appropriate matching of the treatment to the tumour characteristics [46,47]. In most cases, treatment selection is usually based on a clinical assessment which considers a number of factors that are known to influence tumour prognosis. These factors include tumour size, tumour location, clinical subtype and ability to define tumour margin. In addition to the tumour characteristics, other factors such as the patient's age, adequacy and success of previous treatments and coexisting medical conditions that influence tumour biology or treatment tolerability need to be considered. For reasons that are still unclear, BCC recurring following radiotherapy are particularly difficult to eradicate by conventional surgical excision and this needs to be taken into account when selecting the most appropriate therapy [48].

Destructive therapies used appropriately with careful tumour selection can offer an effective alternative to surgical excision for small primary tumours at non-critical sites. A number of studies have shown that curettage and cautery of low-risk BCCs can give cure rates of up to 97% [49]. Similar high cure rates have also been reported for cryotherapy for low-risk BCCs [50,51]. Tumour size has an important effect on prognosis for BCCs and there is good evidence that the recurrence rate following curettage and cautery or cryotherapy increases significantly with increasing size [52,53]. In addition to recurrence risk, it is also important to bear in mind that the morbidity associated with cryotherapy also increases with increasing size.

Conventional surgical excision with predetermined margins based on the clinical characteristics of the tumour is regarded by many as the most appropriate therapy for most nodular BCCs and provides a specimen for histological examination and assessment of the lateral and deep margins. Information from studies of Mohs' surgical specimens have provided useful information about the probability of achieving complete excision in tumours with predetermined margins in different sized BCCs. For BCCs less than 2 cm in diameter with well-defined clinical margins, a 3-mm margin will clear the tumour in 85% of cases and a 4–5-mm margin in 95% of cases [54,55]. Although it has been estimated that careful inspection of the common nodular and plaque forms of the tumour with a loupe allows the margin to be determined to within 0.5 mm of the histologically proven border, inaccuracies in the clinical assessment of tumour margins is an important cause of incomplete excision of nodular BCCs as underestimation of tumour size can lead to overlap of the predetermined margin with lateral extension of the tumour [38]. Small ulcerated nodular BCCs, which present as non-healing erosions, not infrequently extend several millimeters beyond the clinically defined margin. For these tumours and others where the margin is less clearly defined, curettage prior to excision is a useful technique for more accurately defining the true borders of the BCC [56]. Even in experienced hands there is a risk that nodular BCCs with apparently well-defined clinical margins may have infiltrated more extensively, leading to incomplete excision with residual tumour. In some cases, strands of cells extend along the fine nerves of the skin for a considerable distance beyond the obvious clinical edge of the tumour [57]. The outlook is poor when cartilage, bone or the orbit have been invaded.

Although a clinical recurrence is not inevitable in patients with incompletely excised BCCs, there is a significant risk which is dependent on the extent of the infiltration and aggressiveness of the tumour based on histological assessment. It is well recognized that total removal of a BCC is not an absolute requirement to effect cure and that many incompletely excised BCCs do not recur [58,59]. Based on information generated over the years on residual tumour in re-excision specimens and recurrence rates of incompletely excised tumours, it may be reasonable in cases where there is incomplete excision of the lateral margin only, not to re-excise if the BCC is a primary tumour on a non-critical site with a non-aggressive histology. For all other cases and in cases where the surgical defect has been repaired using a skin graft or local flaps, immediate re-excision with frozen section control or using Mohs' micrographic surgery is the treatment of choice [60–62].

The management of morphoeic BCC, large BCCs (more than 2 cm), some smaller nodular BCCs with poorly defined clinical margins and recurrent BCCs needs to take into account the increased likelihood of subclinical extension. In the absence of either frozen section control or Mohs' surgery, these tumours will require large predetermined margins; even a 5-mm margin will only give complete excision of 82% of morphoeic BCCs [54].

Management of recurrent BCCs is a difficult problem as cure rates are consistently poorer than those achieved for primary tumour. Mohs' surgery is an important treatment option for the treatment of high-risk BCCs as it offers consistent high cure rates for even the most difficult BCCs. For primary BCCs, 5-year cure rates of 99% have been reported [63]. For recurrent BCCs treated with Mohs' surgery, the reported 5-year cure rate in a large review was 94% [64]. The proportion of BCCs treated using Mohs' surgery varies considerably between different countries as it is a relatively specialized technique and is more resource-intensive than simple surgical excision. Tumour characteristics that warrant consideration of Mohs' surgery include BCCs at high-risk sites (nasolabial fold, periocular and nose), BCCs larger than 2 cm, morphoeic, infiltrative or micronodular BCCs and recurrent BCCs [46].

Basisquamous or metatypical basal cell carcinoma [65,66]

This term is used for tumours that on pathological study appear to have features of both BCC and SCC. The biological significance is that this pathological pattern is associated with a significantly higher incidence of metastatic spread [67]. The pattern in these lesions is of small aggregates of cells lacking classic palisading and embedded in dense and profuse fibrous stroma. The cells are larger with a larger paler nucleus than in the classic BCC and have a more eosinophilic cytoplasm.

Squamous cell carcinoma

Definition. A malignant tumour arising from the keratinocytes of the epidermis.

Incidence and aetiology. The epidemiology and risk factors important for cutaneous SCC development have been described in detail in the previous sections on NMSC. SCC of the skin is a heterogeneous disease both aetiologically and clinically, with different risk factors implicated in its development in different populations. The epidemiology of the disease has changed over the last 50 years, with a decrease in the importance of occupational exposure to chemical carcinogens and an increase in the proportion of cases caused by recreational sun exposure. In addition, new diseases such as HIV infection, and therapeutic advances such as the introduction of effective immunosuppressive therapies to prevent rejection of transplanted organs, and PUVA therapy have resulted in the emergence of new populations that are highly susceptible to cutaneous SCC development [1,2].

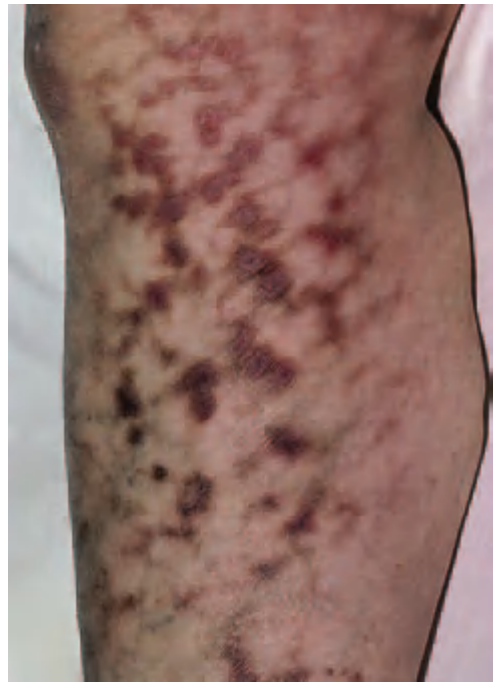

Fig. 36.5 Area of erythema ab igne on the lower leg of an elderly female.

Cutaneous SCC is predominately a disease of white populations and is especially prevalent in this group in areas of high ambient sun exposure [3,4]. Although the incidence is low in non-white populations, SCC is still the most common skin cancer in these populations but shows differences in the anatomical location of the tumours, in recognized aetiological factors and in prognosis [5]. Factors implicated in the pathogenesis of cutaneous malignancy in Africans and African Americans include trauma, albinism, burn scars, ionizing radiation, chronic inflammation and chronic discoid lupus erythematosus [5,6]. There is a high incidence in albinos in Tanzania but no evidence of an increased incidence in vitiliginous skin of black people [6,7]. Additional aetiological factors implicated in cutaneous SCC development in some populations include chronic exposure to thermal radiation and chronic scarring. Radiant heat from coal and peat fires may cause SCC in women who habitually sit with their legs close to the fire [8,9]. The preceding lesion is called erythema ab igne (Fig. 36.5). SCC is also an occasional complication of long-standing chronic granulomas such as venereal granulomas, syphilis, lupus vulgaris and leprosy and lupus erythematosus, chronic ulcers,

Fig. 36.6 Multiple invasive squamous cell carcinomas in a patient with a history of exposure to arsenic.

Fig. 36.7 Raised erythematous invasive squamous cell carcinoma in an elderly patient on a light-exposed site.

osteomyelitis sinuses, old burn scars and hidradenitis suppurativa. It may complicate scarring dermatoses such as poikiloderma congenitale, dystrophic epidermolysis bullosa [10] and porokeratosis of Mibelli [11].

Clinical features (Figs 36.6 & 36.7). SCC does not often arise from healthy-looking skin. Commonly, there are signs of photodamage: solar elastosis of the dermis, hyperkeratosis, irregular pigmentation and telangiectasia, or leukokeratosis and fissuring of the lip. The first clinical evidence of malignancy is induration. The area may be plaque-like, verrucous, tumid or ulcerated, but in all cases the lesion feels firm when pressed between the finger and thumb. The limits of the induration are not sharp and usually extend beyond the visible margin of the lesion. The resistance to pressure is much greater than that given by an inflammatory lesion or benign epithelial hyperplasia.

The tissue around the tumour is inflamed and the edge is an opaque yellowish red colour. The better-differentiated tumours are usually papillomatous and are capped by a keratotic crust in the earlier stages. This may be shed later to reveal an ulcer or eroded tumour with an indurated margin and a purulent exuding surface that bleeds rather easily. The outline may be rounded, but is often irregular, and in premalignant lesions the induration and elevation is often asymmetrical at first. On mobile structures such as the lip or genitalia the presenting sign may be a fissure or small erosion or ulcer which fails to heal and bleeds recurrently.

The most common sites for SCC are those most exposed to the sun. They occur on the backs of the hands and forearms, the upper part of the face and, especially in males, on the lower lip and pinna.

The histological susceptibility of the scrotum in chimney sweeps, mule spinners and capstan-lathe operators was a result of the retention of the carcinogen on the skin surface. The relatively high incidence of lesions on the lower leg in the natives of tropical countries is related to the frequency of ulcers and scars. The nailbed is an uncommon site, which may be overlooked until the lesion is large enough to produce radiographical changes in the distal phalanx [12].

The evolution of SCC is usually faster than that of BCC, but is conspicuously slower than that of keratoacanthoma, which may attain the same size in as many weeks as SCC does in months or even years. Tumours arising in keratoses on the dorsum of the hand are particularly indolent and late in metastasizing. Early ulceration, and the absence of tumid outgrowth, are usually a result of an anaplastic lesion [13], and are more commonly seen on the lip and genital area than elsewhere. Regional nodes may become enlarged, either as a result of infection of the ulcer or from metastases. In the latter case, they feel harder, are more irregular and become fixed to the adjacent tissues. Spread by the bloodstream is uncommon [14].

Pathology [15–17]. SCC is a tumour that may arise in any epithelium, and its behavour in the skin is essentially similar to its behaviour in the respiratory tract and elsewhere. Because of the accessibility of the skin, the precancerous

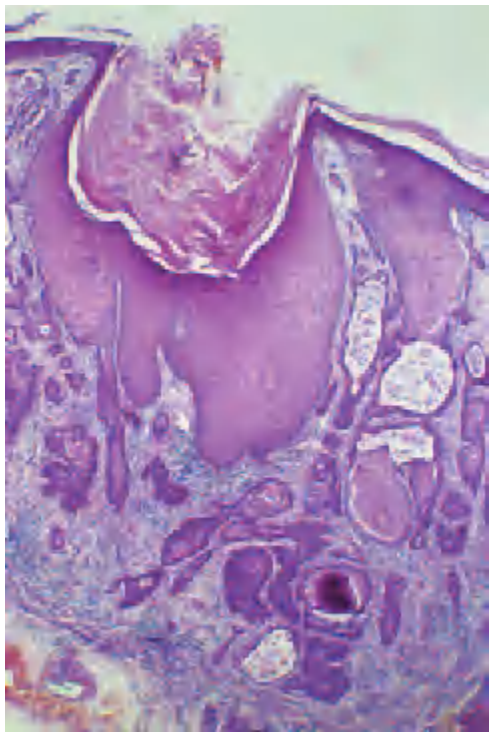

Fig. 36.8 Pathological features of well-differentiated early invasive squamous cell carcinoma, showing differentiated keratinocytes invading the underlying dermis.

changes that lead to the tumour are more easily observed and followed.

Potentially precancerous conditions include actinic keratoses, Bowen's disease and leukoplakia. Invasive SCC begins when atypical keratinocytes breach the dermal basement membrane and invade the dermis (Fig. 36.8). The distinction is thus architectural rather than cytological, and is based on the presence of descending strands of morphologically malignant keratinocytes, which can no longer be regarded as distorted interpapillary ridges. The distinction may be further complicated by the phenomenon of pseudoepitheliomatous hyperplasia [15], which may occur at an ulcer margin or over certain inflammatory or neoplastic states in the dermis (see below).

The cells of SCC vary from large well-differentiated polygonal cells with vesicular nuclei, prominent nucleoli and an abundant cytoplasm containing numerous tonofibrils and well-developed intercellular bridges, through to completely anaplastic cells with basophilic cytoplasm, which provide no cytological evidence of their origin. Some tumours have large bizarre cells, in others the cells may have a clear, almost vacuolated cytoplasm and in yet others the cells may be spindle-shaped. Well-differentiated tumours show areas of maturation that form parakeratotic horny pearls and individually keratinized cells, and also dyskeratosis, with lacunae and lumina that contain shed rounded degenerating cells. The latter appearance is pseudoglandular, and is termed adenoid or acantholytic SCC [16,17].

Most tumours invade as coherent strands and columns, and reproduce the same pattern in their metastases. Many are composed of cells uniform in type and showing only moderate mitotic activity. They stimulate an inflammatory reaction in the dermis. The capillary pattern is abnormal and the number of vessels considerably increased [18]. Increasing anaplasia is associated with hyperchromatic nuclei, decreasing eosinophilia and tonofibril formation in the cytoplasm, and lessened intercellular adhesions. The cell outlines may be rounded or spindle-shaped. Mitotic figures become more frequent, and abnormal mitoses can be found. Even in extensively ulcerated tumours, the connection with the epidermis is usually maintained, and the origin can be traced to atypical epidermal cells, which may enable a distinction to be made from an anaplastic amelanotic melanoma. Its origin from an area of abnormal epidermis distinguishes it from keratoacanthoma. In rare instances, SCC may appear to arise in a keratinous cyst. Many reported instances of this occurrence, however, can now be considered as proliferating trichilemmal cysts.

Local extension of SCC may occur around nerves, sometimes for considerable distances, and may require extensive surgery [19]. Biological differences in the aggressiveness of SCCs arising in different locations and/or resulting from different aetiological factors are well recognized [20]. It is unusual for SCC originating in an AK on the hand or arm to show evidence of anaplasia or to metastasize until well advanced. In a Scandinavian series [21], fewer than 8% of tumours of the upper limb metastasized. Lesions of the vermilion of the lip, and to a lesser extent of the ear, metastasize much earlier even when they are relatively well differentiated. Those elsewhere on the face appear to be less aggressive. SCC of the external genitalia is also inclined to early invasion and metastasis. Spread is almost always by the lymphatic route.

Various ways of predicting the likelihood of metastasis from the histological features have been suggested. One that has been widely used is Broders' classification based on the proportion of differentiated to atypical tumour cells. From the practical point of view, this method needs to be supplemented by the depth of invasion. For tumours of the hand, for instance, metastasis is unlikely when the penetration does not extend deeper than the sweat coils [16]. At the two extremes of differentiation this criterion does not apply. A well-differentiated lesion such as 'epithelioma cuniculatum' may invade the soft tissues of the foot extensively without metastasis [22,23], while a completely undifferentiated tumour, of the lip for instance, may disseminate at an early stage.

Epithelioma cuniculatum [24] *and verrucous carcinoma* [25]. There are several uncommon tumours that are so well

differentiated that the diagnosis may be in doubt if the unrelenting course is not taken into account. One such has been reported as the 'epithelioma cuniculatum' [22]. There is a soft bulbous mass with a squashy consistency on the distal part of the sole of the foot. Multiple sinuses open on the surface and, when pressed, greasy, rancid and foul-smelling material can be expressed. It is possible that the appearance of a vegetating pyoderma may at times be caused by the same process. In such cases, the distinction from pseudoepitheliomatous hyperplasia may be very difficult. A few examples of 'giant condyloma acuminatum' have eventually become low-grade SCC [26,27].

In both the oral cavity and on the genital mucosa [28], a strikingly verrucous lesion may develop [25,29]. These lesions, because of the site involved, may become massive, moist, cauliflower-like and often malodorous because of secondary infection. The clinically apparent relentless growth contrasts with the pathologically less aggressive appearance characterized by a lack of mitotic figures and a well-demarcated lower margin with no strands of cells becoming detached from the main bulk of the lesion.

At the other extreme, anaplastic SCC rarely may arise from skin not showing a premalignant lesion and in a form very difficult to recognize. The lesion is a red papule or nodule, relatively fast growing and looking inflammatory rather than neoplastic. It tends to ulcerate early. It may resemble a keratoacanthoma, but the central keratin core is usually absent. Induration is present, but may be less marked than in well-differentiated tumours. It can infiltrate deeply and metastasize quite early. It has been designated 'squamous cell carcinoma *de novo*' [30].

Squamous cell carcinoma following immunosuppression after organ transplantation. Recipients of organ transplants receiving immunosuppressive therapy have a much higher than expected incidence of SCC [1,31,32]. The development of carcinomas is directly related to time from transplantation, and appears to be independent of the immunosuppressive regimen used. The normal ratio of BCC : SCC is reversed, and SCC is more common. The lesions are most numerous on sun-exposed sites and are frequently multiple. They may clinically be deceptively banal, and resemble either keratoacanthoma or actinic keratosis. All such lesions should be regarded with suspicion in transplant patients, and biopsied to establish their true nature. Female transplant recipients also have a much higher than expected incidence of genital premalignancy.

Careful regular supervision of transplant patients by a dermatologist is required, and advice on sun avoidance should be part of the post-transplant care regimen.

Diagnosis. The indurated well-differentiated SCC arising in skin damaged by sunlight presents no problems in diagnosis. The distinction from keratoacanthoma is usually easy, as the rate of growth and domed appearance of keratoacanthomas are characteristic. On occasions, however, a tumour develops like a typical keratoacanthoma, but proves by its progress to be an SCC [33]. In such cases, the histology of the early stage may not be conclusive one way or the other. The most important clinical distinction is between a poorly differentiated carcinoma arising *de novo* from normal skin, and an inflammatory ulcer or granuloma on the one hand, or an amelanotic melanoma or BCC on the other. The characteristic induration and opaque colour are the most important signs but any doubt is usually clarified by biopsy. Warty lesions such as viral warts or seborrhoeic keratoses are not indurated and are frequently multiple.

Treatment. The aims of any therapy selected for the treatment of cutaneous SCCs are to ensure complete removal and destruction of the primary tumour and to prevent metastasis. From published series on treatment outcomes it is clear that these aims can be achieved by any one of a range of therapies subject to appropriate matching of the therapy to the tumour characteristics [34]. The relative effectiveness of different therapies, however, cannot at present be determined as there are no prospective randomized trials examining different approaches for clinically matched tumours. Treatment selection in clinical practice is based on an assessment of tumour characteristics that have been shown to be important in determining the level of therapy required and in identifying tumours with a poor prognosis. Although there are considerable differences in clinical practices in different countries, it is possible to make some generalizations. Destructive therapies used appropriately with careful tumour selection can offer an effective alternative to surgical excision for small (less than 1 cm) slow-growing well-differentiated SCCs on sun-exposed sites. For tumours with similar characteristics between 1 and 2 cm in diameter, surgical excision with a 4-mm margin is an appropriate starting point but it may be necessary to consider wider margins, subject to other factors such as poorly defined clinical margins and tumour depth [35]. Tumour size has an important effect on the probability of both local recurrence and metastatic risk, with a doubling of local recurrence risk and a threefold increase in metastatic risk for SCCs greater than 2 cm. In addition to tumour size, other criteria used in the selection of appropriate therapy include the location of the tumour, the likely aetiological factor and histopathological characteristics [34,36,37]. UVR-associated SCCs on the ear, lip, scalp, eyelids and nose have a worse prognosis than UVR-associated SCCs at other sites. The basis for this difference has not been established but it is possible that some of the increased risk for cutaneous tumours may result from technical considerations at the time of surgery. SCCs on non-sun-exposed sites where aetiological factors other than UVR exposure are important are also associated with a worse prognosis. It has long been recognized

that SCCs at sites of scarring, ulcers, chronic sinuses or previous thermal or ionizing radiation injury have a worse prognosis. SCCs arising in areas of Bowen's disease are also thought to have greater malignant potential. Although deaths resulting from metastatic cutaneous SCCs are more common in immunosuppressed patients, it is not clear if this increase is brought about by differences in the biology of SCCs in these patients or a reflection of the marked increase in the prevalence of SCCs in this group, which in itself could lead to more deaths from metastatic disease. Histopathological characteristics associated with a worse prognosis include tumour depth, degree of differentiation and presence of perineural involvement. SCCs extending into the subcutaneous fat or greater than 4 mm in depth are almost eight times (45.7% metastatic rate) more likely to recur than SCCs confined to the upper dermis (6.7% metastatic rate). Poorly differentiated tumours have a doubling incidence of local recurrence and a threefold increase in metastatic rate [34]. Histological evidence of perineural involvement is also associated with a worse prognosis. The worse prognosis and difficulties in managing recurrent SCCs highlight the importance of adequate initial treatment based on accurate clinical assessment and appropriate selection of therapy.

It is essential that the planning of treatment for cutaneous SCCs takes into account these prognostic factors. While destructive therapies such as curettage and cryotherapy have a role in the treatment of small low-risk SCCs, surgical excision is the treatment of choice for high-risk lesions less than 1 cm in diameter and for all lesions greater than 2 cm in diameter. Radiotherapy is rarely the treatment of choice but may be indicated for some very large or rapidly enlarging tumours or in patients where aggressive surgical management may not be tolerated. Radiotherapy may also have a role as an adjuvant therapy in some high-risk SCCs where there are concerns about residual microscopic disease. Mohs' micrographic surgery offers advantages over conventional surgical excision and is widely regarded as the treatment of choice for high-risk SCCs as it reduces the risk of local recurrence and metastatic disease.

The final results of any of the methods depends on the experience of the person using it rather than the technique itself. In experienced hands, all the techniques give 5-year cure rates of approximately 90% in a wide variety of SCC at different sites.

Prevention. Patients presenting with SCCs or related premalignant lesions on sun-exposed skin should be advised about the importance of reducing exposure to solar radiation. In high-risk patients, regular follow-up and targeted treatment of small low-risk tumours with cryotherapy and other destructive therapies may help reduce the frequency of tumours requiring surgical excision. Although intermittent 5-fluorouracil use may improve skin texture and reduce the rate of development of AK, there is no published evidence at present that this is associated with a decrease in the rate of development of invasive SCCs. In patients such as organ transplant recipients and patients with XP, where the rate of new SCC development makes surgical management difficult, then it may be necessary to consider treatment with systemic retinoids to reduce the rate of development of new lesions and help target surgical excision to retinoid unresponsive tumours. Etretinate and isotretinoin have both been shown to reduce the rate of development of new lesions in XP patients [38,39]. More recently, acitretin has been shown to reduce the rate of development of new SCCs [40]. In contrast to cytotoxic drugs, retinoids do not appear to eliminate neoplastic clones from the epidermis and discontinuation of therapy is associated with the rapid growth of numerous dysplastic lesions that were growth inhibited but not eliminated by retinoid therapy.

Premalignant epithelial lesions

Premalignant epithelial lesions are conditions that can be recognized clinically or histopathologically and are associated with an increased risk of cancer development. Although premalignant lesions frequently share many of the histopathological changes seen in invasive cancers, the ability to order lesions on the basis of severity does not in itself imply that the lesions identified represent consecutive changes in a neoplastic process [1]. The histopathological changes seen in premalignant lesions include nuclear pleomorphism, increased mitotic rate, abnormal mitotic figures and abnormal differentiation. In the skin, a number of premalignant epithelial lesions have been identified and there is convincing clinical and epidemiological evidence of an association between many of these lesions and an increased risk of NMSC. Some lesions, such as AK and leukoplakia of mucosal surfaces, may show relatively little evidence of cellular atypia, whereas others, including Bowen's disease and erythroplasia of Queyrat, can show marked dysplasia of the epidermis that is histologically indistinguishable from the changes seen in well-differentiated SCC. Premalignant lesions are distinguished from their invasive counterparts by the absence of histological invasion with the microscopical features of intraepidermal carcinoma confined above the dermal–epidermal junction. In addition to the epidermal changes, a common feature of many premalignant lesions is the presence of a chronic inflammatory cell infiltrate in the papillary dermis immediately beneath the abnormal epidermis [2]. The importance of premalignant lesions as indicators of increased NMSC risk is well illustrated by AK, Bowen's disease, tar keratoses, ionizing radiation keratoses and arsenical keratoses, which are frequently found in patients with NMSC or at high risk of developing this type of cancer. With the exception of arsenical keratoses, which are the result of systemic carcinogen exposure, all of the other premalignant lesions localize to areas of skin exposed to carcinogen and these areas are the same as those at risk of NMSC development. Premalignant lesions frequently develop before the development of invasive cancers and can be useful in identifying individuals at high risk of NMSC development.

Conventional models of multistage carcinogenesis, such as the human colon cancer model and murine skin cancer models, are based on tumour systems that show an orderly progression through well-defined clinicopathological changes. In these models, cancer development is indirect, progressing through discrete clinicopathological changes and this is supported by molecular studies, which have shown that 'early' lesions have less genetic abnormalities than 'late' lesions. Other tumours develop in the absence of any recognizable precursor lesions, that is, they arise directly. Clinical observation suggests that most human cancers including cutaneous SCCs may not progress through intermediate stages and that progression of AK and Bowen's disease to invasive SCC may be the exception rather than the rule [1]. A full consideration of the natural history of most premalignant lesions including AK and Bowen's disease is difficult as therapeutic removal or destruction provides evidence of what the lesion looks like but destroys any chance of consideration of future behaviour. Notwithstanding these limitations, a number of longitudinal studies indicate that AKs frequently undergo spontaneous regression and have a low potential for developing into invasive SCCs [3,4]. Support for the hypothesis that most AKs are not likely to progress into invasive SCCs comes from molecular studies, which have shown that AKs frequently show more extensive chromosome losses than SCCs, in contrast to findings in the colon cancer model where indirect cancer development as part of a linear progression process is the norm [5,6]. These findings do not undermine the importance of regular skin examination of high-risk skin cancer patients and the treatment of lesions based on clinical need but they do not support the concept that aggressive treatment

of some types of premalignant lesions such as AK will prevent cancer development in these patients.

Actinic keratosis [1–3]

SYN. SOLAR KERATOSIS; KERATOSIS SENILIS

Definition. Hyperkeratotic lesions occurring on chronically light-exposed adult skin, which are focal areas of abnormal proliferation and differentiation that carry a low risk of progression to invasive SCC.

Aetiology and incidence. The great majority of AKs occur on sun-exposed sites in fair-skinned people who have had excessive exposure to solar UVR [4]. Lesions with similar clinical and histological features may be induced by ionizing radiation or radiant heat and in workers exposed to pitch and other products of coal distillation.

The prevalence of these lesions is high in many countries and is influenced by the amount of ambient UV, the proportion of susceptible individuals in the population, the age structure of the population and the time spent in outdoor occupations and recreations. In the UK, a recent study has reported an overall prevalence of 15.4% in men and 5.9% in woman over the age of 40 years and 34% and 18% in men and woman, respectively, aged 70 years and over [5]. In areas with high ambient UVR levels such as Australia, a prevalence rate of 43% with 18% (of a population of 197) having more than 10 AKs is recorded [3]. Longitudinal studies in patients with AK have established first that there is a high probability of developing new lesions and, secondly, that many lesions undergo spontaneous resolution [6]. Although the rate of progression of an individual AK to invasive SCC has been estimated to be low (less than 0.1%), the presence of AK is an important biomarker of excessive UV exposure and increased NMSC risk [7].

Clinical features [8–10]. These lesions occur usually in middle-aged or elderly subjects on habitually sun-exposed areas such as the face, scalp and dorsa of the hands. The sides of the neck are involved in both sexes, but the ears predominantly in men. The vermilion of the lower lip but not often of the upper lip may also show keratosis, with a much higher incidence in men than women. Lesions are usually multiple and comprised of either macules or papules with a rough scaly surface resulting from disorganized keratinization and a variable degree of inflammation. Lesions vary in size from less than 1 mm to over 2 cm and are usually asymptomatic. In many individuals, the number of lesions can be better appreciated by skin palpation, which is a sensitive way of detecting the characteristic roughness associated with smaller lesions. Many of these small lesions may pass unnoticed by most patients, and the diagnostic changes often only appear later as a dry, rough, adherent and often yellow- or brown-coloured scale (Fig. 36.9). The adherent scale can only be picked off with difficulty, revealing a hyperaemic base with punctate bleeding points. In some cases, scaling may be prominent and in time may become thick and horny. The edge of the keratosis is usually sharply demarcated and the reddening is usually closely confined to the area immediately below the area of abnormal scaling. The flat, atrophic or lichenoid variety is most commonly seen on the face.

Many patients give a history of relapsing and/or remitting lesions, which can often disappear either spontaneously or after sun avoidance and use of sunscreens.

Pathology. The boundary between unaffected and affected epidermis is a sharp line that slopes upwards and inwards, and there is a similar margin where the appendage ducts perforate the epidermis as funnel-shaped columns of orthokeratosis. The epidermal cells have a paler cytoplasm and mature through an absent or diminished granular layer to form a parakeratotic scale of varying thickness. There is usually some acanthosis, and the more dysplastic lesions show epidermal hypertrophy with hyperkeratosis and parakeratosis (Fig. 36.10). The interpapillary ridges may be reduced in number and

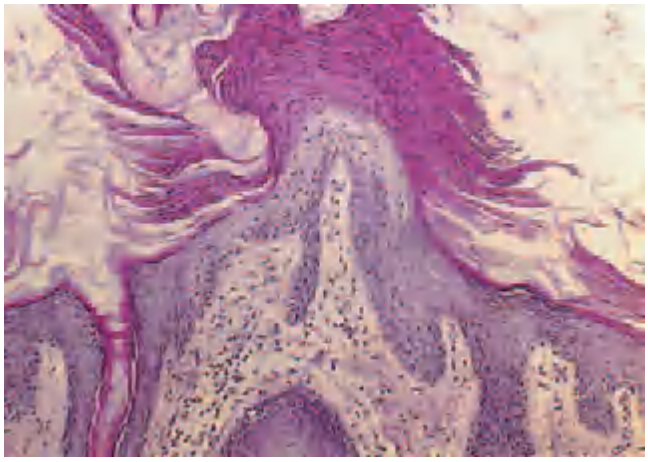

Fig. 36.10 Pathological features of actinic keratoses showing alternating parakeratosis and hyperkeratosis.

broader than normal. The affected zone tends to grow under the normal epidermis and around the ductal epithelium, and may separate from it by a cleft. The basement membrane is intact but basaloid cells may form multiple buds at the junction; the combination of clefting, budding and papillomatosis produces a Darier-like change. Within the epidermis there may be a simple dysplasia or a range of abnormalities up to a picture indistinguishable from Bowen's disease. These are the Bowenoid AK.

The papillary vessels are irregularly increased and there is a lymphoid infiltrate beneath the lesion. There is a variable degeneration of dermal collagen and deposition of material staining like elastin in the upper half of the dermis, except for a narrow band at the basement membrane; this change is more or less uniform, unlike the discontinuous keratosis.

The flat type of AK, most common on the face, may resemble discoid lupus erythematosus. The distinction is made by the altered epidermal cells, deficient granular layer and parakeratosis, the band-like rather than perivascular inflammatory reaction, and the absence of immunoglobulin in the basement membrane region. Occasionally, the appearance may appear pseudoepitheliomatous [8] or similar to lichen planus [9].

The occurrence of funnel-shaped columns of normal epidermis, derived from appendage ducts that appear to be trying to cover the diseased epidermis like an umbrella, suggests an effort at biological compensation [10]. It must be remembered, however, that in keratoses and Bowen's disease, sleeves of dysplastic cells growing down appendage ducts may survive damage by freezing or cytotoxic applications. The presence of an inflammatory response appears to be a warning sign of early malignant transformation [11].

Diagnosis. The diagnosis is usually based on clinical findings which take into account the morphology of individual lesions and the clinical setting. For lesions less than 3 mm, clinical discrimination from an early SCC may be difficult. This diagnostic uncertainty, particularly for small lesions, is one of the reasons why it is difficult to establish accurate rates of progression for AK to SCC. Clinical pointers favouring the diagnosis of an early invasive SCC include the presence of tenderness, induration or a raised shoulder that extends beyond the area of disorganized scaling. Other diagnoses that need to considered, particularly in patients with large confluent areas of erythema and scaling, include discoid lupus erythematosus. The brown colour of lichenoid AK, particularly when these lesions have only minimal scaling, can sometimes cause these to be mistaken for focal areas of lichen planus. When AK is pigmented, it may resemble a superficial seborrhoeic keratosis, but can usually be distinguished from such lesions by the lack of organization of the hyperkeratosis. Bowen's disease on the exposed areas usually has a more irregular contour and a more erythematous base.

Treatment. Management of patients with AK needs to take into account the clinical impact of individual lesions, the probability that the clinical diagnosis is likely to be correct, the significance of the presence of AK with respect to NMSC risk and the importance of general advice such as sun avoidance and sunscreen use. Although AKs are frequently asymptomatic, the skin roughness can cause considerable distress and can be complicated by bleeding and pain because of low-grade skin trauma leading to detachment of the overlying scale. The similarities between AK and SCC mean that there is always a small risk, particularly for small lesions less than 3 mm, that the lesion may not be an AK. Effective management of this risk requires a careful clinical assessment, a therapy plan and and clear communication with the patient. Cryotherapy is the treatment of choice for small numbers of superficial lesions and generally gives excellent cosmetic results. Other destructive therapies such as curettage and cautery can be useful for larger lesions and have the advantage of providing a specimen for histological assessment. Where there is significant diagnostic uncertainty then lesions are best excised for pathological examination of the base to be certain that the lesion is not an early invasive SCC.

In many patients, the number of lesions or the rate of development of new lesions makes management more difficult using approaches such as cryotherapy. For patients with extensive clinical lesions, a number of approaches are available that allow treatment of large areas of AK in severely photodamaged skin. Many of these treatments offer the added advantage that they also target early lesions, which means that a more sustained clinical effect may be achieved. These treatments can be subdivided into two broad groups based on their ease of use. The first group includes topical 5-fluorouracil and diclofenac in hyaluron gel, which have been shown

to be effective therapies for AK [12–14]. Although 5-fluorouracil is a very effective therapy, the marked local inflammation that commonly develops after 2–4 weeks of treatment makes it unacceptable to many patients. Once weekly application for 9 weeks with 5-fluouracil has been shown, in a small study, to reduce the treatment-induced inflammation while maintaining efficacy [15]. A recent study has surprisingly reported greater efficacy and fewer side effects in patients treated with 0.5% fluorouracil cream compared with 5% fluorouracil cream [16]. The relative effectiveness and tolerability of 5-fluorouracil and diclofenac in hyaluron gel have not, however, as yet been formally addressed in a clinical trial. A number of other approaches including retinoids and the immune modifier imiquimod are currently being investigated as topical therapies for AK [17–19]. The second group of therapies involves procedures that are normally carried out in the office or clinic setting and includes PDT therapy, dermabrasion and chemical peels. PDT with topical 6-aminolaevulinic acid has been shown to be an effective well-tolerated therapy for patients with widespread photodamage and AK [20]. A recent comparison of PDT with cryotherapy has established that PDT is as effective as cryotherapy and superior to the latter in patient satisfaction and cosmetic result [21]. Dermabrasion and chemical peels have been widely used in some countries for the treatment of AK and severe photodamage. There is some evidence that this approach may provide more long-term effective prophylaxis against AK [22].

The demonstration that regular sunscreen use reduces the rate of development of new AK indicates that continuing UVR exposure plays an important part in promoting the development of clinical lesions and highlights the importance of ensuring that patients with AK are provided with practical advice on sun-avoidance strategies [23].

Bowen's disease [1,2]

Definition. A form of intraepidermal SCC characterized by a persistent, non-elevated, red, scaly or crusted plaque with a small potential for invasive malignancy. Progressive growth is usual but spontaneous partial regression occasionally occurs.

Aetiology and incidence. Most cases of typical Bowen's disease in white populations are found on the lower legs of elderly women. The distribution in the context of differences between men and women in coverage of the lower leg by clothing and molecular epidemiological evidence of UVR-specific *p53* mutations in typical Bowen's disease suggests that exposure to solar radiation is an important cause of these lesions [3]. Bowen's disease is uncommon in individuals with pigmented skin and, in these individuals, aetiological factors other that UVR exposure may be important [4].

In the past, arsenic exposure was also important [5]. Although fewer than 5% of a large series of patients with Bowen's disease gave a history of ingestion of arsenic-containing medications, arsenic was found in a significantly higher proportion of the patients' skin than in that of the controls [6]. The possible sources of arsenic vary in different localities. Agricultural workers may be exposed

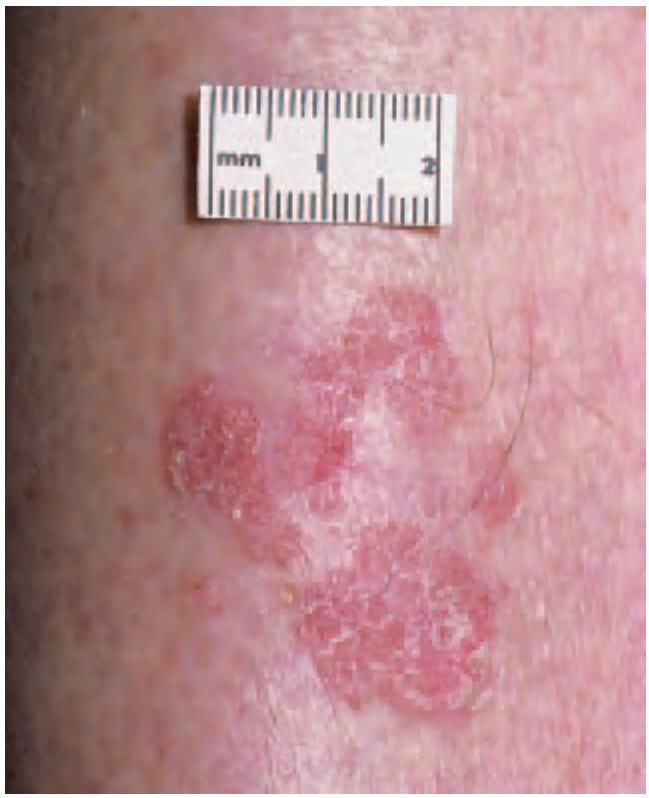

Fig. 36.11 Area of Bowen's disease on lower leg.

Fig. 36.12 Bowen's disease on the lower leg of a patient with a history of arsenic contact.

to arsenic salts used as a fungicide, weedkiller, sheep dip or pesticide, and they frequently take inadequate precautions against accidental ingestion or inhalation. It may be a hazard in smelting and other industrial processes. In some countries, notably parts of Argentina, Bangladesh and Taiwan, the water supply has been contaminated [7].

Clinical features [8,9]. Although the lesions may occur anywhere on the skin surface or on mucosal surfaces, they are most frequently found on the lower legs of elderly women. The initial change is a small, red and slightly scaly area, which is symptomless and gradually enlarges in a somewhat irregular fashion. The scale is white or yellowish, detached without much difficulty to give a moist, reddened and at times granular surface, but without producing bleeding (Fig. 36.11). The margin is well demarcated and the lesion slightly raised; the surface is usually flat, but may become hyperkeratotic or crusted. Ulceration is usually a sign of development of invasive carcinoma, and may be delayed for many years after the appearance of the intraepidermal change. Persistent superficial ulceration may, however, be the early clinical evidence of Bowen's disease of palmar skin without invasion. There may be several lesions, either widely spread or sometimes close and becoming confluent with extension.

When there is good evidence of chronic arsenicalism (Fig. 36.12), either from the history or because of associated changes such as pigmentation or punctate palmoplantar keratoses, the possible evolution of a visceral malignancy, especially of the lung, should be borne in mind. Although studies in the 1950s suggested that there was a significant link between the presence of Bowen's disease on the skin and internal malignancy [10–14], more recent studies using carefully selected control populations have failed to confirm the results of these earlier studies [15–19].

Pathology [20]. The normal epidermis is replaced by abnormal keratinocytes, which show disordered differentiation and loss of epithelial polarity. There is variable acanthosis, with increase in the length and thickness of the interpapillary ridges but retention of a distinct dermal–epidermal junction. The atypical cells have hyperchromatic nuclei, often larger than normal, giving an irregular appearance to the epidermis. Giant forms and multinucleate cells are seen and mitotic figures can be frequent (Fig. 36.13). There is a conspicuous disturbance of epidermal organization, and cells keratinize prematurely and lose their intercellular connections. The surface is formed by a thickened, loose, parakeratotic scale. The papillary body shows an inflammatory infiltrate that is often quite dense. In some cases, the proliferating cells may be surrounded by relatively normal epidermal cells to give a 'Borst–Jadassohn' appearance. The epidermis above the ducts of appendages may be normal, as in AK, but the cells of the lesion of Bowen's disease often grow down around the ducts like a collar. The condition can become invasive, and when it does it is always squamous cell in type. Arsenical Bowen's disease is said to be characterized by the presence of numerous vacuolated atypical cells. Electron microscope features have been described [21–24].

Diagnosis. The condition must be distinguished from lichen simplex, psoriasis and other papulosquamous

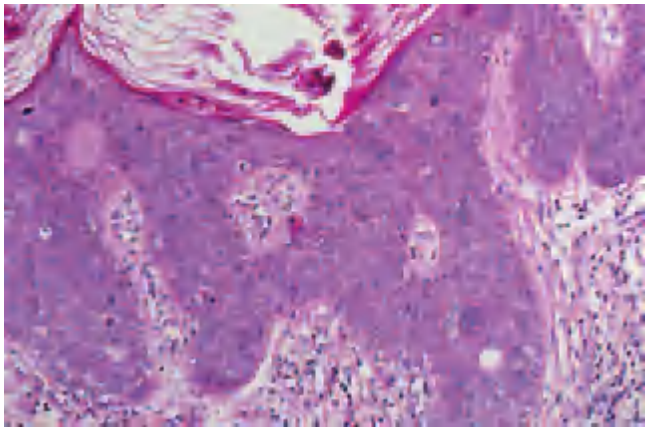

Fig. 36.13 Typical pathological features of Bowen's disease showing loss of polarity of the epidermis and the presence of atypical mitoses and giant cells.

dermatoses. If the diagnosis is uncertain on the first examination, the lack of improvement when steroids are applied is suggestive of Bowen's disease. The superficial ('pagetoid') type of BCC can produce a very similar appearance, but can usually be differentiated by the finely elevated, 'thread-like' margin. Bowen's disease and superficial BCC can be seen in the same patient. Differentiation from the flat type of solar keratosis may be impossible.

Treatment [24]. Destructive therapies such as curettage and cautery, or cryotherapy are widely used in clinical practice and usually effective. Comparison of the relative effectiveness of different therapies and regimens is difficult as the published studies do not fully control for factors such as site and size and there are inconsistencies between treatment regimens between different centres. Cryotherapy is an effective therapy with a recurrence rate when used optimally of less than 10% at 12 months. Regimens used include single freeze–thaw cycles, single freeze–thaw cycles repeated on more than one visit and multiple freeze–thaw cycles repeated at a single visit [25–27]. Prolonged single freeze cycles for larger lesions is painful and may be better performed under local anaesthesia. Slow healing can be a problem, particularly for larger lesions on the lower leg. Curettage and cautery is widely used in practice but poorly studied. Reported recurrence rates are higher than those described with cryotherapy but these findings are difficult to interpret as the treatment regimens and equipment used are not well described. Surgical excision is a useful approach, particularly for larger lesions where wound healing following destructive therapies can be slow.

Local cytotoxic agents such as 5-fluorouracil can be applied to good effect. Treatment regimens vary and include once daily application of a 5% cream for 4–8 weeks or more prolonged treatment using a once weekly application. There is some evidence that occlusion may increase efficacy. Recurrences are common, and may come from extensions of the carcinoma *in situ* around appendage ducts that were not affected by treatment. Current studies suggest that PDT, using a topical photosensitizer such as aminolaevulinic acid and a laser or non-laser light source may also be an effective method of treatment [27,28].

Arsenical keratosis

Definition. A corn-like, punctate keratosis caused by arsenic, characteristically affecting the palms and soles, which may progress to SCC.

Incidence. A considerable proportion of any population exposed to chronic arsenic intoxication develops keratosis, the frequency increasing with the degree of intoxication and its duration [1]. There is great individual variation in tolerance, and it is not possible, on present data, to construct a precise dose–response curve. The problem is greatest in parts of Bangladesh, West Bengal and Taiwan resulting from well water contamination [2].

Clinical features. The keratoses usually begin on the palms or soles as small areas of hyperkeratosis resembling corns. These enlarge, thicken and increase in number. The fingers, backs of the hands and more proximal parts of the extremities may be involved. Induration, inflammation and ulceration occur when the lesion becomes malignant. There may be areas of Bowen's disease in other sites and multiple BCCs, mainly of the trunk, may occur in association.

Pathology. A range of changes may be seen from a benign-looking hyperplasia or dysplasia, through mild or moderate atypia, to frank Bowen's disease [3–5]. There is no microscopic feature that allows a positive diagnosis of arsenic as the cause. In most lesions there is no elastotic degeneration of the upper dermis.

Diagnosis. The palmar lesions have to be differentiated from the various types of punctate keratosis, such as disseminated punctate keratoderma (see Chapter 34), which usually appears in early life, and Darier's disease and lichen planus, which usually have characteristic lesions elsewhere. Plantar warts differ in being papillomatous.

Treatment. The multiplicity of the keratoses makes treatment difficult. Where it is necessary, the use of a keratolytic ointment and trimming down of the surface is helpful. Two recent case reports suggest that oral acetretin may be beneficial [6]. All affected patients should be examined periodically for evidence of malignant change and for signs of visceral malignancy.

Disseminated superficial 'actinic' porokeratosis

This disorder was first recognized in Texas [1,2], and is common in Australia [3]. It appears on sun-exposed areas of white-skinned individuals, becomes more prominent in summer and may improve in winter. New lesions have been provoked by exposure to a UV sun lamp [4]. The tendency to develop these lesions is inherited as an autosomal dominant [4]. The preponderance of females in reported cases has been attributed to their greater tendency to seek help for skin problems. The average age at which Texan patients first notice it is about 40 years, and its frequency in members of affected families increases with age. There are UK patients with multiple lesions who have never lived abroad, and the true role of the sun in the aetiology of the condition has been questioned, as has its degree of premalignant potential [5,6]. Genetic studies have mapped a gene, *DSAP1*, for this condition to chromosome 12q23.2–24.1 and a Chinese family with disseminated superficial 'actinic' porokeratosis (DSAP) has recently been reported with a second affected locus, *DSAP2*, on chromosome 15q25.1–26.1 [7].

Clinical features [2]. The lesion begins as a 1–3 mm conical papule, brownish red or brown in colour, and usually around a follicle containing a keratotic plug. It expands and a sharp, slightly raised, keratotic ring, a fraction of a millimetre thick, develops and spreads out to a diameter of 10 mm or more. The skin within the ring is somewhat atrophic and mildly reddened or hyperpigmented, but a hypopigmented ring may be seen just inside the ridge. The ridge itself is sometimes darkly pigmented. The central thickening usually disappears, but it may persist with an attached scale, follicular plug or central dell. Sweating is absent within the lesions. Sun exposure may cause them to itch. In sunny areas, lesions may be present in very large numbers and may change from a circular to a polycyclic outline. In less sunny climates, like the UK, patients have fewer lesions, which tend to remain circular (Fig. 36.14). In a few cases, the centre of the area has become considerably inflamed and covered by thick hyperkeratosis, or has even ulcerated and crusted. The disorder affects areas exposed to sunlight, appearing mainly on the distal extremities and arising more frequently on the lower legs in women than men. The malar

Fig. 36.14 Disseminated superficial actinic porokeratosis on the lower legs.

regions and the cheeks may be affected. It has not been seen on areas habitually covered by clothes, or on the scalp, palms or soles.

Pathology [8]. There is no microscopic feature that separates this disorder from porokeratosis of Mibelli (see Chapter 34), and both have been explained as the result of localized clones of abnormal epidermal cells [8], an idea supported by the successful autotransplantation of the disseminated superficial variety [4].

The distinctive pathological feature of porokeratosis is the cornoid lamella at the margin. This is a narrow column of altered or parakeratotic keratin, seated in a slight depression in the epidermis and directed obliquely inwards in some cases. It may involve the ostia of follicles and sweat ducts. The granular layer of the indented epidermis is usually missing and there may be dyskeratotic cells. The epidermis enclosed by the ridge is usually thinned, the interpapillary ridges and dermal papillae may be flattened, and the basal cells may show liquefaction degeneration. In addition to solar elastosis, decrease in collagen and telangiectasia, the upper dermis may have a non-specific inflammatory infiltrate with vascular proliferation, oedema and fibrosis. Malignant change has not been recorded.

Diagnosis. Porokeratosis is distinguished from other dermatoses by its sharp margin and history of outward expansion. The rim of DSAP is very much smaller than in Mibelli's porokeratosis and never contains a cleft. The onset of Mibelli's porokeratosis is often in childhood, and the lesions are usually solitary or few in number and do not necessarily affect exposed parts. Where the central keratosis and inflammation are prominent, the disseminated superficial variety may be mistaken for solar keratosis if the marginal ridge is not noticed.

Treatment. Lesions respond satisfactorily to cryotherapy with liquid nitrogen, but new lesions tend to develop [2,3].

Cutaneous horn [1]

This is a clinical diagnosis. Horny plugs or outgrowths may be caused by various epidermal changes, such as epidermal naevus, virus wart, molluscum contagiosum, keratoacanthoma, seborrhoeic keratosis, or marsupialized trichilemmal or epidermoid cyst (Fig. 36.15). In most of these cases, the primary diagnosis is suggested by the

Fig. 36.15 Typical cutaneous horn. Underlying this lesion, a carcinoma *in situ* was identified after biopsy.

appearance and clinical course and, in most, the horn has a friable quality.

Clinical features. Clinical examination shows a hard, yellowish brown horn, often curved and having circumferential ridges, which is surrounded either by normal-looking epidermis or by an acanthotic collarette. Recurrent injury may cause the base to be inflamed; a combination of inflammation and induration beneath the horn is suggestive of malignant transformation. The lesions are most common on the exposed areas—particularly the upper part of the face and the ears. They are commonly single, but may be multiple; it is usual to find some more typical solar keratosis or other evidence of solar damage. Nodular AKs, which are largely confined to the dorsum of the hand and forearm and in which the histology may show an almost pseudoepitheliomatous picture, occupy a position midway between cutaneous horns and the more usual flat AKs.

Pathology. The gradual continuing development from relatively normal-looking skin to a hard keratotic protrusion resembling an animal horn in miniature is the result of dysplastic epidermal changes similar to those in a solar keratosis. Histologically, there is usually no atypicality or loss of polarity of the epidermal cells, but the granular layer is deficient or absent. In long-established lesions there may be budding from the basal layer, indicating early development of an SCC.

Erythroplasia of Queyrat [1–3]

This condition is described with the genital disorders (see Chapter 68). The histological appearance and natural history suggest that the lesion is Bowen's disease of the mucosa of the penis. However, its prevalence only in the uncircumcised indicates a different and locally acting cause.

Bowenoid papulosis of the genitalia [1]

This entity is fully discussed in Chapter 68. It is likely that some of the cases previously described as Bowen's disease [2,3], frequently multifocal, of the genital area were in fact Bowenoid papulosis. The lesions regress spontaneously over time and aggressive surgery is therefore not required [4,5]. There are reports of the presence of viral particles and of certain HPVs in a small number of cases to date.

Intraepidermal carcinoma of the eyelid margin

This condition (see Chapter 64), which may resemble a banal warty lesion in its early stages, represented about 6% of all eyelid malignancies in one series [1]. Occupational exposure to oils and grease may be important. The dysplastic changes seen on biopsy may not be sufficiently severe to warn of the dangers of inadequate treatment. One clue is the way the intraepidermal carcinoma invades the deepest ciliary adnexae, causing loss of eyelashes and nodularity of the margin on clinical examination. SCC may supervene and complete excision is essential.

Leukokeratosis of the lips

SYN. ACTINIC CHEILITIS [1]

This disorder is an AK that occurs on the vermilion border (see Chapter 66). The patient almost always gives a history of recurrent sunburn of the lips, and the lower lip is predominantly affected. It has been suggested but not proven that cigarette smoking may also be contributory. Some observers have not found a correlation [2], but others claim that this is the reason for the high incidence in men. The use of lipstick by women may be protective [3], especially in preventing dehydration. It is common experience that a hot, dry wind potentiates the burning effect of the sun. Actinic cheilitis is relatively common in renal transplant recipients [4].

The lower lip shows persistent dry scaling, a tendency to fissure and atrophic changes beneath and around the keratosis.

Treatment. Removal of the affected area by shaving through the superficial dermis and allowing healing by secondary intention often produces a good result.

Post-ionizing radiation keratoses

These may occur in an area of scarring following radiotherapy or excessive fluoroscopy where there is obvious dermal damage. They may also be seen in radiologists, surgeons, dentists and others who have exposed their skin to frequent small doses of X-rays and where the dermis is less grossly changed, although such cases are now rare. The epidermal changes are similar to solar keratosis. Histologically, the dermis shows a much more extensive replacement of collagen by scar and elastotic material, obliterative changes in the vessels and, at times, the presence of abnormally large and irregular fibroblasts (Fig. 36.16).

Tar keratoses [1–4]

These are now very rare entities. In the past, they were seen in workers with tar and pitch. There were small keratotic plaques, not unlike plane warts, or flat seborrhoeic keratoses on the face and hands, which have the microscopic features of benign acanthomas. These usually disappeared when the exposure ceased. There were also lesions resembling solar keratoses, which persisted and a few became malignant. Other lesions with the appearance of keratoacanthomas were seen. Their course was usually more prolonged and, particularly on the scrotum, a relatively high proportion became malignant.

Benign epidermal tumours

Seborrhoeic keratosis

SYN. SEBORRHOEIC WART; SENILE WART; BASAL CELL PAPILLOMA

Definition. A benign tumour, frequently pigmented, more common in the elderly and composed of epidermal keratinocytes.

Aetiology and incidence. Multiple seborrhoeic keratoses may be a familial trait, with an autosomal dominant mode of inheritance [1]. It has been suggested that the lesion is a naevoid tumour; its occasional association, in the same patient, with the fibroepithelial type of BCC [2] is said to support this concept. A genetically determined predisposition, based perhaps on a mosaic pattern of aberrant response to epidermal growth factors and inhibitors [3], would explain those cases where a profuse eruption follows an inflammatory dermatosis [4] or occurs as a manifestation of visceral malignancy, usually cancer of the gastrointestinal tract. The latter is known as the sign of Leser–Trélat [5].

Seborrhoeic keratoses are very common in white races and are often of little concern to the patient, being accepted as a harmless and inevitable consequence of ageing. Males and females are equally affected. The seborrhoeic keratoses may be large and have a tendency to crumble on covered truncal skin. A flat variant is more common on the light-exposed skin of the face and may be confused with early lentigo maligna. The keratoses usually appear in the fifth decade in a temperate climate but may develop earlier in tropical regions. There is little tendency to spontaneous disappearance and new lesions may continue to appear for many years.

Stucco keratosis [6] is probably a non-pigmented variant of seborrhoeic keratosis, occurring principally on the limbs.

Seborrhoeic keratoses are uncommon in black and Indian people. Multiple tumours of the face found in dark-skinned races, and termed dermatosis papulosa nigra, have a similar histology to seborrhoeic keratosis, but appear earlier in life [7].

Clinical features. Seborrhoeic keratoses occur on any body site. They are usually asymptomatic but may be itchy. They are most frequent on the face and the upper

Fig. 36.17 Clinical illustration of basal cell papilloma showing dull, non-reflective, hyperkeratotic surface. This contrasts with melanocytic lesions.

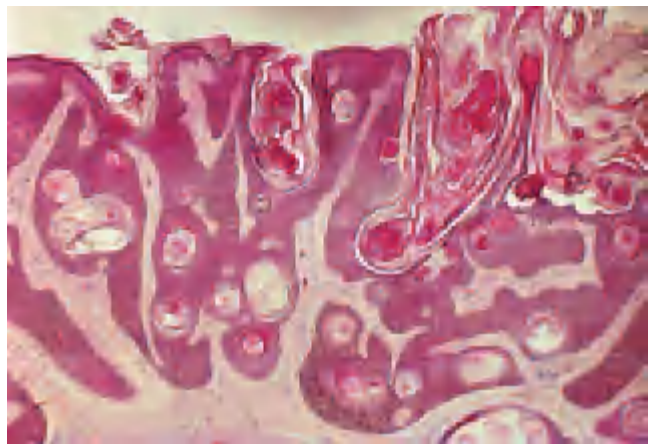

Fig. 36.18 Histology of classic basal cell papilloma showing hyperkeratotic surface and numerous horn cysts.

trunk. The first evidence is slight hyperpigmentation. On the hand and face, seborrhoeic keratoses may remain superficial for a long period, and can be mistaken for melanocytic lesions. It may be difficult to distinguish superficial seborrhoeic keratoses from lentigo maligna and pigmented AK. More florid examples may be pedunculated or acanthotic, smooth-surfaced, domed and heavily pigmented, but in contrast to melanocytic naevi do not reflect light and usually have plugged follicular orifices on the surface, giving an almost cerebriform appearance. Most seborrhoeic keratoses have fewer hairs than the skin they arise from. The most common appearance is that of a very superficial verrucous plaque which appears to be stuck on the epidermis, varying from dirty yellow to black in colour and having loosely adherent greasy keratin on the surface (Fig. 36.17). The shape is round or oval and multiple lesions may be aligned in the direction of the skin folds. The size varies from 1 mm to several centimetres. The smallest lesions are placed around follicular orifices, particularly on the trunk. On the eyelids and major flexures, seborrhoeic warts may be pedunculated and less keratotic. Irritation or infection causes swelling, sometimes bleeding, oozing and crusting, and a deepening of the colour because of inflammation. An eruption of seborrhoeic keratoses may be precipitated by an inflammatory dermatosis [4] or severe sunburn.

Seborrhoeic keratoses usually increase in number over the years, and some elderly patients have very large numbers.

Pathology [8]. The essential change is an accumulation of normal keratinocytes between the basal layer and the keratinizing surface of the epidermis. Melanocytes may proliferate among these immature keratinocytes and transfer melanin to them. The dermal papillae may be elongated. Focal keratinization may occur within the mass of immature cells to produce horn cysts, which enlarge, may coalesce and can be carried to the surface by the tide of epidermal cells. If the formation and discharge of horn cysts is excessive, a verrucous surface will be formed. Marked papillomatosis will also cause an irregular 'church steeple' outer border which retains keratin. If, in contrast, the main mass of the lesion is composed of immature cells, the surface will be smooth and rounded, and the melanocyte population and degree of pigmentation will vary, so that the lesions may be surprisingly pigmented. The parenchymal cells are rather small and polygonal, possessing tonofibrils and intercellular bridges, and they are arranged in an orderly fashion.

The most common pathological type is the solid variant, in which a mass of immature keratinocytes is seen mainly above the level of the surrounding epidermis (Fig. 36.18). Occasional cystic areas containing fragments of stratum corneum are seen in these areas. A rarer variant is the hyperkeratotic variety, which may be clinically mistaken for an AK. The reticular form is a third variant composed of strands of keratinocytes; this type is frequently seen as a flat lesion on the face.

If a seborrhoeic keratosis becomes irritated, or develops a pattern of apparently inverted growth, frequently in association with a hair follicle opening, the pathological differential diagnosis may include an early invasive SCC. An irritated seborrhoeic keratosis shows focal areas of whorls of keratinocytes in so-called squamous eddies, but mitotic figures are rare, and the base of the lesion shows a clear separation from dermal tissue, with no single-cell invasion (Fig. 36.19).

Diagnosis. The superficial type of seborrhoeic keratosis has to be distinguished from simple and malignant lentigo (see Chapter 38) and from AK, especially on the

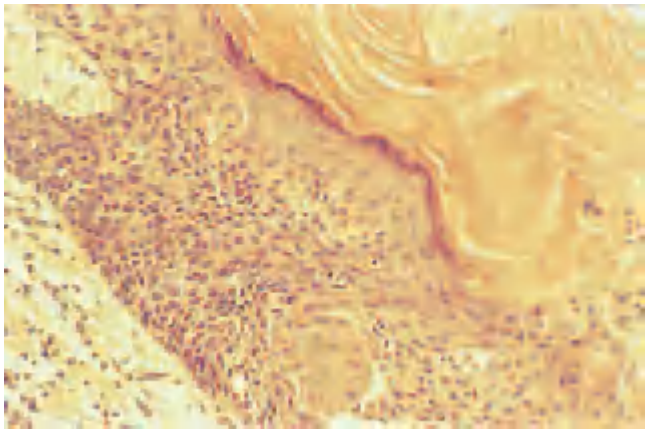

Fig. 36.19 Histology of irritated basal cell papilloma. The squamous eddies are clearly seen in this illustration.

face. The patterned fine fissures on the surface may be helpful. The pigmented domed variety may closely resemble a melanocytic naevus, but the surface is less lustrous and the follicular orifices are plugged. An inflamed keratosis may be confused with a malignant melanoma. If the lesion is treated with a topical antibiotic and occluded for 3–5 days the diagnosis may become obvious, but if clinical doubt persists an excision biopsy and pathological examination is indicated. Pigmented BCCs may also have to be considered in the differential diagnosis. They are usually rather irregular with a rolled edge, a thin shiny epidermis with telangiectases and a depressed or ulcerated centre.

Treatment. Removal with a small sharp curette leaves a flat surface that becomes covered by normal epidermis in a week. Cautery or diathermy should be used as little as possible to avoid scarring. Satisfactory results can be obtained by freezing briefly, a technique especially suitable for large superficial lesions, or by carefully painting the surface with pure trichloracetic acid and repeating if the full thickness is not removed on the first occasion. Seborrhoeic keratoses tend to recur, and it is often wise to encourage patients to accept them rather than to keep returning for further treatment.

Melanoacanthoma

This term has been used for a very rare lesion, originally described by Bloch as 'non-naevoid melanoepithelioma, type 1', and has been considered to be a benign neoplasm composed of epidermal keratinocytes and large dendritic melanocytes [9]. The current general view is that this is not a discrete entity. Some deeply pigmented acanthotic seborrhoeic keratoses contain, dispersed among the parenchymal cells, numerous dendritic melanocytes, which are demonstrable by the dopa technique [10]. Normally they transfer melanin to the surrounding immature keratinocytes. However, if irritation or inflammation caused the parenchymal cells to become more mature, the transfer of melanin would be impeded and pigment might be retained in the melanocytes, producing a microscopic appearance similar to that described as melanoacanthoma.

Stucco keratosis [6,11]

This title has been given to small rough whitish keratotic plaques that are easily lifted off the skin with a fingernail and come away without causing bleeding. They are situated principally on the extremities, especially the ankle region, and occur in middle-aged or elderly persons. They have the same stuck-on appearance of seborrhoeic warts and a similar microscopic architecture. Basaloid cells and horn cysts are not seen and the histology is more that of a regular spiky papillomatosis, with loose lamellated hyperkeratosis capping the epidermis. If treatment is called for, curettage or cryotherapy are effective.

Dermatosis papulosa nigra

Definition. A pigmented papular eruption of the face and neck caused by a naevoid developmental defect of the pilosebaceous follicles, with histology resembling seborrhoeic keratoses. The condition is most common in black races.

Aetiology [1]. This lesion is probably genetically determined. The incidence in black people rises from about 5% in the first decade to over 40% by the third, and is rather higher in females than males.

Clinical features [1–3]. The individual lesions are black or dark brown, flattened or cupuliform papules 1–5 mm in

diameter. They are rare under the age of 7 years, after which they increase steadily in frequency, number and size. They are most numerous in the malar regions and on the forehead. They are rare on the lower parts of the face and the chin, but in a few individuals may be found on the neck, chest and back [2].

Pathology [1,4]. The lesions, which are naevoid developmental defects of the pilosebaceous follicles, show irregular acanthosis and hyperkeratosis, and somewhat resemble seborrhoeic keratoses.

Treatment. Treatment is seldom requested. Removal with the diathermy or cautery is effective.

Skin tags

SYN. SOFT WARTS; ACHROCHORDON

Definition. A common benign lesion composed of loose fibrous tissue and occurring mainly on the neck and major flexures as a small soft pedunculated protrusion.

Incidence and aetiology. These lesions are very common, particularly in women at the menopause or later. They are frequently found together with seborrhoeic keratoses.

Clinical features. The lesions are pedunculated and may have a long stalk. They vary in size and are about 2 mm in diameter on average. They are round, soft and inelastic. The colour may be unchanged, but they are frequently hyperpigmented. The most common site is on the sides of the neck, where they may be mixed with typical small sessile seborrhoeic keratoses. When more profuse, they can extend on to the face or down to the back and chest. Similar lesions may be found in and around the axillae and groins.

Pathology. The protruding mass is connected to the skin by a narrow pedicle. The bulk of the lesion is loose fibrous tissue, similar to that of the papillary dermis. The epidermis is thin, and the basal cell layer is flat and often hyperpigmented. Melanocytic proliferation and naevus cells are not usually seen and the majority of such lesions probably come within the seborrhoeic keratosis spectrum. However, there is an overlap with melanocytic naevi and neurofibromas. Some skin tags may be the last remnants of a pre-existing melanocytic naevus.

Diagnosis. The lesions are unmistakable. They are smaller than the average pedunculated melanocytic naevus or the lesions of neurofibromatosis.

Treatment. Both cautery and cryotherapy with liquid nitrogen are effective.

Haber's syndrome

Definition. A familial condition characterized by a persistent rosacea-like eruption, associated in some cases with keratotic plaques on the trunk and limbs.

Incidence. A family in which five members were affected was originally described [1]. Another case, with 15 affected relatives, has been described from Japan [2]. The rosacea-like eruption appears in childhood, and the keratotic lesions somewhat later. The mode of inheritance seems to be a simple autosomal dominant.

Clinical features. The cheeks, nose, forehead and chin are permanently flushed. The skin surface shows a combintion of erythema and telangiectasia, prominent follicles, comedones, small papules, some of which are scaly, and tiny atrophic pitted areas. There is little fluctuation in the erythema, although sunlight may aggravate it. The warty lesions occur mainly on the trunk and thighs and are static, scaly or keratotic, flat and non-indurated plaques.

Pathology. The facial eruption shows perivascular inflammation leading to fibrosis, acanthosis and parakeratosis of the epidermis, distortion of pilosebaceous complexes with dilated follicular orifices, and proliferation of immature glands and basal cell strands. The warty lesions are produced by papillomatosis, acanthosis in the interpapillary ridges and dyskeratosis with areas of pale-staining cells giving a parakeratotic stratum corneum. Mitotic figures are present, but there is no evidence of malignancy.

Treatment. The facial eruption was controlled in the young patient in the first family and in the Japanese patients by steroid creams locally. The warty lesions respond to radiotherapy. Simple destructive measures are also effective.

Clear cell acanthoma [1–3]

SYN. DEGOS' ACANTHOMA; ACANTHOME A 'CELLULES CLAIRES'

Definition. A scaly plaque or nodule that has a characteristic accumulation of clear glycogen-containing cells in the epidermis.

Incidence and aetiology. Clear cell acanthoma is a relatively uncommon condition of adults. The sexes are equally affected [3]. The cause is unknown [4].

Clinical features (Fig. 36.20) [1,3,5]. The lesion is usually solitary. It is a slightly elevated to dome-shaped plaque or nodule with an abrupt margin and a wafer-like scale adherent at the periphery, which leaves a moist or bleeding surface when removed. The colour varies from pink to brown, but is most characteristically red with vascular puncta and it blanches on diascopy. It varies from 3 to 20 mm in diameter, and occurs most commonly on the lower limbs. The duration may be of many years, and there are usually no symptoms. The diagnosis can be suspected on the clinical evidence. The lesion may be mistaken for a histiocytoma, seborrhoeic keratosis or pyogenic granuloma.

Pathology [1,6,7]. The epidermis is thickened and papillomatous with sharply demarcated areas of light-coloured cells, which contrast with the normal basal cells below and Malpighian cells around them (Fig. 36.21). The cytoplasm of the clear cells contains an abundance of glycogen, which on electron microscopy is seen to displace tonofibrils [7,8]. The cells do not have the enzymes characteristic of eccrine sweat glands. There is intercellular oedema and an infiltrate often containing many polymorphonuclear leukocytes. The papillary body is oedematous and the superficial capillaries and veins are increased in number. There may be syringomatous sweat gland elements and evidence of sebaceous differentiation beneath the lesion [9].

Treatment. Excision is often needed to confirm the diagnosis [1].

Keratoacanthoma

SYN. MOLLUSCUM SEBACEUM

Definition. A rapidly evolving tumour of the skin, composed of keratinizing squamous cells originating in pilosebaceous follicles and resolving spontaneously if untreated.

Incidence. Keratoacanthoma is relatively common, and in white races tends to occur with about one-third of the frequency of SCC, despite differences in climate [1]. It is uncommon in dark-skinned races and in the Japanese [2].

Males are affected about three times more often than females. The adjusted age distribution shows that it is most frequent in middle life and does not increase in incidence in old age, unlike basal and squamous cell carcinomas.

Aetiology. The epidemiological data suggest that incidence is related to sun exposure, and the localization of the tumours mainly on the head and upper limb supports this. Contact with tar and mineral oil has also been shown to cause an increased incidence [3,4] and very similar lesions have been produced in animals by painting with carcinogenic hydrocarbons. In some cases, the lesion follows injury to the skin, which suggests that infection may play a part in its origin, a view supported by the occurrence of multiple keratoacanthomas in skin grafts of patients with the tumour in the recipient site [5], the donor site [6] or both [7]. Proof of a viral cause is lacking. Cases are reported of keratoacanthoma associated with carcinoma of the larynx [8], multiple internal malignancy [9], leukaemia [10], deficient cell-mediated immunity [11] and in transplant recipients.

Clinical features [1,12,13]. The first evidence of keratoacanthoma is a firm, rounded, flesh-coloured or reddish papule, which may resemble molluscum contagiosum or, if keratotic, a virus wart. The patient rarely seeks advice at this stage. There is then a rapid growth phase and in a few weeks it may become 10–20 mm across. There is no infiltration at the base. The epidermis over the nodule is smooth and shiny; the lesion is skin-coloured to red with telangiectases just beneath the surface. The centre contains a horny plug or is covered by a crust which conceals a keratin-filled crater (Fig. 36.22). As the lesion matures, the accumulating keratin expands the outermost part making the edge overhang the base somewhat, but the radial symmetry is usually well preserved. The keratin may project like a horn or it may soften and break down. Spontaneous resolution is achieved by the epidermal covering receding towards the base and the horny core being shed. The base is revealed as irregular and puckered and the edge may remain as soft but thickened epidermis, either as a continuous rim or a series of tags. The process of spontaneous healing usually takes about 3 months.

A small proportion of keratoacanthomas grow to much larger dimensions—50 mm or more in diameter being not exceptional on the forearm. One lesion on the chest became over 150 mm across [14]. In some cases, the maximum size may be reached in a month or two; others may enlarge for many months. After growth ceases, involution may not occur for some months or may occur at part of the periphery while growth continues elsewhere. There may be recurrences after curettage or excision, more frequently in lesions on the lips and fingers and when treatment is carried out in the early stages [15]. Recurrence may happen after spontaneous resolution [16].

(a) (b)

Fig. 36.22 Typical keratoacanthomas, both found on the face, showing raised margin and central keratin-filled crater.

The most frequently affected area is the central part of the face: the nose, cheeks, eyelids and lips. The dorsum of the hand, the wrist and the forearm are commonly affected; the thigh, chest, shoulder and scalp less so; and the anogenital area uncommonly except in those exposed to occupational hazards. Lesions have occurred in the subungual region [17,18], in the vermilion of the lips [15] and on the buccal mucosa.

In most cases, the tumour presents as a solitary lesion. Multiple or recurrent tumours are more likely to be present in several circumstances. Recurrent lesions occur in the patient who has been exposed to pitch or tar [3] and in rare cases as a familial disorder, although there are reasons to keep this Ferguson-Smith type as a separate entity (see below). There are a few cases of eruptive keratoacanthoma recorded. Multiple lesions have occurred with defective cell-mediated immunity and also as part of Torre's syndrome, with multiple internal malignancies [9] and with sebaceous adenomas (see Chapter 37).

Pathology. The distinctive features are best seen when the fixed specimen is being cut before processing or in sections under low magnification. The tumour has a symmetrical, more-or-less globular form and is situated in the dermis, usually extending down no deeper than the sweat glands, although deep penetration has occasionally been recorded. The epidermis around the tumour is normal or slightly acanthotic, but becomes thinned as it rises over the tumour. A narrow spur of connective tissue separates the epidermis from the proliferating squamous cells, except where the two connect at the mouth of the keratin-filled crypt. Serial sections of an early lesion have shown connection of the masses of squamous cells with the upper part of a hyperplastic follicle [19].

The histological features vary with the stage of evolution. The early lesion is composed of a mass of rapidly multiplying squamous cells. These are large and rather pale with vesicular nuclei, prominent nucleoli and frequent mitoses. Hyperchromatic cells, atypical mitotic figures, individual cell keratinization and other evidence of loss of polarity may be found. The marginal cells invade the surrounding dermis aggressively, while those more centrally placed keratinize to form a branched core of keratin that communicates with the surface. The stroma is vascular and is infiltrated with round cells and histiocytes.

Resolution occurs through maturation of the hyperplastic masses. The accumulating keratin dilates the central pore, the epidermal lips recede from the centre and the lesion opens like a flower bud. When the horn is finally shed, the irregular epithelium beneath it replicates the scalloped outline of the active mass. The cells take on the morphology of epidermis, and a scar is formed, which is depressed and may have papillomatous tags at the margin, the remnants of the epidermal lip. Older lesions frequently show clusters of leukocyte microabscesses at the base. Thus, the pathological features vary with the stage of evolution of the keratoacanthoma and, if an adequate specimen is not submitted, it may be impossible for the reporting pathologist to confidently rule out early invasive SCC. Keratoacanthomas may also rarely progress to SCC. In one case [20], it may have been precipitated by treatment with oral methotrexate for a recurrence. The conjunction of two independent lesions in sun-damaged skin may account for the finding of a BCC in the scar of keratoacanthoma in this and other cases.

Experimentally produced lesions differ in their form, depending on whether the hair follicles are in anagen or telogen when the proliferation begins [21,22]. Virus-like particles have been seen under electron microscopy [23].

Diagnosis. The most important differential diagnosis is to distinguish keratoacanthoma from SCC. In most cases, the more rapid evolution to a relatively large size, the regular crateriform shape and keratotic plug, the undamaged surrounding skin and the younger age of onset make a distinction relatively easy for the clinician. Spontaneous healing adds support to the diagnosis of keratoacanthoma. The problem is made more difficult in sunny areas where actinic damage and SCC are more common, and the most important single point is the history of rapid growth. The differential diagnosis includes cutaneous horn and hypertrophic AK, viral wart, molluscum contagiosum, pseudoepitheliomatous hyperplasia and granulomas of various types. Secondary deposits from non-cutaneous malignancies can also occasionally mimic keratoacanthoma.

Treatment. The end result of leaving the tumour to regress is usually a rather unsightly scar. Curettage and coagulation of the base, or excision and suture, produce a much more acceptable result. Excision is desirable if the diagnosis is in doubt, because curetted specimens yield poor sections. Radiotherapy shortens the course and improves the scar, and can be used in patients who refuse surgery. A total of 2000 cGy in two closely spaced doses of adequate penetration can be given.

The application of 5-fluorouracil ointment twice daily may reduce the time taken for natural resolution and diminish the scarring [24]. If there is real doubt about the diagnosis, surgical removal or radiotherapy should be carried out as for SCC, and the patient followed up.

Generalized eruptive keratoacanthoma [9,25]

A small number of cases of widely disseminated lesions, some of them typical keratoacanthomas, have been reported. Both sexes have been affected. The primary lesions are flesh-coloured to red dome-shaped follicular papules 1–3 mm in size and affecting particularly the face, where they may be confluent, the trunk and the roots of the limbs. Itching is a prominent symptom, and ectropion and narrowing of the mouth may be produced by the keratotic facial change. Scattered among the papules are larger, more typical keratoacanthomas, which resolve spontaneously. The palms and soles are spared, but the oral and laryngeal epithelium can be involved.

Pathology. Histological examination shows the papules to consist of a dilated and plugged follicle duct with

acanthotic follicular epidermis around it; the mucosal lesions are irregular acanthosis; and the nodules are keratoacanthomas, but with no inflammatory changes.

Management. The nodular lesions heal in a few months. The papules are not influenced by cytotoxic drugs, but one case responded to topical retinol [25] and current trials of the synthetic retinoids are in progress.

Pseudoepitheliomatous hyperplasia [1]

Aetiology. Epidermal hyperplasia is an early and essential feature in the healing of any breach of the skin surface. Under ordinary circumstances, this is coordinated with the repair of the dermis, and the down-growths are eventually broken up [2]. When the dermis is diseased, however, a persistent and much more extensive hyperplasia may occur. This is seen, for instance, at the margin of chronic leg ulcers, over chronic granulomas such as lupus vulgaris, tuberculosis verrucosa cutis, insect-bite granulomas and halogen granulomas and, in a rather unusual form, over a small proportion of histiocytomas. It is also a component of some cases of lupus erythematosus and of lichen planus of the hypertrophic type. It may occur in association with tumours, particularly granular cell myoblastoma and malignant melanoma.

Clinical features. The appearance will vary with the primary disorder. Granulomas may be covered by a thickened, warty or heaped-up epidermis, perhaps best seen in chromomycosis. In chronic ulcers, the margin is heaped-up, often giving the appearance of being rolled, and has an irregular surface. The edge is not usually indurated to the extent that occurs in SCC. It is characteristic that the hyperplasia will subside as the ulcer is treated and heals. It is wise to remember that an ulcer whose margin has been affected by pseudoepitheliomatous hyperplasia in the past may eventually be the cause of metastasizing SCC.

Pathology. The nature of the primary disorder modifies the picture greatly. In simple ulcers and inflammatory lesions—by far the most common causes—there is disturbance of the upper part of the dermis, often with young fibroblasts and a rather myxomatous connective tissue stroma replacing the normal dermal collagen. Columns of prickle cells grow down into the dermis in an irregular fashion. In some areas, there is maturation of the central parts of the columns to produce horny pearls. The general appearance is that of invasive proliferation of the epithelium. The individual cells, however, do not show the atypical features that suggest malignancy. The columns may be penetrated by inflammatory cells, a feature that is not seen in malignant proliferations. In most instances, a weighing of dermal against epidermal changes suggests that the former are the cause and not the consequence of the latter.

Diagnosis. A good-sized biopsy from a representative area of the lesion is essential.

Cysts

Nomenclature. The term *sebaceous cyst* should be used only to describe steatocystoma multiplex, which contains oily sebum. Histological examination of all other cysts reveals the lining wall to be keratinous in nature. Keratinous cysts can be divided into two types, those with a lining identical in its stratification with epidermis and pilosebaceous duct, and those with a lining resembling the external root sheath of the follicle. The latter variety is less common, and is often familial, multiple and largely confined to the scalp [1]. This type is the trichilemmal cyst [2].

The cysts found in Gardner's syndrome are epidermoid in type [3] and are characterized by their appearance in childhood. There is no genetic overlap between trichilemmal cysts, cysts of Gardner's syndrome or steatocystoma multiplex, although all have an autosomal dominant mode of inheritance.

Histogenesis. Steatocystoma multiplex is most likely to be a genetically determined failure of canalization between the sebaceous lobules and the follicular pore. The common epidermoid cyst is the result of squamous metaplasia in a damaged sebaceous gland. Milia may result from either keratinization within the sebaceous anlagen ('collars') of vellus hair follicles or cystic dilatation of an interrupted sweat duct. Trichilemmal cysts may be caused by survival of fragmented segments of the hair root during catagen.

The following cysts are described in this section or elsewhere in the book:

1 Keratinous cysts, both epidermoid and trichilemmal
2 Dermoid (see Chapters 64 and 66)
3 Milium
4 Steatocystoma multiplex
5 Eccrine hidrocystoma (see Chapter 37)
6 Apocrine hidrocystoma (see Chapter 37)
7 Bartholin's cyst (see Chapter 68)
8 Myxoid cyst of the skin (see Chapter 62)
9 Branchial cyst (see Chapter 15).

Epidermoid cyst

SYN. EPITHELIAL CYST (SEBACEOUS CYST IS A MISNOMER)

Definition. A cyst containing keratin and its breakdown products, surrounded by an epidermoid wall.

Incidence and aetiology. Epidermoid cysts are common, most frequently affecting young and middle-aged adults. They are rare in childhood. Many are the result of inflammation around a pilosebaceous follicle, and they are frequently seen following the more severe lesions of acne vulgaris. Some may result from deep implantation of a fragment of epidermis by a blunt penetrating injury. Those that occur as a part of Gardner's syndrome and of the NBCCS are probably caused by a developmental defect.

Clinical features. An epidermoid cyst is situated in the dermis and raises the epidermis to produce a firm elastic dome-shaped protuberance that is mobile over the deeper structures. It is tethered to the epidermis, and there may be a central keratin-filled punctum. The spherical form can be felt where the skin is sufficiently lax. Cysts near the surface, as in the ear lobe or scrotum, are yellowish or white. The size varies from a few millimetres to 50 mm or so. The common sites are the face, neck, shoulders and chest, which are areas favoured by acne vulgaris. Lesions may be solitary but are commonly multiple. They enlarge slowly and may become inflamed and tender from time to time. Suppuration may occur. Cysts that follow acne and have been subject to recurrent inflammation may be difficult to remove completely. Calcification of the contents of epidermoid cysts cannot usually be detected clinically; when it occurs in multiple cysts of the upper part of the trunk it can give a confusing picture on a chest X-ray.

Traumatic inclusion cysts usually occur on the palmar or plantar surfaces, buttock or knee. A history of penetrating injury is not always obtained.

Pathology. An epidermoid cyst is unilocular and spherical, unless flattened by firm tissue beneath it. There may be an obvious connection with the surface by a keratin-filled duct, but this is probably less common than surgical texts would suggest. The cyst is situated within the dermis. The lining wall reproduces the layers of the epidermis, although attenuated in large cysts. The keratin is lamellated and birefringent. Cholesterol clefts may be seen. The basal layer may be flattened and surrounded by fibrosis, or may show papillary indentations similar to the epidermis. Some cysts have a chronic inflammatory or foreign-body type of reaction around them, at times producing (or caused by) partial disruption of the wall. Occasionally, a hair shaft may be found coiled up within the cyst. These cysts probably result from inflammatory destruction of the sebaceous matrix cells and connective tissue investment of the gland and subsequent re-epithelialization of the abscess cavity, or from squamous metaplasia following impaction of a hair shaft within the sebaceous gland.

Diagnosis. The uncomplicated cyst can usually be diagnosed with confidence. Other benign and rounded dermal tumours may be mistaken for epidermoid cysts, and inflammatory granulomas such as cutaneous leishmaniasis may mimic an inflamed cyst (Figs 36.23 & 36.24).

Treatment. A cyst that has not recently been inflamed can be dissected out. An inflamed cyst is better incised, drained and phenolized.

Fig. 36.23 Calcified cyst just below the eyelid margin.

Fig. 36.24 Inclusion cyst following trauma to the thumb.

Trichilemmal cyst

SYN. PILAR CYST

Definition. A cyst containing keratin and its breakdown products, usually situated on the scalp, with a wall resembling external hair root sheath [4].

Incidence and aetiology. This is quite a common condition, and accounts for about 5–10% of keratinous cysts seen in surgical pathology services. Women are affected more frequently than men. It is seen mainly in middle age [5] and is inherited as an autosomal dominant [1,6].

Fig. 36.25 Clinical illustration of typical pilar cyst on the scalp.

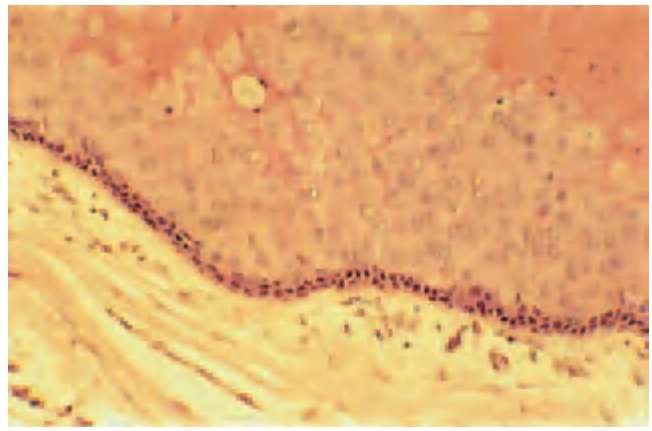

Fig. 36.26 Pilar cyst showing typical pathological features (see text).

Clinical features. The lesion occurs mainly on the scalp, and is a smooth, mobile, firm and rounded nodule (Fig. 36.25). Larger lesions may be lobular and multiple cysts are commonly found. Tenderness occurs with inflammation, and the surface may break down with infection. The cyst wall may fuse with the epidermis to form a crypt (marsupialized cyst), which can occasionally terminate by discharging its contents and healing spontaneously [6]. In contrast, the contents may protrude above the surface to form a soft cutaneous horn.

Pathology. Trichilemmal cysts differ from epidermoid cysts in the way the lining cells mature. They do not flatten and form a granular layer, and keratinization seems to occur mainly in the region of the cell membrane. The cells appear to disintegrate at the inner margin of the lining. The contents are not brightly birefringent lamellae, but may calcify (Fig. 36.26).

The wall of a trichilemmal cyst may become ruptured and the contents invaded by granulation tissue. The reaction is much less acute than in ruptured epidermoid cysts and produces proliferation rather than destruction of the

Fig. 36.27 Clinical illustration of steatocystoma multiplex on the chest.

wall. The proliferation may be progressive and simulate, clinically and histologically, a well-differentiated SCC [7]. Cases of proven malignant degeneration in scalp cysts are very rare.

Treatment. Uncomplicated cysts shell out of the dermis with remarkable ease. Proliferating cysts need to be excised with a margin because they will recur if tissue is left behind.

Steatocystoma multiplex

SYN. SEBOCYSTOMATOSIS; HEREDITARY EPIDERMAL POLYCYSTIC DISEASE

Definition. Multiple cysts in the dermis having sebaceous gland lobules in their wall and containing sebum.

Incidence and aetiology. It is a very uncommon condition, which usually begins in adolescence or early adult life [8]. The condition is inherited as an autosomal dominant in many cases [9,10]. The sexes are affected equally [11].

Clinical features. Multiple smooth compressible nodules are present within the dermis, varying in diameter from a few millimetres to 20 mm or more (Fig. 36.27). They usually appear or become larger at puberty. The trunk and proximal part of the limbs are most commonly involved, particularly the presternal area. No punctum is usually apparent over the cyst, but there may be widespread comedones [12]. The more superficial lesions may have a yellowish colour. If pricked, an oily fluid can be expressed. Some lesions become inflamed, suppurate and heal with scarring.

Pathology. The cyst is situated in the mid-dermis. The wall is thin and composed of keratinizing epithelium. In some sections, lobules of sebaceous glands can be seen to form part of the wall or to empty by ducts into the cyst. The contents are oily, and are composed of the unsplit esters of sebum [13]. They may contain hairs. Hair roots and, occasionally, sweat glands may be found connected with the cyst, and the whole complex is joined to the epidermis by a short strand of undifferentiated cells [14].

Treatment. The number of cysts makes excision impractical in most cases. There is no reason, apart from cosmetic, for treating them.

Milium

Definition. A small subepidermal keratin cyst.

Incidence and aetiology. Milia are quite common at all ages from infancy onwards. Many arise in undeveloped sebaceous glands. This may occur in young women as an eruptive phenomenon, and is sometimes a sequel to sunbathing. Others may arise in the proximal part of divided sweat ducts. The cause of the duct damage is usually avulsion accompanying an acute subepidermal bulla, particularly in second-degree burns, epidermolysis bullosa, porphyria cutanea tarda and bullous lichen planus. They may also follow dermabrasion and occur in areas of chronic topical corticosteroid-induced atrophy. Destruction of skin appendages by radiotherapy may result in a ring of milium-like lesions at the margin of an area treated with tumour doses. These, unlike other forms, can be expressed easily.

Clinical features. The lesions are white or yellowish, rarely more than 1 or 2 mm in diameter and appear to be immediately beneath the epidermis. They are usually noticed only on the face, and occur in the areas of vellus hair follicles, on the cheeks and eyelids particularly. Those that follow blisters are scattered more or less at random in the affected area (Fig. 36.28).

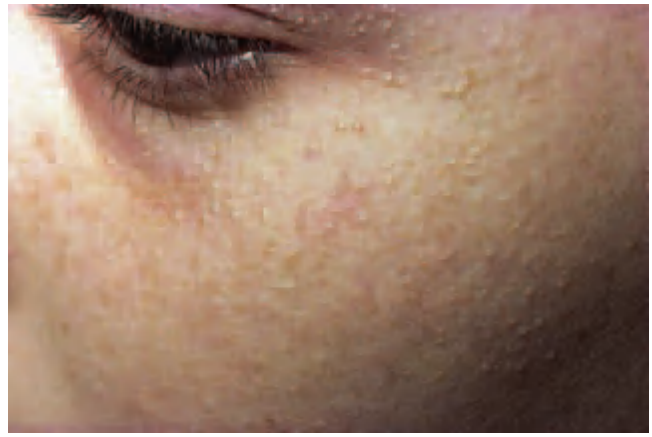

Fig. 36.28 Multiple milia on the upper cheek area.

Pathology. The lesion is so easily treated that specimens for histological examination are uncommon. However, the milia that follow blistering can often be traced to eccrine sweat ducts in serial sections. Those at the margin of an irradiated area are usually situated in the distorted remnant of the pilosebaceous duct. The much more common milia of the face are found within the undifferentiated sebaceous collar that encircles many vellus hair follicles. The white milium body is composed of lamellated keratin.

Diagnosis. Milia are recognized as groups of small uniform spherical white papules with a smooth non-umbilicated top. They are usually whiter and more translucent than syringomas, which appear clinically to be more deeply situated in the skin. Milia tend to occur in isolation and are not associated with papules, comedones and cysts such as may be seen in closed comedones associated with acne and chloracne. Trichoepithelioma may rarely cause confusion, but tend to be larger, more multilobulated structures even on clinical examination.

Treatment. Incision of the epidermis over the milium with a cutting edge needle or sharp-pointed scalpel and squeezing out the contents is usually effective. Recurrence is uncommon. Spontaneous disappearance occurs in many milia in infants.

Premalignant fibroepithelial tumour (of Pinkus)

Definition. A premalignant tumour composed of cells resembling those of BCC arranged in a thin honeycomb around a prominent overgrown papillary stroma.

Incidence. Relatively uncommon. Several examples have arisen in areas treated by radiotherapy for ankylosing spondylitis [1,2]. The author has seen one case on the chest of a patient with multiple postarsenical BCC.

Clinical features. The tumour is sessile with a domed surface and is firm and flesh-coloured. Most of the recorded lesions have been found on the abdomen or loins. There may be seborrhoeic keratoses or BCCs, or both, elsewhere [3]. Increase in size, when it occurs, is slow. The tumour is most likely to be diagnosed as a fibroma.

Pathology. The outline is domed and the surface is formed of normal epidermis. The bulk of the tumour is composed of considerably enlarged dermal papillae, more cellular and fibrotic than normal, which are surrounded by strands of small dark cells that extend down from the underside of the epidermis. Small buds of cells may arise from the strands and enlarge to form BCC, replacing part or all of the tumour [4].

Treatment. The lesions should be surgically excised.

Chapter 37

Tumours of the Skin Appendages

R.M. MacKie & E. Calonje

Introduction

The anatomical relationships of the epidermis and dermis are fully discussed in Chapter 3. The skin appendages are of particular interest in examining this relationship, in that they clearly show a morphological, and also in some instances functional, interrelationship. The appendage tumours discussed in this chapter either differentiate towards or arise from the pilosebaceous apparatus (including the apocrine gland) and eccrine sweat glands [1–9].

The pilosebaceous apparatus can be divided into the hair follicle, the adjacent sebaceous gland and in some body sites the apocrine glands. Small strips of smooth muscle, the arrector pili muscle, are also found in association with these structures.

The pilosebaceous apparatus is concentrated in the head and neck area, with the pilar element predominant on the scalp and the sebaceous element in the face, chest and upper back areas. Thus, tumours arising from these structures are found predominantly in these sites.

The eccrine sweat glands are, in contrast, found on all body sites and are composed of a double-layered, deeply situated secretory structure and a more superficial excretory duct winding through the dermis and spiralling through the epidermis to reach the outer surface.

The excretory (ductal) portions of the eccrine and apocrine glands are identical and cannot be differentiated on morphological grounds unless the apocrine duct can be identified entering the hair follicle. To complicate matters further, the apocrine duct rarely opens directly into the epidermis, and there are no histochemical or immunohistochemical stains that allow distinction between eccrine and apocrine tumours. From this, it can be inferred that adnexal tumours showing ductal differentiation may be

either eccrine or apocrine, and distinction is not possible unless there is concomitant follicular differentiation. In recent years, it has therefore been proposed that the classification of adnexal tumours should follow a more logical approach that takes this into consideration [6]. It has become apparent that tumours traditionally considered to be of eccrine differentiation, such as cylindroma, spiradenoma and mixed tumour (so-called chondroid syringoma), may show either line of differentiation and this is probably most often apocrine. Even a classical eccrine tumour such as poroma has been described occasionally as differentiating towards the apocrine duct [7].

A wide range of cells make up the secretory and excretory components of the appendage ducts, the hair follicles and the sebaceous glands. As each cell type capable of dividing can give rise to a tumour as a result of inappropriate transfer of genetic material and cell division, it follows that an equal number of tumours are theoretically possible. The great majority of these appendage-derived tumours are relatively benign, with behaviour and prognosis similar to that seen in basal cell carcinoma. Thus, although local recurrence is well recorded, metastases are rare, with the exception of the malignant eccrine and apocrine gland-derived tumours and sebaceous carcinoma. It is important to take into account that malignant adnexal tumours with metastasis are over-reported in the literature and that this has led to overestimation of their true malignant potential.

Appendage tumours are relatively rare, and their clinical appearance is commonly non-specific. The great majority are not diagnosed as such until after excision and pathological study. Classification systems for these lesions tend to be controversial, but in general the system groups lesions together according to their morphological similarity to normal appendage structures.

Hair-follicle tumours

A large number of tumours are theoretically capable of arising from the hair follicle and matrix, depending on the exact type of cell and its situation within the dermis. A representative selection of these tumours will be described here. For a pathologically comprehensive list, the reader is referred to specialized publications [1,2]. Recent studies on the role of the sonic hedgehog gene and related proteins in basal cell carcinoma (see Chapter 36) have been extended to hair-follicle tumours [3]. The patched gene is located on chromosome 9q22.3, and loss of heterozygosity has been identified in sporadic trichoepitheliomas [4]. Overexpression of Gli-1, which is integral to this pathway, has been observed in trichoepitheliomas in mice [5].

β-Catenin plays a key role in signal transduction and subsequent tissue modelling, and mutations in the β-catenin gene have been recorded in pilomatricomas [6,7].

Inverted follicular keratosis [1–3]

Definition. A localized area of hyperkeratosis found in association with the pilosebaceous orifice. A number of these lesions arise as a result of infection of the infundibulum of the hair follicle by human papillomavirus (HPV). It is likely that a majority of these lesions may be regarded as the most superficial tumour of the follicular infundibulum (see below), arising as the result of irritation.

Clinical features. In common with many of the lesions described in this chapter, this lesion presents as a solitary papule on the head and neck area. It may reach a considerable size, be inflamed and may cause pruritus.

Pathology. The pathological features show an endophytic lesion connected to the infundibulum of the hair follicle. Irritated keratinocytes form whorls of cells, so-called 'squamous eddies', and keratin cysts. All of these features may give rise to problems with the differential diagnosis of squamous cell carcinoma, especially on small biopsies. This can be relatively easily distinguished on low-power examination, as there is no individual cell invasion into the dermis. At higher power, mitotic figures may be seen, but they are not abnormal mitoses. The appearances are

identical to an irritated seborrhoeic keratosis, but the latter is exophytic.

Management. Local surgical excision is generally needed, for both diagnostic and therapeutic purposes. Occasionally, the lesions recur [3].

Dilated pore [1]

SYN. WIENER'S PORE

Definition. An area of expanded follicular infundibulum with a dilated poral opening extending down to subcutaneous fat [2].

Clinical features. The pore is a comedo-like lesion found mainly on the head and neck area of the elderly.

Pathology. There is a wide, crater-like cavity, from which acanthotic areas of follicular epithelium radiate. The follicle is lined by outer root-sheath epithelium, and there is little evidence of a sebaceous gland or a well-formed emerging hair.

Tumour of the follicular infundibulum

Definition. This lesion may be considered the hair-follicle equivalent of the eccrine dermal duct tumour (p. 37.20).

Clinical features. These lesions are usually found on the facial skin and may be relatively large, irregular nodules. They are usually biopsied or excised to obtain a diagnosis, as the clinical appearance is not specific. It has been suggested that they can be divided into four main groups: solitary lesions; those in association with Cowden's disease; multiple eruptive tumours; and follicular infundibulum-like changes in the epidermis [1].

Pathology [2–4]. The pathology is that of a large, horizontally orientated plate of small, dark cells situated in the superficial dermis, usually with multiple connections to the overlying epidermis. The cellular detail is focally similar to that seen in the trichilemmoma, with large numbers of small polygonal cells with clear cytoplasm contained within a palisaded border. Basaloid cells are often seen. The resemblance to basal cell carcinoma is striking, but the stromal element is lacking.

Pilar sheath acanthoma [1]

Clinical features. These lesions are very rare and are most commonly seen on the upper lip area of the elderly [2,3].

Pathology. The pathology is that of an expanded area of the outer root-sheath epithelium within an irregularly branched cystic cavity, with large lobules of epithelial cells radiating outwards from this cavity area.

3 Vakilzadeh F. Haarscheidenakanthom. *Hautarzt* 1987; **38**: 40–2.

Trichoadenoma [1–5]

Definition. A rare benign tumour, with multiple cystic structures closely resembling the infundibular portion of the hair follicle.

Clinical features. This lesion presents as a non-specific nodule, usually on the face, although there are some reports of lesions on the buttocks.

Pathology. The lesions are in the upper dermis, and on light-microscope scanning power give the impression of a cluster of cysts. On higher power, these cyst-like structures have an appearance similar to the infundibular portion of the hair follicle but turned through 90°; no recognizable hair shafts are seen.

Comedo naevus [1–3]

Definition. A rare abnormality of the follicular infundibulum presenting as a group of comedo-like lesions.

Clinical features. These lesions are rare and are seen on the head and neck area. They may be present at birth or develop throughout adult life. They appear as a cluster of comedos or as a single giant lesion.

Pathology. A rudimentary pilosebaceous follicle is present, with a large overlying keratin-filled crater. The surface of the keratinous material oxidizes to give the blackhead-like appearance.

External root-sheath tumours

Trichilemmal cyst

Definition. A cyst apparently arising from the external root sheath, containing keratin and breakdown products [1,2].

Clinical features. These lesions are mainly seen on the scalp and are relatively common. They may be familial, inherited by autosomal-dominant transmission [3]. Females are affected more often than males. They clinically present as firm nodules, which may become infected or inflamed after minor trauma. They are commonly multiple.

Pathology. These cysts are well circumscribed in the dermis and lined by two or three layers of small, dark keratinocytes. There is then an abrupt transition, towards the centre of the lesion, to large, pale cells with features of root-sheath cells. A granular cell layer is absent. The centre of the cyst contains keratin debris. Some lesions are hybrid and show focal changes of an epidermoid cyst, with formation of a granular cell layer.

Management. These are commonly excised to obtain a diagnosis. Lesions which are shelled out may recur [4].

Proliferating trichilemmal cyst

SYN. PILAR TUMOUR

Clinical features. The tumour presents as a rapidly growing large nodule, commonly on the head and neck area of the elderly. Some lesions are more than 10 cm in diameter. The history of rapid expansion frequently gives rise to concern about malignancy. Malignant change has been rarely reported in these lesions.

Pathology. These lesions may arise from pre-existing trichilemmal cysts, and remnants of a classic trichilemmal cyst may be present [1,2]. The architecture is lobular and expansile, without an infiltrative growth pattern. Tumour lobules are cystic and composed of pale squamous cells with mild atypia. However, tumour cells in the periphery of the lobules may display marked cytological atypia. Prominent abrupt pilar keratinization towards the centre of the lobules is a typical feature. In addition, however, there are areas of squamous epithelium containing both squamous eddies and mitoses. If there is frank invasion into adjacent structures in association with tumour necrosis, the diagnosis of a malignant trichilemmal cyst may be appropriate [3,4]. The diagnosis is often very difficult in small samples, and ideally the whole tumour should be submitted for histological examination to avoid confusion with a squamous cell carcinoma.

Management. Local recurrence takes place and complete excision is therefore necessary.

Trichilemmoma [1–3]

Definition. This lesion is considered to be a proliferation of the external root sheath of the hair follicle [4,5].

Clinical features. Clinically, these lesions are small, non-specific papules on facial skin; they present in young and middle-aged adults. Their importance lies in the fact that patients with Cowden's syndrome or multiple hamartoma and neoplasia syndrome [6–13]—which is

associated with a very high incidence of breast, thyroid and gastrointestinal carcinomas—have large numbers of trichilemmomas. The diagnosis of multiple trichilemmomas should therefore stimulate a search for other evidence of Cowden's syndrome. This includes a characteristic 'cobblestone' appearance of the oral epithelium, multiple skin tags, squamous papillomas and sclerotic fibromas (storiform collagenomas). Mutations of the *PTEN* gene on chromosome 10q23 are found in Cowden's syndrome [14,15].

Pathology. These lesions are well-circumscribed, lobular tumours extending down from the epidermis and often connected to a hair follicle. Tumour cells display prominent clear cytoplasm secondary to the deposition of glycogen. The presence of glycogen can be confirmed with a positive periodic acid–Schiff (PAS) stain, which becomes negative after treatment with diastase. There is an irregular enclosing PAS-positive, diastase-resistant membrane. In a number of cases, there is prominent hyperplasia of the surface epithelium, with hypergranulosis, clumping of keratohyalin granules and hyperkeratosis. This indicates induction of some lesions by HPV. A viral aetiology has been confirmed by demonstration of HPV DNA by polymerase chain reaction [16]. Trichilemmomas are often found within a naevus sebaceus.

A variant of trichilemmoma, described as desmoplastic trichilemmoma, has been reported [16]. The periphery of this lesion has histological features identical to those of ordinary trichilemmoma, but towards the centre there are strands of squamous cells embedded in a desmoplastic stroma. This results in an infiltrative appearance that is often confused with a squamous cell carcinoma, particularly in small biopsy samples.

Trichilemmal carcinoma [1–4]

Definition. A very rare tumour with metastatic capacity, usually arising in sun-exposed skin of the elderly.

Clinical features. This lesion presents as a solitary, expanding, often ulcerating lesion on the face. It may be clinically diagnosed as basal cell carcinoma. Multiple tumours have exceptionally been described [5]. Trichilemmal carcinoma may arise exceptionally from a trichoblastoma and in the context of a naevus sebaceus [6].

Pathology. These lesions invade downwards from the epidermis or outer root-sheath areas in a multilobular and infiltrative fashion. They may have a surrounding PAS-positive membrane, and there is central trichilemmal keratinization. There is a high mitotic rate, with abnormal mitoses present. The diagnosis of trichilemmal carcinoma should only be made in the presence of clear evidence of trichilemmal differentiation. The presence of clear cell change is not enough to make this diagnosis. Most malignant cutaneous tumours with clear cell change are squamous cell carcinomas and often show at least focal evidence of keratinization.

Management. Surgical excision with clear margins is the treatment of choice.

Hamartomas and hair germ tumours and cysts

Hair-follicle naevus [1,2]

Clinical features. These naevi are very rare and are recognized as plaque-like lesions with small tufts of hairs. They present in children and may be congenital. The so-called

'faun tail naevus' is a hair-follicle naevus on the sacral skin. Rare cases occur following Blaschko's lines [3].

Pathology. The pathology of this entity consists of a group of normal vellus hair follicles clustered together.

Eruptive vellus cyst

Definition. Occlusion and cystic dilatation of vellus hair follicles.

Clinical features. These present as small red or brown papules on the chest, commonly in the second decade of life [1]. They are usually multiple, and family clusters have been reported [2]. They are commoner than expected in patients who also have pachonychia congenita [3,4].

Pathology. Cysts are located in the mid-dermis, and are lined by squamous epithelium. They contain vellus hair and keratin debris. Biopsies from some lesions show features indistinguishable from steatocystoma, with absence of vellus hairs. This finding suggests that there is an overlap with steatocystoma multiplex [5].

Management. If treatment is requested, the lesions may clear after application of topical retinoids. Curettage and laser therapy may also be effective, but it is easy to cause scarring.

Trichofolliculoma [1]

Definition. This lesion is a hamartoma of the pilosebaceous follicle, which results in several hairs being formed within the follicular opening and all protruding onto the epidermal surface from the one pilosebaceous orifice [2–6].

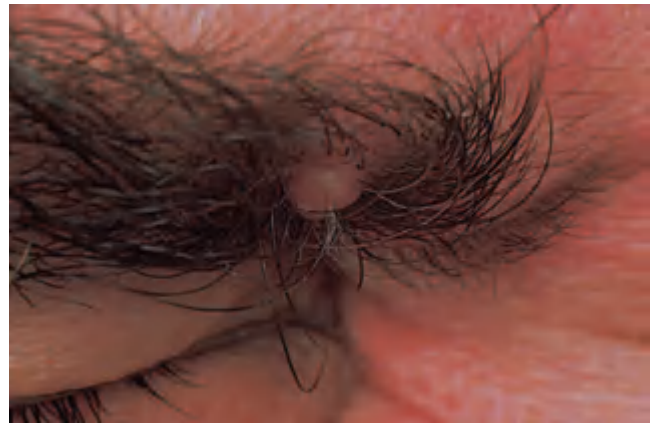

Fig. 37.1 Typical example of a trichofolliculoma, with a small tuft of hairs in the centre.

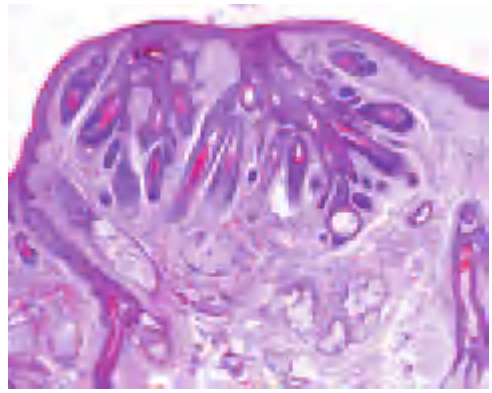

Fig. 37.2 Trichofolliculoma. A large central follicular structure from which immature follicular structures radiate.

Clinical features. Most cases occur in young adults. Clinically, lesions can be recognized as small, raised nodules with two or three hairs protruding together in a small tuft (Fig. 37.1).

Pathology. The pathological appearance is that of a dilated and abnormally large pilosebaceous canal containing numerous, poorly formed hairs, with several pilosebaceous-like structures opening into the canal (Fig. 37.2). Malignant change has been suggested in a single case with perineural invasion [7]. The so-called folliculosebaceous cystic hamartoma is considered to be a variant of trichofolliculoma in a late stage of development [8].

Management. Surgical excision is recommended.

Trichoepithelioma [1]

SYN. EPITHELIOMA ADENOIDES CYSTICUM; BROOKE'S TUMOUR

Definition. A hamartoma of the hair germ composed of immature islands of basaloid cells with focal, primitive follicular differentiation and induction of a cellular stroma.

Clinical features. The presentation of a solitary lesion is that of a smooth nodule, usually on the face, which clinically resembles a non-ulcerated basal cell carcinoma. Most affected patients are young adults. Multiple lesions, which are inherited by autosomal-dominant transmission, are seen as multiple small, pearly lesions, mainly on centrofacial skin (Fig. 37.3).

Pathology [2–5]. The pathology is identical for solitary or multiple lesions and consists of lobules of small, dark cells, often with a degree of peripheral palisading surrounding a central area of eosinophilic amorphous material (Fig. 37.4). Occasionally, hair shaft-like structures can be seen in these central areas. A fibrous cellular stroma is seen around the cellular lobules. There is frequently a strong resemblance to basal cell carcinoma, and at times the differential diagnosis between the two can be very difficult. However, the stroma induced in trichoepithelioma is distinctive and contains clefts, and there is absence of retraction artefact between tumour cells and the surrounding stroma. The gene for multiple trichoepitheliomas has recently been mapped to a locus on chromosome 9p21 [6]. The commoner sporadic cases of trichoepithelioma have, in a proportion of cases, deletions

Fig. 37.3 Multiple trichoepitheliomas on the central face.

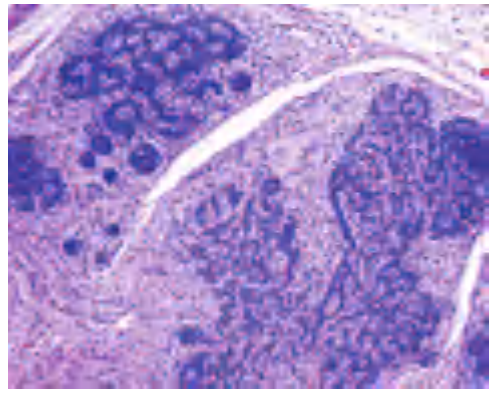

Fig. 37.4 Trichoepithelioma. A lobular basaloid tumour with induction of stroma and immature follicular differentiation.

at chromosome 9q22.3, the site of the human homologue of the *Drosophila* patched gene [7]. Familial basal cell carcinomas and some cases of sporadic basal cell carcinomas also show this deletion.

In multiple lesions, which are present in epithelioma adenoides cysticum [8–12], larger lesions may be yellow, pink, or sometimes bluish from pigmentation, and there may be dilated blood vessels over the surface. Individual tumours reach a limiting size, but the numbers may increase over the years. Continued growth or ulceration raises the suspicion of change to basal cell carcinoma [13].

Treatment. Any suspicion of malignant change calls for adequate excision and histological examination. The only other reason for treatment is cosmetic. Partial destruction is usually followed by regrowth.

Desmoplastic trichoepithelioma [1–3]

SYN. SCLEROSING EPITHELIAL HAMARTOMA

These two terms were introduced almost simultaneously. The US group of Brownstein and Shapiro used the term 'desmoplastic trichoepithelioma' [2], while MacDonald, Wilson-Jones and Marks in the UK suggested the term 'sclerosing epithelial hamartoma' [3].

Definition. A slowly expanding plaque of tissue containing hair follicle-like structures.

Clinical features. Lesions are found mainly on the face of young patients and have a depressed centre and a raised, rolled edge in many cases, causing clinical confusion with basal cell carcinoma. To date, more females than males have been reported with the condition.

Pathology. Tumours are symmetrical on scanning magnification. The three features that characterize this lesion are large numbers of small, keratin-filled cysts, strands and ribbons of small, dark, epithelioid cells, and a dense fibrous stroma surrounding the first two structures. Perineural invasion is not a feature.

The striking palisading of the basal cell carcinoma is absent. There is, however, a considerable similarity to the sclerosing variant of basal cell carcinoma, although the number of cysts is very much greater in the desmoplastic trichoepithelioma. Distinction from microcystic adnexal carcinoma may be impossible in a small and superficial biopsy. The latter, however, shows a diffuse infiltrative pattern, with prominent perineural invasion.

Occasional desmoplastic trichoepitheliomas are combined with a benign melanocytic naevus [4].

Treatment. Local excision is effective in the majority of cases.

Solitary giant trichoepithelioma [1,2]

This is a rare condition with a dramatic clinical presentation that may cause concern about a rapidly growing malignancy. It has also been described under the name 'trichoblastic fibroma'. Trichoepithelioma and giant trichoepithelioma represent the more mature end of the spectrum of trichoblastoma. These tumours are described separately because they represent distinctive clinicopathological entities. However, it should be remembered that histological overlap is often seen.

Clinical features [3–5]. The clinical presentation is of a very large, polypoid lesion presenting on the lower trunk, frequently in the perianal area, with a history of recent rapid growth. The lesions may cause considerable discomfort because of their size. They affect both sexes equally.

Pathology. The pathology shows the features of the smaller, classical trichoepithelioma but the lesions are much larger, deeper and are often located in the subcutaneous fat. An oedematous myxoid stroma is frequently seen and focally, various stages of follicular differentiation are identified. Mitotic figures are frequent, but abnormal mitoses are not seen.

Management. Excision is required, both to confirm the diagnosis and because of discomfort. Malignant change in these lesions has not been reported.

Trichoblastoma [1–4]

SYN. TRICHOGENIC FIBROMA; TRICHOBLASTIC FIBROMA

Definition. Tumours of the hair germ composed of follicular germinative cells.

Clinical features. These are deeply or superficially situated dermal nodules, found—as is common with follicular tumours—on the head and neck.

Pathology. Nests of basophilic basaloid cells with a lobular architecture and prominent induction of stroma are seen in the dermis and/or subcutaneous tissue. Focal evidence of follicular differentiation is seen, but this usually consists of less mature structures than those seen in trichoepithelioma. Mitotic figures are frequent. Usually, the tumour is not connected to the epidermis. According to the degree of follicular differentiation and the amount of stroma induced, lesions have been subclassified into different categories, including trichogenic fibroma and trichoblastic fibroma. However, all tumours in this category are best classified as trichoblastomas. Some tumours may display sebaceous and even ductal (apocrine) differentiation [5].

Management. Behaviour is benign, but complete excision is often desirable to exclude a basal cell carcinoma.

Cutaneous lymphadenoma [1–6]

Definition. This entity was first described in 1987 [1], and to date there are around 35 reported cases in the literature. Follicular, sebaceous and ductal differentiation has been demonstrated.

Clinical features. The lesions are seen mainly on the head and neck area, and present as non-specific papules or nodules. Both sexes are affected equally. The preoperative clinical diagnosis is frequently basal cell carcinoma or an intradermal naevus.

Pathology. The tumour consists of nests and lobules of basaloid cells in the reticular dermis, with no connection to the epidermis. These aggregates of cells are embedded in a fibrous stroma. Tumour cells are bland and display focal peripheral palisading. A striking feature is the presence of prominent infiltration of tumour lobules and nests by T lymphocytes and histiocytes (Fig. 37.5). These inflammatory cells are mainly located in the centre of the tumour lobules. No cellular atypia is seen, and mitotic figures are rare. Focal areas of keratinization are seen in some cases.

Individual lymphadenomas show varying differentiation towards sebaceous, eccrine and pilar structures, and there is therefore continuing debate as to their exact ontogeny [2–6]. It has been suggested that cutaneous lymphadenoma represents a variant of trichoblastoma [4].

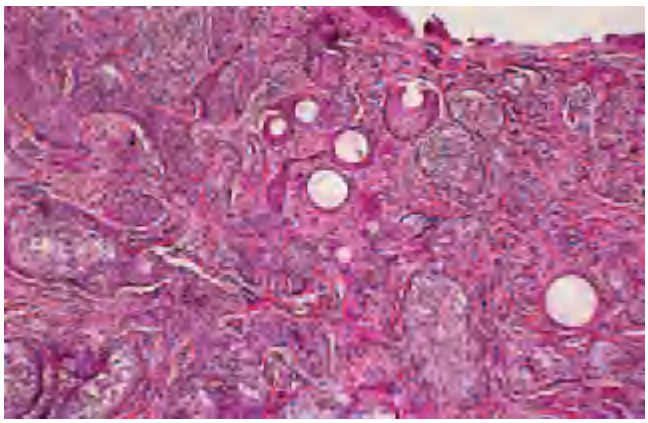

Fig. 37.5 Lymphadenoma. Nests and lobules of epithelial cells with prominent infiltration by lymphocytes.

Treatment. Local excision is recommended. The behaviour is entirely benign.

Basaloid follicular hamartoma [1–4]

Definition. A hamartoma consisting of a proliferation of basaloid cells, with frequent involvement of hair follicles.

Clinical features. These lesions are usually small multiple facial papules. They may be present in isolation or inherited as an autosomal-dominant trait [4].

Pathology. A multifocal proliferation of cords, strands and nests of basaloid cells is seen, with frequent connections to the epidermis. Basaloid cells focally replace neighbouring hair follicles. In addition, immature follicular bulbs may also be seen.

Hair matrix tumours

Pilomatricoma [1–4]

SYN. BENIGN CALCIFYING EPITHELIOMA OF MALHERBE; TRICHOMATRICOMA; PILOMATRIXOMA

Definition. A benign tumour considered to be a hamartoma of the hair matrix composed of cells resembling those of the hair matrix, hair cortex and inner root sheath. The cells usually undergo 'mummification'.

Fig. 37.6 Pilomatricoma. Small red firm papule.

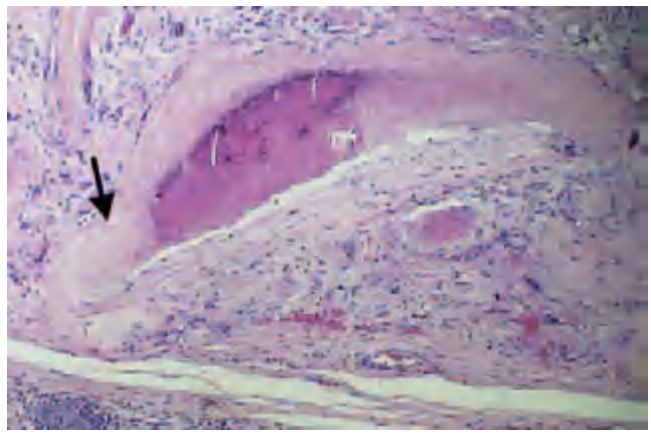

Fig. 37.7 Pilomatricoma. Lobules of basaloid cells intermixed with pale pink areas containing ghost cells.

Incidence. This lesion makes up around 20% of all hair follicle-related tumours in most series and is therefore the commonest hair-follicle tumour. It may occur at any age from infancy and is frequently seen in children [5]. The majority of patients are under 20 years of age, and females are affected more often than males. A number of familial cases are recorded, and an association with myotonic dystrophy has been reported [6].

Clinical features [7–13]. The lesion is usually a solitary, deep, dermal or subcutaneous tumour 3–30 mm in diameter situated in the head, neck or upper extremity (Fig. 37.6). Very large tumours are occasionally seen. The skin over the tumour is normal and the lesion has a firm to stone-hard consistency and a lobular shape on palpation. In adult life, there may be quite a short history [4] and there is usually no evidence of a preceding cyst. It may be subject to periodic inflammation and can present as a granulomatous swelling. Rare ulcerated lesions may show transepithelial elimination [14]. Malignant change has been reported (see below).

Pathology [15–22]. The tumour is situated in the dermis, and is composed of well-circumscribed, rounded islands giving a lobulated contour. The outer cells are small, and their rounded nuclei crowded together make this region deeply basophilic. Normal mitotic figures can usually be seen and are often numerous. The cytoplasm is scanty and the cell margins indistinct, but intercellular connections can be seen. Towards the centre of the mass, the cytoplasm becomes more abundant and eosinophilic. The nuclear outline persists, but the chromatin is sparse and clumped in dark granules; then, all the basophilic material disappears, leaving a mummified 'ghost cell' (Fig. 37.7). The ultrastructure and histochemical characteristics of these cells mark them as hair-matrix cells maturing towards cortex or root sheath [3,21,22]. The central areas often calcify, and calcium can be demonstrated in the basophilic areas of the tumour. In older lesions, the basophilic cells may be much reduced, or disappear entirely. Melanin may be present, and dendritic melanocytes have been found between the tumour cells. The stroma that encapsulates the masses usually contains inflammatory and foreign-body giant cells, and occasionally ossifies.

Recent studies have shown that 75% of pilomatricomas show activating mutations of the β-catenin gene [23–25]. The sites of β-catenin expression within pilomatricomas suggest that this may affect cell–cell adhesion [26].

Diagnosis. The diagnosis can be suspected if a subcutaneous nodule feels hard and lobular. The presence of calcium salts may be apparent on radiographs, but these can also be deposited in other cysts and tumours of the skin. The microscopic picture is, however, diagnostic.

Malignant change is recorded in several cases, and appears to arise chiefly in large pilomatricomas that have been present for many years (see below).

Management. Local excision is required for benign lesions, as there is a tendency for local recurrence. Wider excision will be needed if malignancy is suspected.

Pilomatricarcinoma [1–4]

Definition. The malignant counterpart of the pilomatricoma, possessing metastatic potential.

Clinical features. A rapidly expanding firm nodule. Around 70 cases are reported in the literature, and the average age of the patients is around 70 years. Males are more often affected than females.

Pathology. Many pilomatricarcinomas appear to arise on long-standing benign pilomatricomas. Definition of malignancy is usually very difficult on histological grounds. Malignant tumours usually have a very large predominant basaloid component, an infiltrative growth pattern and extensive tumour necrosis. In addition, there are numerous abnormal mitotic figures, and both lymphatic and vascular invasion may be seen. There can be metastases to distant organs such as the lungs, bone and lymph nodes [5–8]. At least two cases have proved fatal.

Management. Wide local excision is usually curative, but follow-up is required because of the possibility of metastatic spread.

Lesions of the hair-follicle mesenchyme

Trichodiscoma [1]

Definition. This lesion is a hamartomatous proliferation of the mesodermal component of the *Haarscheibe* described by Pinkus [1]. The *Haarscheibe* is considered to be a slowly reacting mechanoreceptor associated with the hair follicle.

Clinical features. The clinical appearance of the trichodiscoma is that of multiple, discrete, flat-topped papules 2–3 mm in diameter. They occur mainly in the central area of the face. Familial cases are recorded [2,3]. Multiple trichodiscomas, trichofolliculomas and acrochordon-like lesions have been described as part of the Birt–Hogg–Dubé syndrome [4]. Interestingly, the acrochordon-like lesions display the histological features of either trichodiscomas or trichofolliculomas [5].

Pathology. A discrete but non-encapsulated area of myxoid, poorly cellular stroma with focal collagen deposition is seen in the dermis, associated with a proliferation of blood vessels, some of which are thick-walled. Pilosebaceous units are often seen on both sides of the myxoid stroma. Trichodiscomas and trichofolliculomas usually show histological overlap.

Perifollicular fibroma [1,2]

The clinical appearance of these lesions has not been well described. The pathology is that of a striking fibrous proliferation around a relatively normal pilosebaceous apparatus.

Fibrofolliculoma

Definition. Rare lesions of perifollicular connective tissue [1].

Clinical features. These lesions usually first appear in middle age and tend to affect the upper part of the body. Multiple lesions are seen in the Birt–Hogg–Dubé syndrome, which is an autosomal-dominant condition recently mapped to chromosome 17p11.2 [2–5]. In this syndrome, fibrofolliculomas are seen in association with trichodiscomas, acrochordon-like lesions, renal tumours most commonly chromophobe carcinoma and spontaneous pneumothorax [6,7]. Colonic neoplasms do not seem to be increased in this syndrome, as previously suggested [6].

Pathology. Histology shows multiple, small, poorly formed pilosebaceous follicles set in a very striking fibrous stroma. There is also an obvious proliferation of the outer root sheath similar to that seen in the perifollicular fibroma.

Sebaceous gland tumours [1]

The following tumours or tumour-like conditions of sebaceous glands are considered elsewhere in the book:

1 Naevus sebaceus (Chapter 15);
2 Senile sebaceous hyperplasia (Chapter 43);
3 'Sebaceous' cyst (Chapter 36);
4 Steatocystoma multiplex (Chapter 36).

The two main conditions discussed in this section are sebaceous adenomas and sebaceomas, and sebaceous carcinoma. The old term 'sebaceous epithelioma' is no longer used, as it causes confusion with the exceptionally rare basal cell carcinoma with sebaceous differentiation.

Sebaceous adenomas and sebaceomas [1–4]

Definition. Benign tumours composed of incompletely differentiated sebaceous cells of varying degrees of maturity. Sebaceous adenoma and sebaceoma are described together, as they do not have distinctive clinical features, and although histological separation is possible in most cases, there is also some degree of overlap.

Incidence and aetiology. These are fairly rare tumours [4]. The solitary type may occur in either sex, and most cases have been in elderly patients. They may be associated with a cutaneous horn [5]. There is no evidence that actinic radiation or other recognized carcinogens are to blame.

Patients with multiple benign sebaceous tumours (other than sebaceous hyperplasia) should be suspected of having the Muir–Torre syndrome, associated with multiple visceral malignancies [6–17]. The latter include gastrointestinal malignancies, especially colonic and, more rarely, renal neoplasms. The internal malignancies tend to be fairly low grade, and often patients develop them earlier in life than the equivalent neoplasm in the general population. The sebaceous neoplasms tend to develop later in life. Patients with Muir–Torre syndrome may also develop sebaceous keratoacanthomas, and the diagnosis of one of these tumours should raise the possibility of the syndrome. Microsatellite instability has been reported in the Muir–Torre syndrome [18,19], and it has been proposed that loss of MLH1 or MSH2 proteins in the skin lesions may be a marker of patients who carry the syndrome and are therefore at risk of systemic malignancy [20,21]. The loss of expression of MLH1 and MSH2 may be demonstrated by immunohistochemical methods [20].

Clinical features. The tumour is rounded, raised and may be either sessile or somewhat pedunculated (Fig. 37.8). It is usually less than 10 mm in diameter, but older lesions may form plaques or ulcerate. Occasional tumours are more deeply located and appear cystic. The colour may be fleshy or of a waxy, yellowish hue, and the surface may be verrucose. The common situation is the face or scalp, and it may occur on the eyelid. It usually grows slowly, but a sudden increase in growth rate can occur.

Fig. 37.8 Sebaceous adenoma. Small yellowish papule.

Diagnosis. A yellow-tinged facial nodule may be suggestive, but clinical differentiation from other epithelial tumours, especially basal cell carcinoma, may be impossible. The microscopic diagnosis is more certain when fat can be demonstrated, but sebaceous differentiation can usually be distinguished in ordinary sections.

Pathology [3,5,14,22]. The tumours are multilobular and usually connected to the epidermis. The lobules are well-defined, and are composed of variable numbers of small, basophilic, sebaceous matrix cells peripherally and larger cells—mature sebaceous cells—containing cytoplasmic fat globules. The proportion of immature, transitional and mature sebaceous cells may vary widely from one area to another. In sebaceous adenoma, mature sebaceous cells predominate towards the centre of the lobules, whilst in sebaceoma, immature basaloid sebaceous cells predominate, occupying large areas of the lobules. In both tumours, there may also be cystic spaces lined by a thin layer of eosinophilic material similar to the intraglandular sebaceous ducts. The outline of the tumour is less regular than the normal sebaceous glands, and may be frankly irregular. However, some sebaceous adenomas closely mimic the normal sebaceous gland, except for an increase in the number of immature sebaceous cells. Mitotic figures are frequent in the immature sebaceous cells, and this feature should not be regarded as evidence of malignancy. Larger and deeper tumours with cystic degeneration usually represent sebaceomas, but adenomas may also be seen. Some of these tumours have atypical histological features [23]. The cystic space contains abundant holocrine (sebaceous) material. It has been suggested that these cystic sebaceous tumours are a marker for the mismatch, repair-deficient subtype of Muir–Torre syndrome, which has a high risk of internal malignancies [23].

Treatment. The best treatment is surgical excision.

Superficial epithelioma with sebaceous differentiation [1–4]

This is a rare tumour that has no distinctive clinical features and presents as a solitary papule on the face or trunk of adults. Occasionally, lesions are multiple. Histological features consist of a multifocal plate-like proliferation of basaloid cells with focal sebaceous differentiation and connections to the epidermis.

Sebaceous carcinoma [1–3]

Definition. A malignant tumour composed of cells showing differentiation toward sebaceous epithelium.

Incidence. The variable incidence reported for this tumour reflects the differing diagnostic criteria of different workers. It is, however, rare, comprising less than 1% of all skin malignancies. The tumour has been reported following radiodermatitis, and in a patient with multiple arsenical skin cancers. It is likely that a number of sebaceomas with high mitotic activity have been reported in the past as sebaceous carcinomas.

Clinical features [4–12]. The tumour is solitary, firm, sometimes translucent and covered with normal or slightly verrucose epidermis. The colour may be yellow or orange. The face and scalp [13] are the commonest sites, especially the eyelid (Fig. 37.9). The evolution may be very slow, and a size of 5 cm or more may be reached after many years without metastasis. Some tumours grow rapidly and invade early, but metastasis is uncommon [14,15]. In the absence of the yellow colour there is no feature to indicate the diagnosis clinically. Sebaceous carcinomas may occur in immunosuppressed organ-transplant patients, and these tumours are associated with microsatellite instability [16]. Sebaceous carcinoma may be associated with the Muir–Torre syndrome [17].

Fig. 37.9 Sebaceous carcinoma. Ulcerated yellowish lesion of the eyelid.

Pathology. The same problem of terminology exists with sebaceous carcinoma as with the adenomas. Basal cell carcinoma with sebaceous differentiation is not included in the description of sebaceous carcinoma. It is uncommon for the lesion to be aggressively invasive on the skin, although it frequently is when situated on the eyelid [4–8]. There are however, individual case reports of aggressive lesions on the axillary skin [18].

The essential feature is cytological evidence of sebaceous differentiation. The proportion of cells showing fat globules and the degree of cytoplasmic vacuolation are variable. The undifferentiated cells are of moderate size, with round, centrally placed nuclei and rather basophilic cytoplasm, and they tend to group themselves in masses of a multilobular configuration. The differentiating cells tend to be more central. There are, in addition, cytological features of malignancy and evidence of an infiltrative growth pattern. Mitotic figures including atypical forms are frequent. Pagetoid infiltration of the epidermis is frequent, particularly in tumours arising in the eye [4].

Treatment. Complete surgical excision is required [9]. Reports of excellent results with Mohs surgery suggest that this may be the treatment of choice [19].

Apocrine gland tumours [1]

Apocrine hidrocystoma [2]

SYN. APOCRINE CYSTADENOMA

Definition. A lesion produced by cystic dilatation of apocrine secretory glands.

Incidence. The lesion is not uncommon, but is most often seen in ophthalmological or surgical clinics. It occurs in adult life, in no particular age group. Males and females are equally affected.

Clinical features [3–6]. The lesions are solitary or occasionally multiple well-defined, dome-shaped, translucent nodules [7]. The surface is smooth and the colour varies from a skin colour to greyish or blue-black. The pigmentation may affect only part of the cyst. The commonest site is around the eye, particularly lateral to the outer canthus (Fig. 37.10). It has also been reported on the penis [1]. There are no symptoms. The cyst increases slowly in size, and may become 10 mm or more in diameter.

Pathology [8–10]. Large cystic cavities are found in the dermis if the lesion has been dissected out carefully. Commonly, the cyst is punctured and has collapsed before fixation. The cavities are lined by cuboidal or high-columnar apocrine secretory cells with decapitation secretion and a peripheral layer of myoepithelial cells (Fig. 37.11). Papillary projections or solid buds of secretory cells may break the smooth contour of the cyst lining. The secretory cells may contain pigment [5,6], which is neither melanin nor haemosiderin. The secretions in the cysts may be coagulated and stained using the PAS technique. There is a well-organized fibrous stroma. Electron microscopy confirms the apocrine nature of the secretory epithelium [11].

Fig. 37.10 Apocrine hydrocystoma. Cystic translucent papule on the right inner canthus.

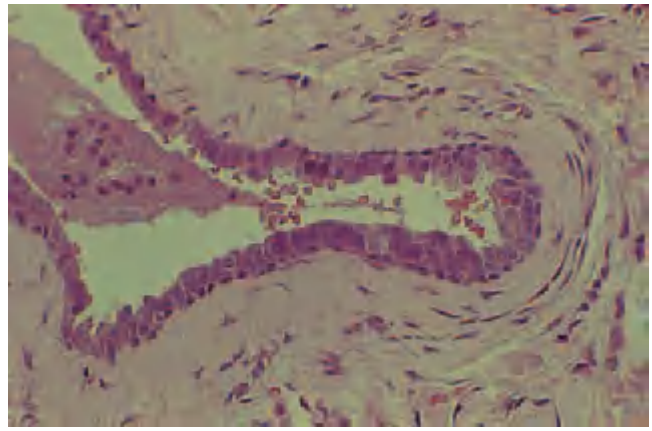

Fig. 37.11 Apocrine hydrocystoma. Cystic cavity lined by cuboidal cells with pink cytoplasm and decapitation secretion.

Diagnosis. Basal cell carcinoma is usually of a firmer consistency, less regular in its surface contour, and has surface telangiectases. The cystic nature of the lesion, which can often be shown by transillumination, separates it from blue naevi and malignant melanoma when pigment is present.

Treatment. The tumour is cured by surgical removal, which is commonly also needed for diagnosis.

Syringocystadenoma papilliferum [1,2]

Definition. An exuberant proliferating lesion, commonly seen on the scalp in association with an organoid naevus, and showing differentiation in an apocrine pattern [3].

Fig. 37.12 Syringocystadenoma papilliferum. Papular lesion with superficial erosion.

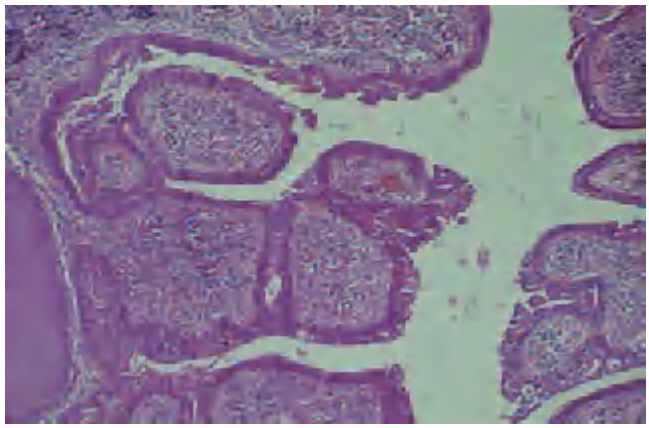

Fig. 37.13 Syringocystadenoma papilliferum. Papillary projections with a fibrovascular stroma.

Clinical features [4]. These lesions may be present at birth, but the majority are seen on the face and scalp of young adults. There is frequently a history of papillomatous expansion of a small pre-existing lesion at or around puberty. There may be a pre-existing organoid naevus. The lesion is composed of multiple papules, some of which are translucent and pigmented (Fig. 37.12).

Pathology [5–8]. The epidermal surface shows papillomatous expansion, and from these areas cystic invaginations are seen. The cystic structures are lined by papillae that have a lining of a double layer of columnar epithelium, which shows an apocrine pattern of secretion (Fig. 37.13) [9,10]. The underlying stroma is rich in plasma cells [11]. Occasionally, basal cell carcinoma or a squamous cell carcinoma develops on a pre-existing syringocystadenoma papilliferum. Development of an apocrine carcinoma is exceptional. Recent molecular biological studies have identified loss of heterozygosity at chromosome 9q22, the locus of the patched gene [12].

Management. Surgical excision is recommended, both to confirm the diagnosis and for cosmetic reasons.

Hidradenoma papilliferum

Definition. A skin tumour of the anogenital area of adult females, composed of frond-like papillae lined by apocrine epithelium.

Incidence. This is an uncommon tumour, which occurs predominantly in women. In one large series, the subjects were exclusively white, and 75% were between the ages of 25 and 40 years. It occurs four times as commonly on the vulva as in the perianal area [1].

Clinical features [2,3]. The patients usually seek advice for a lump in the vulval or perianal area, which may be symptomless or, less frequently, may be tender or liable to bleed. The tumour is rounded, freely mobile, often elevated and may feel firm, soft or even cystic. It may range in size from 1 to 40 mm. The commonest site is the labium majus, but it may occur elsewhere on the vulva or perianal area and, exceptionally, in other sites such as the eyelid [3].

Occasionally, the epithelial surface will ulcerate and the tumour becomes everted to form a reddish-brown papillary mass, which may be suspected of being malignant [1]. Malignant transformation, however, has not been reported.

Pathology. The tumour is well-circumscribed and located just below the skin surface. It is usually spherical in shape

and enclosed by compressed connective tissue stroma. The tumour is composed partly of slender fronds of connective tissue lined by one or two layers of epithelial cells, and partly of glandular structures. The epithelial cells have histochemical characteristics in keeping with an apocrine origin [4,5]. The lesion may receive a pathological diagnosis of adenocarcinoma, but follow-up studies indicate that it is benign.

Diagnosis. The tumour is usually mistaken for a cyst, polyp, angioma or haemorrhoid. A prolonged history and a firm, spherical form make the last three diagnoses unlikely.

Treatment. Simple excision is curative.

Apocrine tubular adenoma [1–3]

Definition. A rare tumour usually arising on the scalp.

Clinical features. These are usually large, slowly expanding lesions on the scalp. The lesion often arises in association with a naevus sebaceus.

Pathology. Clusters of tubular structures are seen in the dermis, with a lining of cells showing decapitation secretion. There is no surrounding inflammatory response. Cytological atypia and an infiltrative margin are absent. As with many adnexal tumours, often one finds histological overlap between tubular apocrine adenoma and papillary eccrine adenoma [3,4].

Apocrine carcinoma [1–3]

Definition. A malignant adnexal carcinoma showing clear evidence of apocrine differentiation—large cells with abundant pink cytoplasm and decapitation secretion.

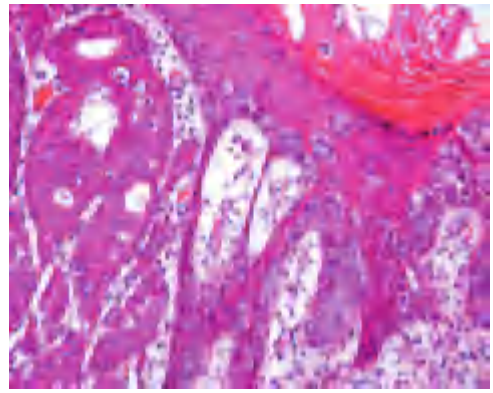

Fig. 37.14 Apocrine carcinoma. Prominent glands with decapitation secretion. Note the epidermotropism.

Clinical features. This is a rare entity. Lesions have been reported mainly from the head and neck area, including the eyelid and external ear, anogenital skin and also the axilla [4]. It is not possible on morphological grounds or with the help of immunohistochemistry to separate a cutaneous axillary apocrine carcinoma from an apocrine breast carcinoma spreading or invading the skin by direct extension. It is therefore important always to rule out a primary breast tumour. Some tumours arise within a naevus sebaceus [5]. The tumour presents as a nodule, usually measuring more than 1 cm in diameter. Rare cases may be bilateral [6]. There is a predilection for females, and patients are middle-aged or elderly. Metastatic spread to regional lymph nodes and internal organs occurs in up to a third of the cases [7].

Pathology. Three histological patterns may be seen: tubular, tubulopapillary and solid (Fig. 37.14). The degree of differentiation varies, and the diagnosis is often difficult in poorly differentiated tumours. Mitotic figures, local invasion and nuclear pleomorphism all suggest a malignant lesion. The most specific pathological feature is the presence of decapitation secretion [1]. Some cases are associated with prominent pagetoid spread, particularly those presenting on genital skin [8]. Tumour cells are positive for gross cystic disease fluid protein-15 (GCDFP-15) [9], and they show variable positivity for oestrogen and progesterone receptors.

Treatment. Wide excision and close follow-up are required.

Eccrine gland tumours [1]

Eccrine gland-derived lesions make up a large and relatively common group of appendage tumours. Hidroacanthoma simplex, dermal duct tumour and eccrine poromas form a fairly homogeneous family derived from eccrine duct and pore. Eccrine syringofibradenoma probably also belongs in this subsection. Eccrine hidradenoma, although closely related, has features suggesting both secretory and ductal differentiation, which makes the term 'acrospiroma' misleading, and this is perhaps best kept in a separate category.

Malignant tumours of sweat glands are relatively rare, but important to recognize. Their morphology and behaviour are variable.

Eccrine hidrocystoma [1–7]

Definition. A tumour produced by mature, deformed eccrine sweat units, whose secretions dilate the ducts. Lesions are usually situated on the face and are often multiple.

Incidence and aetiology. This is a rare tumour that occurs mainly in middle-aged women. It was formerly reported as being more common in those who had to work exposed to heat, such as cooks. A report indicating that the lesion is usually solitary and situated close to the eyelid underlines the problem of differentiating eccrine from apocrine hidrocystomas [1].

Clinical features [1,7]. The lesions are largely confined to the cheeks and eyelids. They may seem to be cystic on examination, and there is frequently a history of enlargement when the skin is exposed to heat. The lesions may be multiple and pigmented [8].

Pathology [2–4]. The general features are similar to those of syringoma, but secretory cells are usually found and the stroma tends to be inflammatory, rather than fibrosing. The histochemical reactions are eccrine in pattern [5,6].

Treatment. Diathermy or excision produce satisfactory results.

Hidroacanthoma simplex [1–3]

Definition. An intraepidermal tumour derived from the eccrine duct epithelium, which could be considered an intradermal eccrine poroma.

Clinical features. Hidroacanthoma simplex is a verrucous plaque or ring with a hyperkeratotic, usually brown surface. It often mimics a flat seborrhoeic keratosis. Ulceration or elevation of the lesion suggests a dermal component. From the few reports available, it appears that the limbs are more likely to be involved than the trunk or head.

Pathology. Nests of clearly discrete, small, rounded cells are seen within the normal epidermal cells. They are smaller and more cuboidal than surrounding keratinocytes and are rich in glycogen and the glycolytic enzymes. These lesions may be confused with intraepidermal or clonal seborrhoeic keratoses, demonstrating what has in the past been called the 'Borst–Jadassohn phenomenon' [4]. The individual cells in these lesions are larger and less rich in glycogen. However, for the diagnosis to be made, ductal differentiation should be demonstrated.

Management. Excision is recommended both to confirm the diagnosis and for management. Malignant change has been reported in hidroacanthoma simplex [5–7]. If this is suspected, wider excision and a period of follow-up is advisable.

Eccrine poroma [1,2]

Definition. A tumour arising from the eccrine duct epithelium in the region of the dermo-epidermal junction.

Clinical features [1–10]. This lesion is one of the easiest of the appendage tumours to recognize in the clinic. The great majority of these lesions are found on the palms and soles (Fig. 37.15), in contrast to other skin-appendage tumours, which tend to be concentrated around the head and neck area. They are moist, exophytic lesions, pink or red in colour, and may reach 1–2 cm in diameter.

Pathology [11–14]. These lesions are relatively easy to diagnose, with a clear margin between adjacent, normal epidermal keratinocytes and a population of smaller cuboidal cells, usually with darker nuclei protruding down into the underlying dermis (Fig. 37.16). The cells are strongly PAS-positive and are similar to those seen in the dermal duct tumour [15]. Recent reports, however, have stressed the fact that some poromas may show either sebaceous or apocrine differentiation [16,17]—highlighting the fact that adnexal tumours with ductal differentiation may be either eccrine or apocrine, as the ducts of both structures are identical.

Malignant change has been recorded on many occasions and may be subtle (see below). Any degree of cytological atypia should alert the pathologist to this possibility.

Management. Benign eccrine poromas are treated by surgical excision.

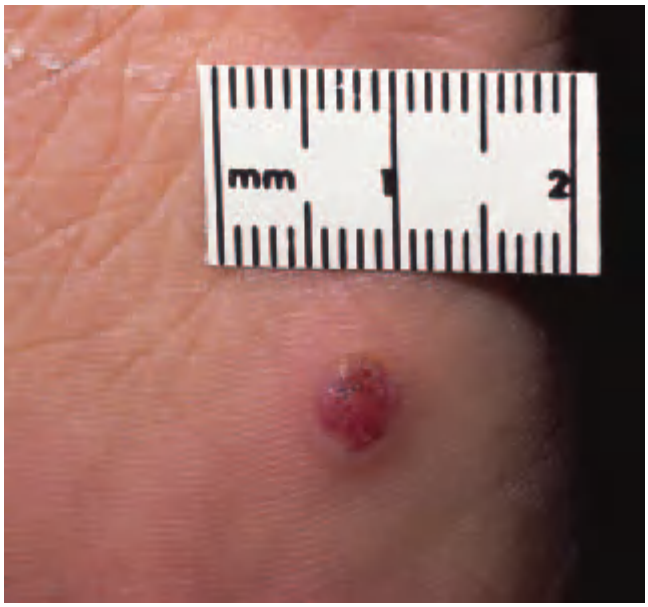

Fig. 37.15 Poroma. Note the red, shiny surface, which often leads to misdiagnosis of a pyogenic granuloma.

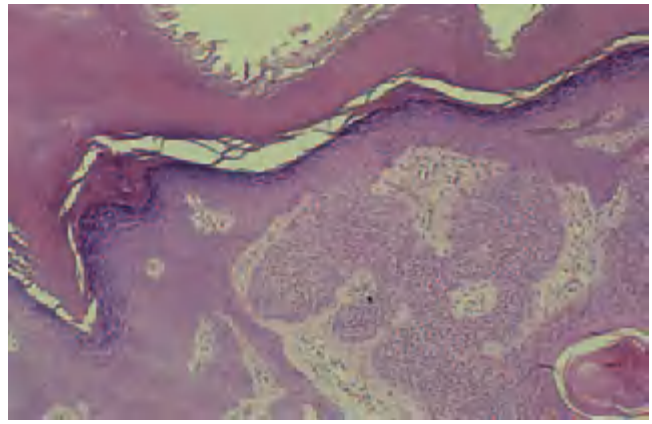

Fig. 37.16 Poroma. Note the clear demarcation between the tumour and the neighbouring epidermis.

Eccrine dermal duct tumour [1,2]

Definition. A benign proliferation of the eccrine dermal duct situated in the papillary dermis.

Clinical features. The clinical picture is that of a dermal nodule, occasionally with verrucous change overlying it.

Pathology. The pathology is similar to that of the hidroacanthoma simplex, but the nests of tumour cells making up the lesion are located in the dermis. The cells are small, cuboidal, regular and stain strongly with PAS. An intraepidermal component may be seen, confirming that this lesion is part of the spectrum of eccrine poroma.

Management. Excision is required for diagnostic and therapeutic purposes.

Eccrine syringofibroadenoma [1]

Clinical features. This is a rare entity, and may present as a solitary nodule on the arms or legs.

Pathology. A network of epithelial cells extends down from the epidermis, forming a mesh-like structure in the underlying epidermis. These cords are composed of smaller cells than in the overlying epidermis, and may contain ductal structures. This mesh is surrounded by a fibrovascular stroma. Unlike basal cell carcinoma, there is no palisading [2,3]. Often, syringofibroadenomatous hyperplasia of sweat ducts is seen in the background of other tumours, a healing ulcer, stasis, or a reparative process after a bullous disease [4–6]. In small biopsies, this type of hyperplasia may be confused with a syringofibroadenoma.

Fig. 37.17 Multiple syringomas on upper cheek area.

Syringoma [1–3]

SYN. HIDRADENOMES ERUPTIFS; SYRINGOCYSTADENOMA; SYRINGOCYSTOMA

Definition. A benign skin tumour that is usually multiple. The histology is characteristic.

Incidence. It is an uncommon tumour, and is more common in females than males. It is most likely to appear at adolescence, and further lesions may develop during adult life. It does not appear to be hereditary.

Clinical features [4–11]. The individual small dermal papules [12] are skin-coloured, yellowish or mauve, but sometimes appear translucent and cystic. The surface may be rounded or flat-topped and the outline sometimes angular. Rarely, injury to the surface will allow a drop of clear, watery fluid to escape. They vary in size from 1 to 5 mm, but most are less than 3 mm. In most cases, there are multiple tumours, and they tend to have a bilateral symmetry in distribution. The front of the chest, face and neck are the chief areas affected. A few lesions are usually found on the eyelids when the cheeks are involved (Fig. 37.17). The lesions are present more often than expected in patients with Down's syndrome [13] and may erupt dramatically (Fig. 37.18) [14].

Pathology [15–17]. The lesion has a characteristic architectural pattern on light-microscope scanning power. Collections of convoluted and cystic ducts are seen in the upper half of the dermis. Most are lined by a double layer of cells similar to, but flatter than, those that line normal eccrine ducts. The lumina contain amorphous debris. A characteristic feature is the tail-like strand of cells projecting from one side of the duct into the stroma, giving a resemblance to a tadpole or comma (Fig. 37.19). The ducts may be enclosed in a fibrous stroma similar to the

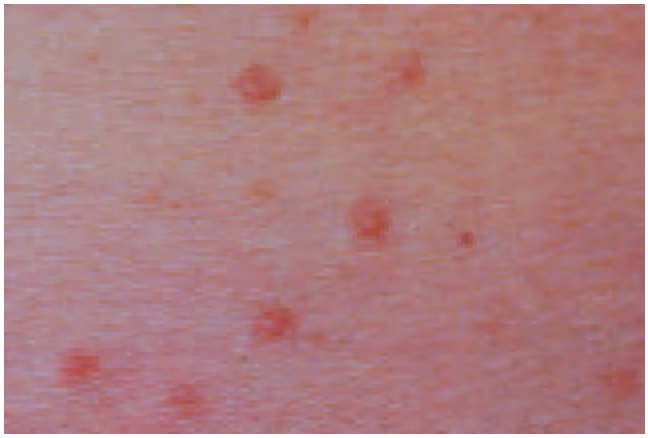

Fig. 37.18 Eruptive syringomas. Multiple tiny brownish or red lesions are often seen on trunk and limbs.

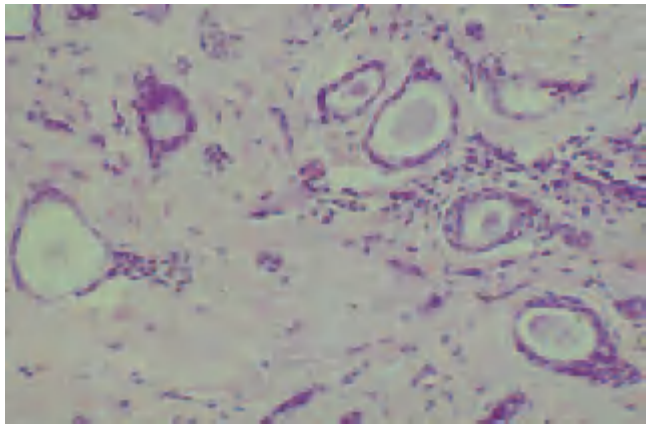

Fig. 37.19 Syringoma. Typical ductal structures with a tadpole appearance.

hair-follicle hamartomas, but in most cases it is narrower and less cellular. When the stroma is dense, it may be difficult to differentiate from the morphoeic basal cell carcinoma, in which, however, well-developed duct structures are not associated with cellular strands.

Diagnosis. Syringoma is most likely to be confused with trichoepithelioma on the face. The syringomas tend to be smaller, rather less superficial, more flat-topped and disposed more evenly over the cheeks and eyelids, rather than favouring the nasolabial creases. There is no family history. Lesions on the lids may be mistaken for xanthelasma, but lack the orange colour. Those erupting on the trunk may be mistaken for disseminated granuloma annulare.

Treatment. The main reason for treatment is cosmetic. Careful destruction with diathermy can produce good cosmetic results.

Papillary eccrine adenoma

Definition. A solitary nodule, usually on the limbs of darker-skinned individuals.

Clinical features. This rare lesion was first described in 1977 [1]. It presents in a non-diagnostic manner as a slowly growing nodule on the limbs.

Pathology. The lesion is in the papillary dermis and consists of ductal structures which may resemble either eccrine or apocrine tissue. Dilated ducts form a complex honeycomb-like structure.

Eccrine hidradenoma [1]

Definition. A relatively rare tumour of sweat gland origin.

Clinical features [2]. This is an uncommon tumour, found mainly in adults, and is excised more commonly in

Fig. 37.20 Hidradenoma. Red/brown irregular papule.

women than in men. The tumours are firm dermal nodules 5–30 mm in size, and may be attached to the overlying epidermis, which can be either thickened or ulcerated (Fig. 37.20). Growth is slow and there may be a history of serous discharge. The lesions are usually solitary and are most likely to be found on the scalp, face or anterior trunk.

Pathology [3–6]. The tumour may connect with the epidermis. It forms lobulated, circumscribed masses and is composed of two cell types—polygonal cells, whose glycogen content may give the cytoplasm a clear appearance; and elongated, darker and smaller cells, which may occur at the periphery. Often, tumours do not contain cells with clear cytoplasm, and the name 'clear cell hidradenoma' is therefore misleading. Cuboidal or columnar cells are seen lining duct-like spaces and clefts. The histochemical reactions [7] and fine structure [8] indicate an eccrine origin, with features of both secretory and duct cells. In cases with a connection to the epidermis, the superficial component displays poromatous features.

Malignant transformation is very rare, and the diagnosis relies on identification of the pre-existing benign component [9–12].

Diagnosis. When the tumour is attached to the epidermis, the diagnosis may be suspected on clinical grounds, especially if there is a history of discharge. Ulcerated lesions may resemble basal cell carcinoma. Dermal nodules are non-diagnostic by clinical inspection.

Treatment. Surgical excision will cure benign lesions. Local recurrences are rarely seen [13]. Malignant eccrine hidradenoma may metastasize.

Eccrine or apocrine/follicular tumours

In recent years, it has become apparent that a number of adnexal tumours that were regarded as exclusively showing eccrine ductal differentiation often display ductal apocrine differentiation. Because of the close relationship between the apocrine and the pilosebaceous unit, these tumours may also show evidence of focal follicular and even sebaceous differentiation [1,2]. The list of tumours with potential to display apocrine ductal differentiation continues to expand and even includes rare examples of poromas showing apocrine differentiation (see p. 37.19).

Cylindroma [1–5]

SYN. TURBAN TUMOUR; SPIEGLER'S TUMOUR

Definition. A skin tumour of uncertain origin with a characteristic histology (see below) that usually manifests as nodules or tumours of the scalp.

Incidence. This is an uncommon tumour, affecting females about twice as frequently as males. It is frequently familial and an autosomal-dominant gene determines its inheritance [6,7]. It has been reported to follow radiotherapy epilation of the scalp. The onset is usually in early adult life, but may be in childhood or adolescence.

Fig. 37.21 Cylindroma. Two large tumours on the head of an elderly woman.

Clinical features [8,9]. The tumours are frequently multiple, smooth, firm, pink to red in colour and often somewhat pedunculated (Fig. 37.21). The lesions may be familial, and a suppressor gene has recently been identified on chromosome 16q, loss of which appears to be associated with cylindroma development [10,11]. The rate of growth is slow and often seems to cease when a certain size has been reached. Some tumours become 50 mm or more in diameter, but most are smaller. Pain is an occasional symptom. The commonest site is the scalp and adjacent skin. Tumours on the scalp may be almost hairless when pedunculated, but the smaller lesions form dermal nodules with little loss of overlying hair. Multiple tumours have attracted much attention in the literature, but solitary lesions are not uncommonly seen by surgical pathology services. A proportion of lesions occur on the face and neck away from the scalp margin; in fewer than 10% of cases, are they situated on the trunk and limbs. When the lesions are multiple, new tumours arise over the years. In some patients, there may be an admixture with trichoepithelioma, either in separate tumours or sometimes in the same tumour. This is a clear indication that these tumours are likely to show ductal apocrine follicular differentiation rather than ductal eccrine differentiation.

Pathology [12–18]. The tumours have a rounded outline and are composed of closely set mosaic-like masses ('jigsaw-puzzle' appearance) and columns of cells that are

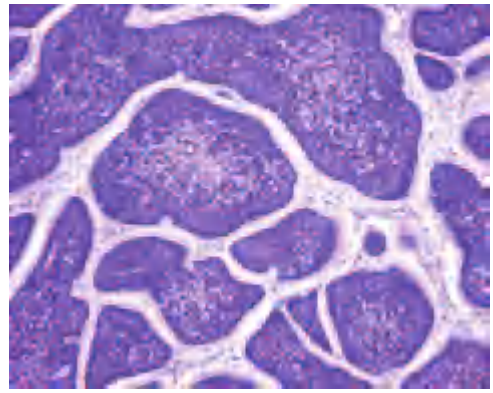

Fig. 37.22 Cylindroma. Classical jigsaw-puzzle architecture, with tumour lobules displaying a thick basal membrane.

invested by a hyaline basal membrane of variable thickness. Thin bands of stroma (Fig. 37.22) separate tumour lobules from one another. The cells are of two types—one large, with a moderate amount of cytoplasm and a vesicular nucleus; and the other small, with little cytoplasm and a compact nucleus. The small cells tend to be peripheral; they also surround duct-like spaces or masses of hyaline material within the tumour lobule. There are strong immunohistochemical similarities between cylindromas and spiradenomas, and they may coexist in the same individual [19,20].

Diagnosis. The multiple type on the scalp is most likely to be confused with tricholemmal cyst, which is, however, usually smoother, firmer and more mobile. Small tumours are difficult to diagnose, and must be distinguished from trichoepithelioma, steatocystoma, or basal cell carcinoma if solitary. Large, pedunculated and lobular tumours are almost unmistakable.

Treatment. Surgery is the treatment of choice. Extensive involvement of the scalp may require wide excision and replacement of the whole area by a graft.

Spiradenoma [1,2]

SYN. ECCRINE SPIRADENOMA

Definition. A benign tumour of sweat gland origin, which is usually solitary and is distinguished by its histology (see below).

Incidence. It is relatively uncommon, appears mainly in young adults, equally in both sexes and is rarely familial.

Clinical features [3,4]. The lesion is usually solitary and painful and consists of a firm, rounded, bluish, dermal nodule 3–50 mm in diameter [13]. The usual site is on the front of the trunk and proximal limbs.

Pathology [5,6]. The tumour is lobular, with two cell types in the islands (Fig. 37.23). Larger, paler cells may be grouped around lumina, and smaller, darker cells form the periphery. Small, tubular structures or cystic spaces may occur, and large, thin-walled, dilated vascular channels are also present [7,8]. The lobules are surrounded by condensed connective tissue, which may encroach on the islands as hyaline droplets. Degenerative changes in old tumours are often prominent. Necrosis and degeneration often obscure the histological features, and only focal areas display the typical features of a spiradenoma. Old tumours with degenerative changes tend to be very large. Malignant transformation may occur and usually presents in long-standing tumours [9–14]. The diagnosis of a malignant spiradenoma is often only made after a residual benign component is identified.

Diagnosis. Clinical differentiation from other dermal tumours and cysts may be made if the tumour is a firm, domed elevation of a dark-blue colour.

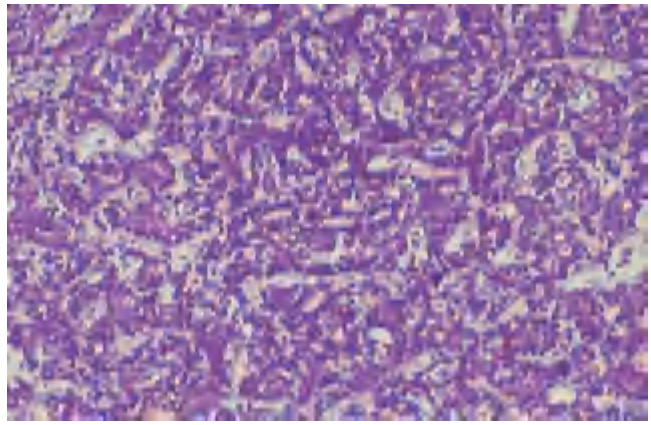

Fig. 37.23 Eccrine spiradenoma. Ductal structures and intermixed pale and dark cells.

Treatment. Surgical excision should be complete, as there may be recurrence.

Mixed tumour of the skin [1]

SYN. CHONDROID SYRINGOMA

Clinical features [1–4]. This tumour is usually found on the head and neck, followed by the trunk and the extremit-

ies, as a solitary nodule. The lesions are frequently large and nodular, sometimes with a diameter of 5–10 cm, and occur most commonly in middle-aged males. Local recurrence is rarely seen.

Pathology [5–11]. This is usually a fairly large, multilobulated tumour located in the dermis and/or subcutaneous tissue. Tumour lobules are separated by fibrous septa. A myxoid, hyalinized or chondroid stroma is variably seen in all tumours. The epithelial component consists of nests and strands of cells with pink cytoplasm and vesicular nuclei with a single, inconspicuous nucleolus. Cytological atypia is absent, and mitotic figures are sometimes seen. Tubular structures and ductal differentiation are frequently seen. Larger tumour cells with a plasmacytoid appearance are a frequent finding and suggest myoepithelial differentiation. Ductal structures usually have a peripheral layer of flattened myoepithelial cells. Immunohistochemical studies reveal positivity for keratin and focal positivity for S100 and smooth muscle actin, confirming myoepithelial differentiation. Areas more suggestive of apocrine and follicular differentiation are identified in some tumours [7,8,12,13]. These cellular areas are set in a dense stroma, and on low-power magnification a rather lace-like or trabeculated pattern may be present. The stroma stains positively with Alcian blue, indicating the presence of chondroitin sulphate and hyaluronic acid. Focal calcification, mature fat and bone formation may also be seen. Rare tumours composed exclusively of myoepithelial cells should be regarded as myoepithelioma.

Malignant chondroid syringomas have been reported [15–22], including a case with metastasis [23].

Management. Local excision is recommended. If there is any suspicion of malignancy, wide excision and follow-up are required.

Sweat gland carcinomas, including ductal apocrine/follicular carcinomas

These lesions can be divided into two broad groups. The first group represents the situation in which malignant change develops in a pre-existing, apparently benign lesion, such as hidradenoma, mixed tumour, spiradenoma, cylindroma and eccrine poroma. The latter is the most commonly recorded example of such malignant progression [1,2]. In most adnexal tumours, with the exception of malignant eccrine poroma, the diagnosis usually requires identification of a benign component. Even when there is unmistakable cytological evidence of malignancy, the biological behaviour of malignant tumours of skin appendages is generally relatively benign, with local recurrence being much more common than cutaneous metastases.

The second group of carcinomas consists of lesions that develop as carcinomas *ab initio*. The primary eccrine carcinomas include microcystic adnexal carcinoma, eccrine epithelioma (regarded by many as part of the spectrum of microcystic adnexal carcinoma), aggressive digital papillary adenocarcinoma, mucinous carcinoma and adenoid cystic carcinoma. Lymphoepithelioma-like carcinoma of the skin is also included in this group.

A recent review of 60 sweat gland carcinomas reported 41 porocarcinomas, three syringomatous carcinomas, eight ductal carcinomas, five adenoid cystic carcinomas and three mucinous carcinomas [1]. The rarity of sweat gland carcinomas makes it difficult to say whether or not this distribution is the norm, but porocarcinoma does appear to be a relatively common lesion.

Eccrine gland carcinomas

Malignant eccrine poroma [1,2]

SYN. POROCARCINOMA

Definition. A malignant tumour with metastatic potential arising from intraepidermal eccrine duct epithelium. In up to 18% of cases, tumours arise from a pre-existing benign eccrine poroma [3].

Clinical features [4–7]. These are relatively common malignancies (0.01–0.005% of all cutaneous tumours), arising most often on the lower limbs (44% of cases) in older patients, with an average age at presentation of 73 years. Females are more commonly affected than males. The lesion presents as an endo-exophytic tumour, which is often ulcerated. Tumours may attain a very large size and are frequently long standing. Local recurrence is seen in 17% of cases. Regional lymph-node metastases and systemic metastases occur in 19% and 11% of patients, respectively [3]. A small number of patients present with multiple lesions, and it is not clear whether this represents epidermotropic metastasis or true multifocality [1,3,8].

Pathology [3,9–11]. Tumours show multiple connections to the epidermis, and a pre-existing benign eccrine poroma may be present. *In-situ* lesions are seen occasionally [3,12]. The tumour infiltrates the dermis and the subcutaneous tissue in nests and lobules composed of relatively small cells that do not have a basaloid appearance. Peripheral palisading is absent. Ductal differentiation is necessary for the diagnosis to be made. This may be demonstrated by the use of immunohistochemical stains for carcinoembryonic antigen (CEA) and epithelial membrane antigen (EMA). A PAS stain may also be used, but this only highlights the ducts in very well-differentiated tumours forming ducts with a cuticle. Comedo necrosis is often present. Clear cell change and squamous differentiation may be seen, but do not tend to be prominent.

Poor prognostic factors are a large number of mitotic figures, lymphovascular invasion, tumour depth greater than 7 mm and an infiltrating rather than a pushing border [3].

Treatment. Wide excision and follow-up are required. Two recent series including a total of 93 cases suggest that these lesions may have less metastatic capacity than had been previously suggested [3,13]. Mohs micrographic surgery is useful in those cases with a prominent infiltrative growth pattern [14].

Malignant hidradenoma

SYN. HIDRADENOCARCINOMA; MALIGNANT ACROSPIROMA

Definition. A malignant tumour traditionally regarded as displaying eccrine differentiation and arising from a pre-existing hidradenoma.

Clinical features. These lesions are most often recorded as red, ulcerated nodules on the face hands or feet. They are commonest in older adults, but cases are recorded in children [1–4]. They may be very aggressive and pulmonary metastases have been recorded.

Pathology. Large clusters of glycogen-rich clear cells are present in some cases, but others may resemble basal cell carcinoma [5–9]. Focal necrosis may be present, and the range of mitoses is highly variable. Squamous differentiation may be prominent [10].

Treatment. Wide local excision is recommended. Mohs surgery has been used successfully for lesions on the foot [11]. Follow-up is essential, as the lesions may recur locally and/or metastasize.

Aggressive digital papillary adenocarcinoma

Definition. A rare tumour found on the hands and feet, with a high risk both of local recurrence and metastasis. Prior publications have described both a benign, aggressive digital papillary adenoma and a carcinoma [1,2], but the lack of pathologically diagnostic or prognostic differentiating features suggests that all lesions in this category should be treated as carcinomas.

Clinical features. Both sexes are affected and at any age. The lesion presents as a non-diagnostic asymptomatic nodule on the fingers, toes, palms or soles. Delayed diagnosis is frequent [1–4].

Pathology [1,2,5]. The lesions are obviously cystic on low-power examination, and have papillary projections into the cystic cavities, Ductal and tubuloalveolar structures are also present. There may be focal necrosis and both nuclear hyperchromatism and a high mitotic count. In some cases, a tubular architecture tends to predominate and papillary projections may not be so prominent. Histological features do not allow accurate prediction of behaviour, as tumours with low-grade histology may metastasize [2].

Tumours may invade surrounding soft tissues and blood vessels and can destroy bone.

Treatment. Wide local excision and follow-up are recommended in view of the high recurrence rate, both locally and via metastatic spread [1,2,6]. It has been suggested that sentinel lymph-node biopsy is appropriate for these lesions [6].

Eccrine or apocrine/follicular carcinomas

Malignant cylindroma [1–7]

Definition. A rare tumour, which develops from a pre-existing benign dermal cylindroma.

Clinical features. These unusual tumours develop as expanding nodules, usually on the scalp. They may be suspected by expansion of a previously static dermal cylindroma or turban tumour. They have been reported in familial cases of cylindromas [1,2].

Pathology. These lesions have the characteristic architecture of a dermal cylindroma, with deeply basophilic small cells surrounded by an eosinophilic basement membrane [3–6]. In addition, however, there is marked nuclear atypia, irregularity of cell size and an infiltrative growth pattern. Mitotic figures, both normal and abnormal, are present.

Treatment. Wide local excision and follow-up are required.

Malignant eccrine spiradenoma

SYN. SPIRADENOCARCINOMA

Definition. A rare tumour, which usually arises in a pre-existing spiradenoma.

Clinical features. Sudden expansion of a pre-existing nodule is the most likely presentation [1]. A recent study of

12 cases reports the commonest site as the trunk, with limbs and head and neck less frequently involved [2]. The sex distribution appears equal, and the likely age at presentation is in the seventh decade.

Pathology [2–4]. These lesions usually show evidence of origin from a pre-existing benign spiradenoma. Necrosis, a high mitotic count, loss of the dual cell population and an infiltrative growth pattern are features that raise the possibility of malignant transformation.

Treatment. Excision and follow-up are required. Up to 20% of these tumours have been reported to metastasize [2–5].

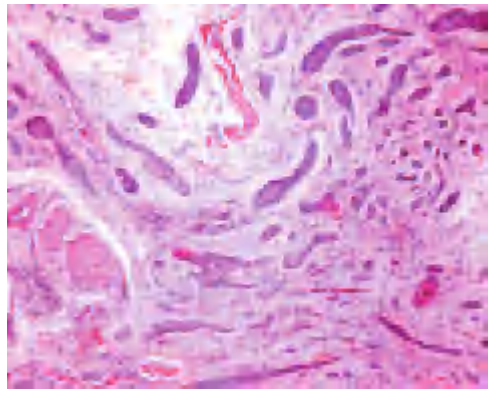

Fig. 37.24 Microcystic adnexal carcinoma. Strands and small nests of bland epithelial cells with an infiltrative growth pattern.

Microcystic adnexal carcinoma

SYN. SCLEROSING/SYRINGOMATOUS SWEAT DUCT CARCINOMA; MALIGNANT SYRINGOMA

Clinical features. This tumour is relatively rare, has an equal sex incidence and a predilection for the central area of the face, often as an inconspicuous, elevated or depressed sclerotic plaque or nodule in the upper lip area [1–4]. The trunk is also rarely involved. The age range is very wide, but young and middle-aged patients are more frequently affected. If the lesion is not promptly treated, or if local recurrence occurs, the lesions may present with pain or a burning sensation because of perineural spread. Cases have been reported both in patients with generalized immunosuppression and in sites of previous radiotherapy [5–7]. The rate of local recurrence is very high (up to 40%).

Pathology [8,9]. The salient histological features are the presence of cords of cytologically banal epithelial cells with focal, variable ductal differentiation set in a very sclerotic desmoplastic stroma [2–4]. Horn cysts are seen in many cases and pilar and sebaceous differentiation may also occur (Fig. 37.24) [8,9,11]. Superficial areas show a resemblance both to the syringoma and desmoplastic trichoepithelioma. The diagnosis can therefore be impossible if only a small, superficial biopsy is evaluated, as clues to the correct diagnosis reside in an infiltrative growth pattern and prominent perineural invasion. Cytogenetic analysis of a case of microcystic adnexal carcinoma has shown a deletion on chromosome 6q (23–25) [12].

Management. The importance of this tumour is that perineural permeation is common, and for this reason microscopically controlled surgical excision is recommended. Mohs surgery has been recommended as the surgical approach of choice.

Metastatic spread is very rare, but extensive local recurrence can be a major problem. Tumours may rarely extend into the brain as a result of perineural invasion.

Eccrine epithelioma [1–4]

SYN. BASAL CELL CARCINOMA WITH ECCRINE DIFFERENTIATION; SYRINGOID ECCRINE CARCINOMA

Freeman and Winkelmann, who considered it to be a basal cell tumour with eccrine differentiation [1,2], first described this rare tumour in 1969. However, the tumour does not represent a basal cell carcinoma with eccrine differentiation [3]. Some authors have proposed that it is part of the spectrum of microcystic adnexal carcinoma. At least 12 cases are currently reported in the world literature. The lesion has some resemblance to both benign syringoma and to dermal cylindroma.

Clinical features. Two-thirds of the cases so far reported have occurred on the scalp as large, non-specific, sometimes ulcerated nodules. They may be painful, due to their position in the deep dermis.

Pathology. The tumour consists of cords and clusters of small, dark-staining, cuboidal basophilic cells set in a very dense stroma. The cells are cytologically abnormal, with a high nuclear/cytoplasmic ratio, and mitotic figures are seen. These features occur in the lower part of the dermis, extending into the subcutaneous fat. The islets of cells have a surrounding PAS-positive membrane.

Management. Wide local excision is required. Follow-up is essential, as repeated local recurrences are common. In one case, metastasis to a local lymph node was recorded.

Mucinous carcinoma

Definition. A rare, adnexal, mucin-producing carcinoma arising on the head and neck area in more than 90% of the cases.

Clinical features. The most frequently described clinical presentation is that of a grey nodule on the face of an elderly male, often in the periorbital area [1–5]. Rare tumours are bilateral [6]. An important clinical differential diagnosis is from a cutaneous secondary deposit from a more common site for mucinous carcinoma such as the stomach and breast [7]. The distinction between a primary skin tumour and a metastasis cannot be made on the basis of the histological and immunohistochemical findings and has to rely on clinicopathological correlation and additional studies to rule out an internal primary. In the case of a suspected metastatic mucinous breast carcinoma, staining for oestrogen and progesterone receptors is not useful, as primary cutaneous mucinous carcinomas are often positive for these markers [8].

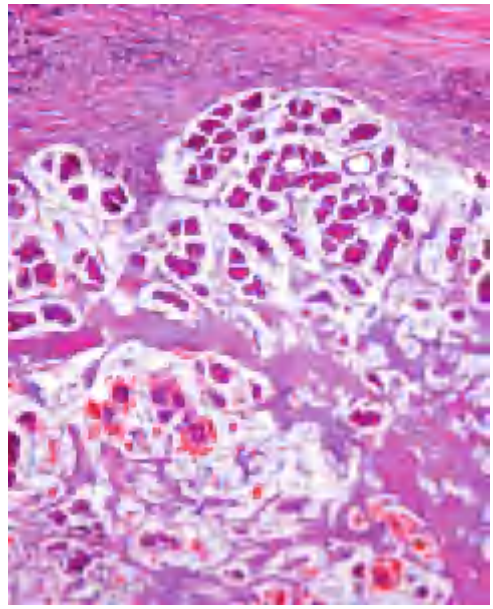

Fig. 37.25 Mucinous carcinoma. Nests of tumour cells surrounded by pools of mucin.

Pathology. These lesions are relatively deeply situated and consist of clusters of cells with pink cytoplasm and some degree of cytological atypia. The central cells are paler and surrounded by darker-staining cells arranged in a palisaded fashion. Broad, fibrous septa run between these cytologically malignant cells, and both cells and septa are separated by lakes of mucin (Fig. 37.25) [9,10]. The mucin stains with diastase-resistant PAS, and acid Alcian blue (pH 2.5).

Management. Wide local excision, possibly with microscopically controlled excision margins, is recommended. Extensive metastatic spread and invasion of bone is very rare [11,12]. Local recurrence is often seen and the risk of metastatic spread to regional lymph nodes increases after a recurrence.

Adenoid cystic carcinoma

SYN. PRIMARY CUTANEOUS ADENOCYSTIC CARCINOMA

This is a particularly rare variant of adnexal carcinoma, which has only been recognized as an entity since 1975. Adenoid cystic carcinomas arise relatively frequently from salivary glands, and direct spread or even metastasis from this site should be ruled out before the diagnosis of primary cutaneous adenoid cystic carcinoma is made. Around 20 cases are presently recorded in the literature.

Clinical features [1,2]. These lesions are non-specific, sometimes painful, nodules on the head and neck area. The pain is attributed to perineural spread. Rarely, tumours develop elsewhere in the skin including the scrotum [3].

Pathology [4–7]. The pathology is that of large masses of cells with mild or no cytological atypia, arranged in a distinct adenoid or cribriform pattern. The cystic spaces are occupied by mucin, which stains with Alcian blue (pH 2.5). The lesion occupies the middle to deep dermis and may extend to the subcutaneous tissue. A more solid variant may be seen occasionally. Many of these tumours show at least focal evidence of myoepithelial differentiation.

Management. The management of these lesions is by wide local excision. Local recurrence is common and metastasis to the lung and regional lymph nodes has rarely been reported [5,8–10]. Metastatic spread to the lungs has also been reported many years after removal of the primary cutaneous tumour [11]. Erosion of bone at the primary site has also been recorded.

Lymphoepithelioma-like carcinoma

Lymphoepitheliomas are well-recognized tumours of the nasopharynx, and an entity with similar histological features has also been observed in the skin [1]. However, the latter is not associated with Epstein–Barr virus (EBV) infection and its behaviour appears to be less aggressive than that of upper respiratory tract lesions [2,3].

Clinical features. The clinical appearance is of non-specific nodules on the head and neck area of older patients. The trunk and vulva are also rarely involved.

Pathology. The pathological features are those of a very dense infiltrate of inflammatory mononuclear cells, including lymphocytes and histiocytes, with small strands and nests of atypical epithelial cells. Inflammatory cells extensively infiltrate nests and strands of tumour cells, and the epithelial nature of these cells is often not immediately apparent unless more or less intact nests of epithelial cells are found. Confusion with a lymphoma is therefore a possibility, and often immunostaining for keratin and lymphoid cells is necessary to distinguish the two populations of cells. Cytological atypia is usually present, and mitotic figures are common. Focal evidence of adnexal differentiation may be seen [4–7]. Some tumours appear to be arising from a squamous cell carcinoma. It has therefore been suggested that this is not a distinctive entity but a morphological pattern in various cutaneous carcinomas [8].

Treatment. Surgery followed by radiotherapy is recommended. However, the lesions are aggressive, and both local recurrence and distant metastases, with one tumour-associated death, have been recorded [5,7].

Paget's disease of the nipple [1]

Definition. A progressive, marginated, scaling or crusting of the nipple and areola due to invasion of the epidermis by malignant cells, which are currently thought to originate in the intraduct carcinoma of the breast that frequently accompanies the condition.

There is a strong current view that Paget's disease arises from apocrine duct-derived epithelial cells.

Incidence and aetiology [2]. Paget's disease of the nipple is an uncommon occurrence, considering the frequency of breast cancer [3,4]. In one series, it occurred in fewer than 3% of breast cancers. It occurs chiefly in women, although rare cases have been recorded in men [5]. It is rare before the fourth decade and is most frequent in the fifth and sixth. Published cases suggest that the disease is more common in Anglo-Saxon countries. The current view is that the majority of cases of Paget's disease arise from either invasive or *in-situ* ductal carcinoma in the deeper breast tissue.

Clinical features [6,7]. The early changes may be minimal, with a small, crusted and intermittently moist area on the nipple giving a brownish stain on clothing, or producing itching, pricking or burning sensations. Less often, there is a serous or blood-stained discharge from the nipple, or a lump may be noticed in the breast (Fig. 37.26). The surface changes persist and gradually spread to produce an eczematous appearance. The nipple, areola and, at a later stage, skin of the breast are erythematous and moist or crusted (Fig. 37.27). The change is sharply marginated and may spare a segment of the areola. The edge is slightly raised and irregular in outline. If the crusts are removed, a red, glazed, moist or vegetating surface is revealed. Itching may be a prominent symptom and excoriations may be found in the established lesion. Some areas may

Fig. 37.26 Paget's disease of the nipple. Distant clinical view, showing unilateral lesion.

Fig. 37.27 Paget's disease of the nipple. Close-up view, showing erythema and well-marked lateral edge of the lesion.

be ulcerated. The change is confined to one nipple. The nipple itself may be retracted, and a subjacent mass or a lump deeper in the breast may be felt. The regional glands should be examined; they are rarely enlarged when a mass cannot be felt, but are enlarged in more than half the cases with a detectable tumour. The rate of spread of the skin changes is slow, and patients often wait a year or more before seeking advice. The change may occasionally involve not only the skin of the breast but also spread on to the chest wall.

Pathology [8–10]. The epidermis is thickened, with papillomatosis, enlargement of the interpapillary ridges and hyperkeratosis or parakeratosis on the surface (Fig. 37.28). Within the epidermis, characteristic Paget's cells are dispersed between the prickle cells. They vary in number, and when profuse the Malpighian layers may be disrupted and the surface covered by a crust. There is a chronic inflammatory reaction in the upper dermis. In the later stages, the epidermis may be atrophic or eroded.

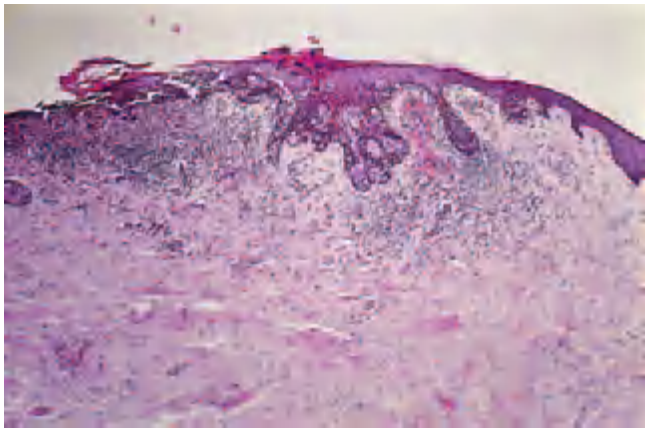

Fig. 37.28 Pathology of Paget's disease of the nipple, showing epidermal ulceration, colonization of the epidermis by large pale Paget's cells and an underlying brisk lymphocytic infiltrate.

On scanning microscopy, the differential diagnosis may include superficial spreading malignant melanoma.

The Paget's cells have a clear, abundant cytoplasm and do not establish intercellular bridges with the adjacent normal keratinocytes. Both the cells and their nuclei are rounded; the nuclei are vesicular or hyperchromatic with a high nuclear/cytoplasmic ratio. The cytoplasm PAS is positive and diastase-resistant [11], which indicates the presence of neutral polysaccharides and supports the glandular origin of the cells [12]. Staining with antibodies to CEA is also positive [13,14]. The cells are distributed singly among the prickle cells, or in clusters in a pattern similar to that seen in superficial spreading melanoma. The Paget's cells may also be seen in appendage ducts, so that it can be impossible to determine if these cells are migrating from these ducts to the epidermis, or invading downwards into the ducts from the epidermis.

An underlying breast carcinoma, if present, is not always seen on biopsy, as it may be deeply set. Careful examination of the amputated breast may show an intraduct carcinoma, sometimes of quite small dimensions, situated most usually distally, but sometimes in the terminal ducts, and often appearing to spread between the two layers of epithelial cells of the duct. The cells may accumulate within and distend the ducts and spread in both directions. A number of ducts are usually involved. At a later stage, the carcinoma becomes invasive and behaves like classic breast carcinoma.

Diagnosis. The principal differential diagnosis is eczema of the nipple. This is frequently bilateral and runs a more fluctuating course, improving in response to local treatment and spreading rapidly when irritated. Eczema lacks the sharp, raised and rounded margin and the superficial induration of Paget's disease. In doubtful cases, biopsy will be required. Bowen's disease and superficial basal cell carcinoma may also produce a similar clinical picture. They are both very uncommon on the nipple and can be differentiated histologically. Psoriasis and erosive adenomatosis of the nipple may also need to be considered in the clinical differential diagnosis, and again a biopsy to obtain pathology will clarify the situation. The chief pathological problem is to distinguish Paget's disease from superficial malignant melanoma. Paget's disease cells will be CEA-positive, EMA-positive and Cam 5.2-positive, while those of melanoma will be positive for Melan A mart melanoma antigens [13,14]. Positivity to antibody to S100 protein is not useful, as although it is positive in the great majority of melanomas, it is also positive in a proportion of Paget's disease. The absence of melanophages and the presence of neutral mucopolysaccharides in the cells are also helpful.

Treatment [15]. All patients should have a mammogram or ultrasound to establish whether or not there is deeper pathology in the underlying breast, as this will help determine the extent of surgery required. Surgery should be carried out as for carcinoma of the breast. In patients with no evidence of an underlying breast carcinoma, conservation may be a realistic option [16,17].

Extramammary Paget's disease [1]

Definition. A marginated plaque resembling Paget's disease clinically and histologically, but occurring in sites rich in apocrine glands, such as the vulva, anogenital region and axilla.

There is currently controversy as to how often this condition arises on the background of an underlying carcinoma, and how often it arises primarily in the epidermis or apocrine ductal tissue of the affected area. This has given rise to the concept of primary and secondary extramammary Paget's disease [2].

Incidence and aetiology. This is a rare disease. It occurs more frequently in women and starts usually in the fifth decade or after. The current view is that in about 75% of cases, extramammary Paget's disease arises as a primary intraepidermal neoplasm, possibly from apocrine gland ductal cells or from keratinocyte stem cells. In the remaining 25%, an underlying primary adenocarcinoma is found. These cases are referred to as secondary Paget's disease.

Clinical features. The lesion has many features in common with Paget's disease of the nipple. The margin is sharp, rounded and slightly raised, and encloses an area that is somewhat erythematous or distinctly red. The surface may be scaly, and small, greyish crusts may cover erosions. Itching is a prominent feature and there may be excoriations or lichenification. Variable hyperpigmentation may be present, adding to the pathological confusion between extramammary Paget's disease and superficial spreading melanoma. In a proportion of cases, there may be leukoplakia.

The appearance varies somewhat according to the site. The commonest area involved is the vulva [3–5] (Fig. 37.29), followed by the perianal area, which is more frequently affected in men than women, the scrotum, penis and axilla [6,7]. The first symptom, especially in vulval lesions, is itching and burning, which may be persistent and spread. Quite often it is regarded as a dermatitis, and may be irritated by topical therapy. The mucosal surfaces of the labia are frequently a rather more vivid red than the skin when both areas are involved, and the change may spread to the thighs, mons pubis and into the vaginal introitus. There may occasionally be a papillomatous surface. Perianal lesions may extend up into the anal canal. Lesions on the scrotum spread to the thigh or onto the shaft of the penis. Very occasionally, extramammary Paget's disease may be present on the eyelids or ears. Characteristic clinical features include the relentless progression, despite all local applications, and the sharp margin. Eventually, one area may become thickened and ulcerated as evidence of invasion downwards. Lymph node or distant metastases can occur.

Although most of the cases in which a primary carcinoma is found result from an underlying sweat gland adenocarcinoma, it is necessary to examine the patient for evidence of an adenocarcinoma of the cervix and rectum.

Fig. 37.29 Extramammary Paget's disease of the vulva showing inflamed eczematous presentation.

Pathology. The changes in the epidermis are essentially similar to Paget's disease. The cells stain positively for acid as well as neutral mucopolysaccharides. They may contain melanin granules. Immunohistochemistry shows cells positive for CEA and Camp 5.2 and other low-molecular-weight keratins such as CK7. GCDFP-15 is a marker of apocrine epithelium [8] and is frequently strongly expressed in primary vulval or perianal Paget's disease with no detectable underlying malignancy.

Diagnosis. The differential diagnosis from eczema, intertrigo and pruritus vulvae is made by the steady spread, lack of response to topical anti-inflammatory agents and the sharp and extending margin. Bowen's disease is usually more raised and verrucous, and superficial basal cell carcinoma has a thread-like margin. It may be difficult to differentiate leukoplakia or Bowen's disease of the mucosal surfaces, and biopsy may be required. As with mammary Paget's disease, superficial spreading melanoma is an important pathological differential diagnosis.

Treatment. Adequate tissue sampling and other investigations are essential to establish whether or not there is an associated underlying malignancy requiring surgical excision. If an underlying malignancy is present, it should

be excised together with all clinically abnormal epithelium. If no underlying malignancy is detected on careful examination, the entire affected area of epithelium should be excised. Mohs surgery with careful control of excision margins may be useful, as a common cause of recurrence is inadequate excision of the lesion [9,10].

Promising results are reported with photodynamic therapy, but larger series and longer periods of follow-up are required [11].

Merkel cell tumours [1]

SYN. TRABECULAR CELL CARCINOMA OF SKIN; PRIMARY NEUROENDOCRINE CARCINOMA OF THE SKIN

Definition. An aggressive and frequently lethal tumour thought to arise from the cutaneous Merkel cell, a neuroendocrine cell [2].

Incidence and aetiology. The first definitive report of Merkel cell tumour dates from 1977 [2], although there are reports in 1972 of 'trabecular cell carcinoma of skin' [1], which is almost certainly synonymous. De Wolf-Peeters *et al*. [3] were the first to suggest the use of the term 'Merkel-cell tumour'. More than 2000 cases have been recorded to date. This is a rare tumour of the elderly, with a high concentration of primary tumours on sun-exposed sites. An unexpectedly high proportion of Merkel cell tumours arise in association with either squamous cell or basal cell carcinomas, or in patients who have a past history of such lesions. These facts suggest that excessive ultraviolet exposure may play an aetiological role in the development of Merkel cell tumours.

Clinical features [4]. The lesions appear to have few distinctive features, and are described as raised, reddish-blue nodules, which may develop on any body site, although the head and neck area is over-represented in terms of surface area.

Pathology [5,6]. The cells making up the tumour may be either a solid mass or a more diffuse collection of cells, initially situated in the mid-dermis. They are intensely basophilic, with abundant mitotic figures and also many apoptotic cells. Lymphatic and vascular invasion is frequently present. On light microscopy, they may resemble small lymphocytes or a poorly differentiated metastatic deposit, particularly of small cell carcinoma of lung or of naevoid melanoma. The cells are argyrophilic, with sparse cytoplasm, dispersed chromatin and inconspicuous nucleoli.

Electron microscopy [7] is required for positive identification of the multiple, round, secretory granules that pack the cytoplasm of these cells. There may be a dense lymphoid infiltrate.

Immunohistochemistry is useful in confirming the diagnosis. Merkel cells show a characteristic 'dot' positivity with antibodies to low-molecular-weight keratins such as Camp 5.2 and CK20.

Treatment. Surgical excision is required [8], but metastases occur early and 30–50% of patients may die from metastases. Arterial limb perfusion has been used for lesions on limbs and may be beneficial [9]. Merkel cell tumours are considered to be radiosensitive, and trials of postoperative radiotherapy suggest a survival advantage [10]. There are ongoing studies of the benefit of sentinel lymph-node biopsy and full lymph-node dissection if the sentinel node is positive for limb lesions.

Chapter 38

Disorders of the Cutaneous Melanocyte

R.M. MacKie

Introduction

Factors responsible for variation in cutaneous pigmentation are discussed in Chapter 39. Melanin pigment is synthesized and distributed to adjacent cells by cutaneous melanocytes, which are found in normal skin in the basal layer of the epidermis. Melanin synthesis and distribution is accelerated by exposure to UV radiation. Cutaneous pathology attributable to the melanocyte may arise as a result of overproduction of melanin by a normal quota of melanocytes as in the simple freckle, or by an increased number and altered distribution of cutaneous naevomelanocytes as in melanocytic naevi, or as a result of malignant transformation of the melanocyte as in malignant melanoma.

The freckle or ephelis

Definition. A pale-brown, macular lesion, usually less than 3 mm in diameter with a poorly defined lateral margin which appears and darkens on light-exposed skin sites during periods of UV exposure.

Clinical features. Simple freckles are commoner in children, and in individuals of all ages who are red- or fair-haired and fair-skinned (Fig. 38.1). They fade away almost completely during the winter months.

The clinical distinction between a freckle and a lentigo is that the lentigo persists in the absence of UV stimulation and on biopsy the lentigo will be seen to have a linear increase of melanocytes at the dermal–epidermal junction.

Pathology. The simple freckle shows no anatomical abnormality on biopsy [1,2]. It arises as a result of temporary overproduction of melanin by a normal quota of melanocytes due to stimulation by UV radiation. It has been claimed that the melanocortin 1 receptor gene is the major freckle gene, and that *MC1R* gene variants are required for the development of freckles [3].

Diagnosis. This is usually obvious with the presence of regular macular brown lesions on light exposed skin. The freckles and café-au-lait spots of neurofibromatosus (Chapter 12) are commonly on the trunk and axilla, and other features of neurofibromatosis may be present. An isolated patch of tinea nigra (Chapter 31) could rarely cause confusion but is likely to be larger than a freckle,

Fig. 38.1 Multiple freckles on a young girl with red hair.

and solitary. In contrast, freckles are usually present in reasonable numbers rather than as solitary lesions.

Management. No treatment is needed for these benign lesions, and their biological significance lies in the fact that they have been identified in case–control studies as an independent risk factor for melanoma [4].

Lentigines

These lesions are also macular increases in melanin pigmentation on the skin, but they persist throughout the year, and on microscopy have an increase in the number of melanocytes at the dermal–epidermal junction for the body site in question.

Lentigines can be divided into simple lentigines, actinic lentigines, psoralen UVA (PUVA) lentigines, and the more recently described ink-spot lentigo. In the case of the first three variants, excessive exposure to natural or artificial UV radiation is the major aetiological factor.

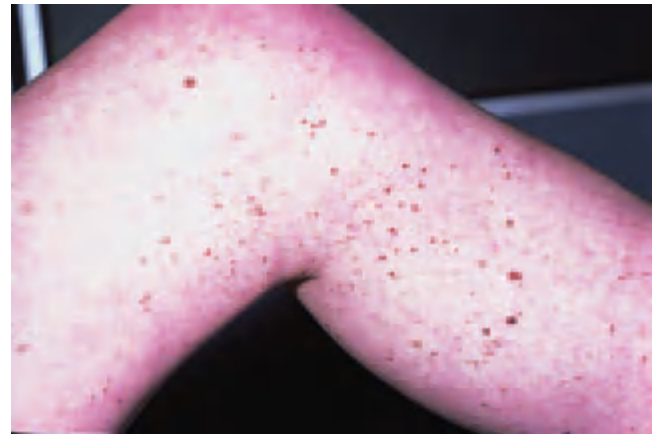

Fig. 38.2 Multiple lentigines on a young woman with cardiac defects.

Simple lentigo [1]

Definition. A brown macule arising as a result of an increased number of melanocytes at the dermal–epidermal junction without evidence of proliferation of these melanocytes downwards into the dermis.

Aetiology and incidence. Multiple benign lentigines occurring as an isolated phenomenon are very common, particularly in those with red hair, and skin with a high phaeomelanin/eumelanin ratio. Lentiginosis is a characteristic feature of a number of rare but potentially serious hereditary multisystem syndromes (Chapter 12).

Clinical features. A lentigo is a macular area of brown or brown-black pigmentation, usually circular or oval, although several individual lentigines may coalesce. There may be slight scaling of the surface, but the skin markings are unaltered. The pigmentation is usually light brown and fairly uniform. Any area of the skin, the mucocutaneous junctions or the conjunctivae may be affected (Fig. 38.2).

Pathology. There is a linear increase in the number of melanocytes along the dermal–epidermal junction. There is more melanin than normal in the adjacent epidermis and stratum corneum, and melanophages are abundant in the papillary body. The papillae and interpapillary ridges may be elongated.

Lentigines usually appear in childhood and may increase in number in the second and third decades. Rarely, they may erupt profusely [2] or occur in vast numbers [3]. They may fade or disappear over the course of years. Lentigines are found in the Peutz–Jeghers syndrome [4–6] and in centrofacial lentiginosis. The majority of lentigines remain static or disappear spontaneously in adult life.

If, however, very large numbers of lentigines are present and there is no history of excessive sun exposure, the possibility of one of the multisystem disorders should be considered [7–11]. These include the LEOPARD syndrome (*l*entigines, *e*lectrocardiogram anomalies, *o*cular anomalies, *p*ulmonary stenosis, *a*bnormal genitalia, *r*etardation of growth and *d*eafness), the NAME syndrome [7] and the LAMB syndrome [9]. The patient should be fully investigated for potentially serious systemic asssociations in such cases.

Diagnosis. Lentigines are distinguished from freckles by their darker colour, comparative sparseness and scattered distribution, and by the fact that they do not darken or increase in number on sun exposure, and do not disappear during the winter months.

It is often impossible to distinguish lentigines from flat junctional or compound naevi on clinical grounds.

Treatment. As these lesions are usually multiple, and have no premalignant potential, the patient should be reassured. Excision or even shave biopsy is likely to leave a residual scar more obvious than the lesion itself. Laser therapy may be effective if treatment is considered essential [12].

Solar or actinic lentigo

Definition. A macular area of brown pigmentation appearing after either acute or chronic sun exposure.

Clinical features. In younger patients, solar lentigines are most commonly seen on sun-exposed sites, such as the face in both sexes and the shoulders in males. They are macular, tan coloured and may be very large with a striking irregular border. There is frequently a history of acute sunburn, followed by the sudden appearance of large numbers of these irregular and unsightly macular lesions. In the UK they are rare before the age of 12 years, but in sunnier countries they may appear at a very young age.

Solar lentigines are also seen on older fair skinned patients who have had chronic sun exposure. The backs of the hands and the face are common sites. Once again the lesions are large and macular, have an irregular edge and are usually a uniform shade of brown. They are situated in an area of obviously sun-damaged epidermis.

Pathology. The pathological features of solar lentigo are similar to those of the smaller simple lentigines. There is a linear increase of melanocytes at the dermal–epidermal junction, but no cytological atypia of these melanocytes, and no budding down of these cells into the underlying dermis. There is frequently associated actinic damage to the adjacent dermal collagen.

Treatment. Because of the large size and unsightly appearance of some actinic lentigines, patients frequently request treatment. Prevention of further UV-induced damage should be encouraged by sun avoidance and the use of a high sun protection factor, broad-spectrum sunscreen. With these measures, there is often some spontaneous resolution of existing lesions. The use of cryotherapy may also be effective, but this should be used lightly to avoid scarring.

Photochemotherapy (PUVA) lentigo [1,2]

Lentigines associated with PUVA therapy are a well-recognized complication of long-term use of PUVA therapy. They are relatively large, macular, pigmented lesions, which develop on the skin of patients receiving photochemotherapy. The number of melanocytes in the relevant body site are increased, and on ultrastructural examination there are morphological abnormalities of the melanosomes. Follow-up of PUVA-treated patients in the USA have indicated that PUVA lentigines are a marker of patients at increased risk of both melanoma and non-melanoma skin cancer [3–5].

Ink-spot lentigo

Definition. A small (less than 5 mm in diameter), densely black macule, usually on sun-exposed skin [1].

Clinical features. These are relatively rare lesions but, as both doctors and the public become more expert at suspecting and diagnosing very early melanoma, such lesions may give rise to concern, partly because of their very dark pigmentation, and also because they may have an irregular lateral margin. They are usually solitary intensely pigmented macules with an irregular lateral margin (Fig. 38.3).

Pathology. The pathology of the lesion is that of a lentigo, with a linear increase in melanocytes in the basal layer of the epidermis, and an associated increase in melanin pigmentation both in the basal cells of the epidermis and also lying free in the underlying epidermis. The melanocytes are normal, and there is no evidence of cellular atypia.

Management. These lesions are commonly excised to obtain a pathological diagnosis because of their clinical resemblance to possible early melanoma.

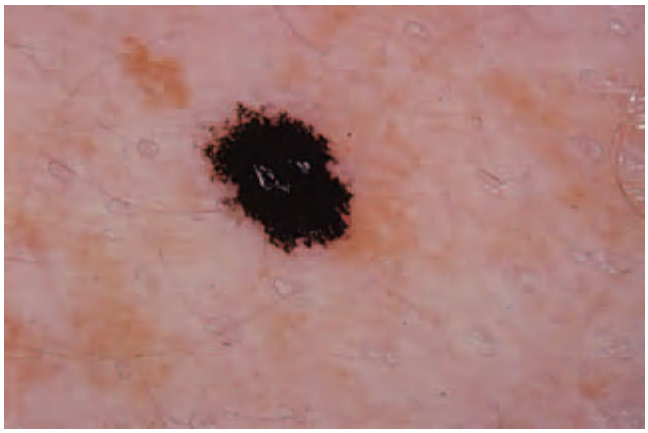

Fig. 38.3 Ink-spot lentigo.

Mucosal melanotic lesions

Essential melanotic mucosal hyperplasia

Relatively large, macular, melanotic lesions may develop on the oral mucosa or genital mucosa [1–3]. These lesions may slowly expand laterally to reach a diameter of several centimetres with a strikingly irregular lateral border. The pigmentation is usually relatively uniform. The vital point concerning these lesions is the fact that early and even moderately advanced oral or genital mucosal melanoma may look deceptively benign. A tissue diagnosis is therefore essential.

Clinical features. These lesions are relatively large macular areas of uniform brown or grey pigmentation. They may have slowly expanded to reach a large diameter over several years.

Pathology. The pathology of these lesions is usually much less dramatic than their clinical appearance [4,5]. There is a clear increase of melanin pigment in the basal layer keratinocytes with some overspill into the dermis, resulting in pigment-laden macrophages. The melanocyte count is relatively normal with only a slight linear increase and no junctional activity.

Treatment. No treatment is required if an incisional biopsy of an appropriate area has confidently excluded melanoma. This can, however, be extremely difficult, and the patients may require long-term follow-up.

Labial melanotic macules [1,2]

Definition. Flat areas of benign non-progressive melanin pigmentation on the lips.

Clinical features. Labial melanotic macules usually affect the lower lip in the central third. More females than males seek treatment for these lesions. The site suggests that excessive exposure to natural UV radiation may be an aetiological factor.

Fig. 38.4 Melanotic macule of the lower lip.

The natural history is of the relatively rapid appearance of a brown macule on the lower lip in a young adult. The macules rarely become larger than 1 cm in diameter, and are usually single lesions (Fig. 38.4).

Pathology. The pathology is that of linear increase in melanin pigment in the basal cells. Malignant transformation has not been reported in these lesions.

Treatment. Reassurance is all that is needed on medical grounds. If removal is requested for cosmetic reasons, cryotherapy, use of the infrared coagulator or laser therapy may all be effective [3].

Melanocytic naevi

Epidemiology. Acquired melanocytic naevi are extremely common, and the great majority are benign with little malignant potential. Only a very small proportion progress to melanoma.

A broad initial subdivision of melanocytic naevi can be made into those appearing after birth—acquired naevi—and those present at or shortly after birth—congenital melanocytic naevi. In the UK, Australia and US 1–3% of infants examined in the first month of life have melanocytic naevi [1,2]. The great majority of individuals have acquired naevi which appear throughout childhood and puberty, so that in the third decade young white adults in the UK have 20–50 naevi. Thereafter, these naevi slowly disappear throughout life and by the ninth decade very few melanocytic naevi remain [3].

From studies in the cities of Brisbane, Sydney and Melbourne in Australia, which all have a marked latitude gradient, it appears that naevi appear earlier and in larger numbers in white skinned children in Brisbane, which is closest to the equator, but that by the early teenage years the numbers of naevi in children in these cities have equalized [4,5]. Similar studies looking at Italian schoolchildren in Europe also show higher naevus counts in those who have had greater sun exposure [6]. Patients with atopic dermatitis have significantly lower naevus counts than age-matched controls for reasons that are not yet understood [7].

The interaction between genetic susceptibility to naevi development and environmental stimuli is currently a subject of active research particularly using monozygotic and dizygotic twin pairs as models. These studies show very strong correlation of naevus counts in monozygotic twins, suggesting a strong genetic influence for total numbers of naevi [8–10]. Much of the current interest in and search for genetic and environmental factors affecting naevus development relate to the fact that large numbers of banal melanocytic naevi are the most significant risk factor yet identified for development of malignant melanoma [11,12].

Terminology commonly used in describing melanocytic naevi is included in Table 38.1.

Table 38.1 Terms commonly used in the description of melanocytic naevi.

Melanocyte	A pigment-producing cell characterized by its ability to synthesize melanosomes. Contains the enzyme 3,4-dihydroxyphenylalanine (DOPA)
Theque	A group of melanocytes (generally four or more) in contact with the basal layer of the epidermis but budding downwards into the dermis
Freckle	An area of increased melanin pigmentation. The only histological abnormality is an excess of melanin pigment. The lesion would therefore appear to be the result of functionally overactive melanocytes. These lesions are stimulated by UV irradiation
Lentigo	An area of increased melanin pigmentation which shows histologically a linear replacement of keratinocytes in the basal layer of the epidermis by melanocytes. This replacement does not reach the level of theque formation; if this were the case, the term junctional naevus would be appropriate
Junctional activity	The presence at the dermal–epidermal junction of theques of melanocytes
Junctional naevus	A pigmented or cellular naevus in which the main histological feature is that of junctional activity. A few naevus cells are usually observed scattered in the underlying dermis
Compound naevus	A pigmented or cellular naevus in which the histological features include both junctional activity and the presence of naevus cells in the dermis. Such naevi usually contain melanin
Intradermal naevus	A cellular naevus in which there is little or no abnormality of melanocytes in the epidermis. The main feature is the presence of packets of naevus cells in the dermis. Melanin pigmentation is often absent and such naevi may be clinically non-pigmented

Acquired melanocytic naevi

SYN. CELLULAR NAEVUS; NAEVOCYTIC NAEVUS; MOLE

Definition. A benign cluster of melanocytic naevus cells arising as a result of proliferation of melanocytes at the dermal–epidermal junction. These may all remain in contact with the basal layer of the epidermis, giving rise to the junctional naevus. In other naevi some of the naevus cells may have become detached from the basal layer giving rise to the compound naevus. The end stage of this process is when there are no naevus cells attached to the epidermis and all are lying free in the dermis. This pattern is the intradermal naevus.

Aetiology and incidence. Melanocytic naevi are almost universal, and the great majority appear after birth [1]. The presence of large numbers is associated with childhood sun exposure [2]. Individuals with Turner's syndrome have larger than average numbers of naevi, as do children who have been treated for leukaemia [3].

The prevalence of melanocytic naevi varies with age [4–6]. They increase in frequency gradually during childhood and adolescence, and then more slowly during early adult life, to a plateau in middle age. During old age their prevalence falls [7,8]. The incidence of pigmented naevi on the palms, soles and genitalia has been studied in a large series of normal young men [9], and more than 10% of the sample were found to have one or more.

Clinical features [6,10]. Melanocytic naevi have a wide range of clinical appearances.

The **junctional** naevus is most often seen on the palms and soles and is a macular brown lesion, which may show pigment lying along the normal skin markings. It may have a slightly irregular lateral margin because of this,

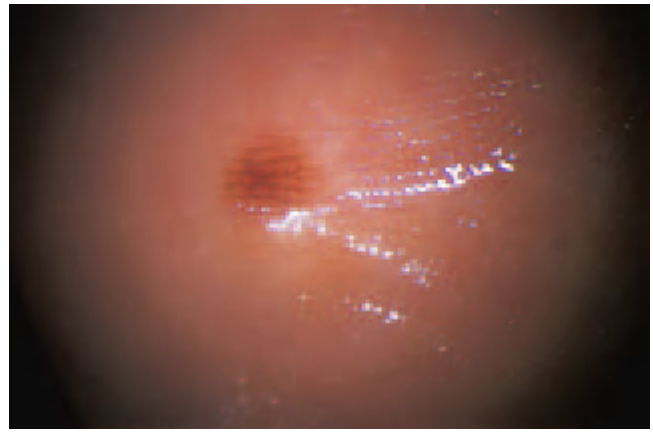

Fig. 38.5 Junctional naevus on the sole of the foot. Note the continuity of the skin markings.

and may have a large diameter of up to 10 mm. The pigmentation tends to be uniform and regular (Fig. 38.5).

The **compound** naevus is usually raised above the epidermal surface and may be round or oval. The colour varies with the natural pigmentation of the patient and may be very dark. There is usually little if any pigment on the flat surrounding epidermis in a classic non-dysplastic compound naevus (Fig. 38.6). In late childhood and adolescence, compound naevi often become elevated, giving rise to concern. It is important to recognize that elevation and the transformation of a macular melanocytic naevus to a palpable papule is not a sign of malignant change but a normal maturation pattern of these naevi. This elevation is often accompanied by loss of visible melanin pigment.

The **intradermal naevi** are frequently raised, dome-shaped, non-pigmented nodules, most commonly seen on the face (Figs 38.7 & 38.8). There are often some overlying telangiectatic vessels, and outgrowth of one or two coarse terminal hairs is common [7,8].

Fig. 38.6 Small compound naevus on the trunk of a young adult.

Fig. 38.7 Intradermal naevus. Note the relative lack of pigmentation on this naevus by comparison with Figs 38.5 and 38.6.

The other type of intradermal naevus usually seen only in adult life is a sessile or pedunculated, soft skin tag-like lesion. There is frequently no excess of pigment, or at the most a light-brown surface. They are often seen in the axillae, the groins and on the neck.

It is not uncommon for a naevus on the face or neck to suddenly become swollen and inflamed. Examination shows a tender, firm nodule beneath the naevus, which will usually resolve in a few weeks. This event may follow the plucking of hairs from the naevus or other physical irritation. If the naevus is excised, a foreign-body granuloma will be found in the vicinity of one of the hair roots [11–13]. Fragments of hair shaft can often be demonstrated. The inflammation may recur and leave a fibrous nodule, or one that goes on to calcification or even ossification.

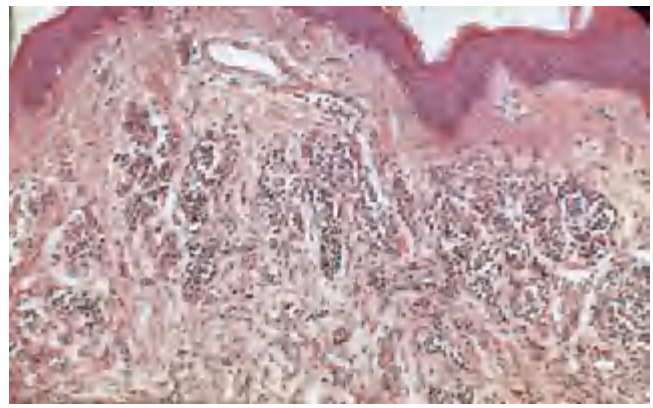

Fig. 38.8 Histology of intradermal naevus. Note the normal overlying epidermis and the maturation of dermal naevus cells, with neural appearance at lower levels.

A small proportion of usually compound melanocytic naevi will show a predominant population of cells with a high volume of foamy cytoplasm. These are called balloon cell naevi because of their pathological appearance [14–16]. The pathological picture is striking, but there is no known biological significance. There is also a malignant counterpart of balloon cell melanoma, but the balloon cell naevus is not a precursor to balloon cell melanoma.

Naevi of the skin adjacent to the eye may be associated with a melanocytic tumour of the iris. Ocular melanosis is also a feature of the naevus of Ota (p. 38.16).

Conjunctival naevi are similar in their behaviour and histology to cellular naevi of the skin. Some lesions involve both the opposed surfaces of the upper and lower eyelid so that when the eyes are shut the naevus takes its normal rounded shape. This shows that the site of the naevus was determined during the period when the lids were fused, i.e. between the second and sixth month of fetal life.

Naevi of the nail matrix or bed may show as a longitudinal brown stripe on the underside of the nail plate (Chapter 62).

Pathology. The possible pattern of evolution of pigmented naevi has been deduced by pathological examination of a large number of lesions removed at different ages [17,18]. In childhood, over 90% of naevi are junctional and show melanocyte proliferation at the dermal–epidermal junction to form small clusters of cells that indent both the overlying epidermis and the underlying papillae [19,20]. The cells have abundant cytoplasm containing melanin granules. The majority of naevi on the palms and soles, and also on the vulva [21], appear to be junctional naevi.

The next stage occurs when some of these melanocytes migrate into the dermis, where they form nests and columns of cells. The speed with which this can occur, even in adult life, is shown in one case of eruptive cellular naevi, where biopsy of a lesion not more than 3-weeks old showed a band of densely packed cells in the papillary dermis [22].

In the compound naevus both junctional proliferation and dermal cells are present. The dermal cells accumulate in the papillary body and extend more deeply around appendages and neurovascular bundles. The more superficial cells (type A) remain recognizable as naevus cells, continuing to form melanin, which is taken up by melanophages in the stroma. The deeper cells (type B) are smaller and usually contain no melanin, although they have been shown to possess tyrosinase and premelanosomes [23,24]. The more superficial cells may throw the epidermis into a series of folds by expanding dermal papillae. The deeper cells are arranged as a band (type B) or as arborizing columns in the deeper dermis, when the cells become spindle shaped (type C).

If the junctional melanocytes stop proliferating, and the overlying epidermis returns to normal, the naevus becomes *intradermal*. Many intradermal naevi have neuroid tissue in their deeper parts, and some are composed of little else. These neural areas in the deeper areas of intradermal naevi are sometimes referred to as Masson's naevic corpuscles, after Pierre Masson who first evolved the theory of evolution of melanocytic naevi [18]. The similarity of these naevic corpuscles to Meissner's corpuscles, the sensory nerve endings found in large numbers on the fingertips, has been confirmed by electron-microscopic studies [20]. The deeper parts of intradermal naevi give a strongly positive cholinesterase reaction, and even the type A cells may react [20,25]. The stroma around the dermal naevus cells is loose and fibrillar, the nests of cells are often enclosed by flattened cells that resemble endothelium and may give an erroneous impression of naevus cells in vessels. Multinucleated naevus cells are commonly seen, but mitotic figures are rare and occur only in the type A cells. It is not uncommon to find an occasional 'ballooned' naevus cell, and in rare instances the entire naevus may be composed of balloon cells with vacuolated cytoplasm [15].

Many intradermal naevi show features very similar to nerve tissue with a sparse naevus-cell population, which is fibrillar in configuration. Schwann cells may be observed in such lesions, and cholinesterase-positive fibres can be demonstrated [26]. These observations give support to the view that naevi are basically hamartomas of both melanocytic cells and neural tissue.

The end stage of a melanocytic naevus is a flesh-coloured, pedunculated skin tag in which very few naevus cells are observed [27]. Pigment is sparse, and fat cells may be present.

Compound and intradermal naevi show related abnormalities of other structures. Pilosebaceous follicles may be large and distorted, dermal collagen may appear disturbed or displaced by fat cells, the vascular supply may be increased and there is frequently a network of non-myelinated nerve fibrils [28]. Hairs from the large follicles may pierce the wall of the follicle and produce a granulomatous foreign-body reaction. Calcification, and even ossification, can follow [11–13].

Diagnosis [29]. The clinical differential diagnosis of melanocytic naevi includes freckles, lentigines, non-melanocytic lesions such as seborrhoeic keratoses and dermatofibroma and, most importantly, early malignant melanoma.

Freckles are usually relatively easy to clinically distinguish from naevi because of their seasonal variation, but it may be clinically impossible to differentiate clinically between lentigines and small junctional naevi.

In older adults, there may be difficulty in clinical differentiation between seborrhoeic keratoses (Chapter 36) and larger papillomatous compound naevi. The seborrhoeic keratosis usually has a 'stuck-on' appearance with its bulk above the normal skin contour, and the colour is usually more grey-brown than the typical melanocytic naevus. In addition, the surface is usually dull and pitted, with a tendency to crumble, and does not reflect light in the same way as the naevi.

The most important clinical differential diagnosis is from early malignant melanoma. Any pigmented lesion in an adult that is growing or changing in any way should be examined carefully. A history of very rapid growth over days rather than weeks and tenderness suggests the development of an underlying granuloma rather than malignant change. Features strongly suggestive of an early malignant melanoma either developing *ab initio* or in a pre-existing naevus are an irregular outline to the lesion and the presence in the lesion of several shades of brown and black. Either of these features, particularly in association with a history of recent growth or change and a history of altered sensation in the pigmented lesion, are indications for excision biopsy with a narrow margin of normal skin and pathological examination.

The techniques of dermatoscopy and of computerized diagnosis are discussed in the section on malignant melanoma (p. 38.35). Several groups have produced useful atlases of the clinical dermatoscopic appearances of melanocytic naevi and the differences between these naevi and malignant melanoma. While both sensitivity and specificity for accurate differentiation between benign and malignant melanocytic lesions have improved greatly in the past decade, the technique is not as accurate as the gold standard of pathology, so excision biopsy and pathological examination is still required in most cases. Excision may not, however, be required if the differentiation is between a pigmented lesion of melanocytic origin

and one in which the pigment is not melanin as in an angioma or incidental as in a seborrhoeic keratosis. In both of these conditions the dermatoscopic appearance is reliably consistent and enables accurate diagnosis without the benefit of pathology.

Management. The great majority of junctional, compound or intradermal naevi are not premalignant lesions, and removal is therefore not required on medical grounds, although a few may merit local excision on cosmetic grounds. There is no evidence to support suggestions that naevi on sites of friction such as the waistband should be removed because of a greater risk of malignant change. Naevi on the palms, soles and genitalia are more frequently of the junctional or compound type than those elsewhere. The incidence of melanoma relative to the prevalence of naevi in these sites does not, however, suggest that these lesions have a greater malignant potential than naevi in other sites, and therefore prophylactic removal is neither necessary nor logical.

If a melanocytic naevus is excised for whatever reason, it should always be sent for pathological examination. In general, scalpel excision with a narrow margin of 1–2 mm of normal surrounding skin is recommended and preferred to shave biopsy, which frequently fails to completely remove the deeper dermal cells [30,31]. When this occurs, residual naevus cells may proliferate and give rise to a pathological picture very like an early melanoma. This picture has been termed 'pseudomelanoma' or, more appropriately, a traumatically activated naevus. This can give rise to needless anxiety and is avoidable.

Spitz naevus [1,2]

SYN. SPINDLE AND EPITHELIOID CELL NAEVUS; JUVENILE MELANOMA

Definition. A compound naevus variant, seen most commonly in children, which has distinctive pathological features. These features may make the pathological differential diagnosis from malignant melanoma extremely difficult.

Incidence. Spitz naevi are usually diagnosed in the first two decades. Although Spitz naevi can be diagnosed in the eighth and ninth decades, this is unusual, and the pathological differential diagnosis should be carefully considered. The sexes are equally affected. Spitz naevi comprise less than 1% of melanocytic naevi removed from children [3].

Clinical features. The naevus usually appears in early childhood as a firm, rounded, red or reddish-brown nodule. A small proportion may show a surrounding halo [4]. The colour is due to excessive vascularity and the naevus can usually be bleached by firm pressure or diascopy to show the residual degree of true melanin pigmentation (Fig. 38.9).

The lesions usually grow rapidly over a period of 3–6 months and may reach diameters of 1–2 cm. The surface

Fig. 38.9 Spitz naevus showing a uniform red facial lesion.

can remain smooth, with a thin fragile overlying epidermis. This may cause bleeding and crusting after minor injury.

The commonest sites for Spitz naevi are the face, particularly the cheeks, and the legs, but other areas may be affected. After rapid initial growth they may remain static for years.

A striking and unusual appearance is that of *multiple Spitz naevi* or *agminate Spitz naevi* [5–10]. This entity appears to be composed of a large number of pathologically independent small Spitz naevi in the same anatomical area. The individual Spitz naevi develop rapidly and thereafter remain relatively static. The pattern is similar to that seen in the satellite lesions that develop around a pyogenic granuloma, and is more common in children than in adults.

Spitz naevi in adults may occur on any site and tend to be more deeply pigmented than those in children. They are well-demarcated, firm, dome-shaped lesions.

Pathology [11,12]. The Spitz naevus is a compound naevus variant. There is frequently a degree of epidermal acanthosis overlying the naevus cells, in the absence of any upward epidermal invasion by naevus cells. The melanocytes at the dermal–epidermal junction are often separated from the underlying dermis by a cleft, and may be associated with amorphous pink globules. These are thought to be degenerating keratinocytes and are called *Kamino bodies*. They are frequently seen in Spitz naevi, but their presence is neither totally sensitive nor specific for Spitz naevi, as they may also be present in early melanoma.

The Spitz naevus cells may be either spindle shaped and stream into the dermis in interlacing bundles, or epithelioid and arranged in clusters with giant and multinucleated naevus cells among them. Mitotic figures may occur but abnormal mitoses are not seen. Mitotic figures are rarer in the deeper naevus cells, and their presence should alert the observer to the possibility that the lesion is in fact a spitzoid melanoma. The deepest naevus cells show some degree of maturation and are usually smaller than those seen at the dermal–epidermal junction. The dermal vessels are usually dilated, and the stroma may be oedematous and infiltrated with lymphocytes. Melanin is rarely abundant, and may often be absent [13–15].

The important and difficult pathological differential diagnosis is the separation of true benign Spitz naevi from spitzoid malignant melanoma. Two useful studies have recently tried to identify pathological factors that may help in this situation. Crotty and colleagues [16] have identified symmetry of the lesion from side to side, the presence of Kamino bodies and the uniformity of cell nests or sheets in the dermis as features of benign Spitz naevi. In contrast, they identify abnormal mitoses, mitotic counts of over $2/mm^2$ and deep mitoses as suggestive of spitzoid melanoma. Spatz *et al*. [17] have identified age over 10 years, diameter over 10 mm, ulceration, invasion to subcutaneous fat and mitotic activity of over $6/mm^2$ as suggestive of spitzoid melanoma rather than Spitz naevi.

Diagnosis. Most Spitz naevi in children are red rather than brown, and are likely to be confused clinically with vascular tumours, pyogenic granuloma, histiocytoma, juvenile xanthogranuloma or granulomas such as lupus vulgaris. When the surface is warty, distinction from an epidermal naevus or occasionally even a common wart may be difficult. Pigmented Spitz naevi may be clinically indistinguishable from compound melanocytic naevi or spindle cell naevi of Reed (see below).

The main problem with the accurate diagnosis of Spitz naevi arises when a pathologist is sent a naevus without an adequate history and, in particular, without being given the age of the patient. In this situation it can be easy to overdiagnose melanoma on the pathological appearance. It is therefore very important for the clinician and pathologist to liaise well in arriving at the correct diagnosis of suspected Spitz naevi. Malignant melanoma is rare before puberty, although it does occur, but the balance of probabilities in spitzoid lesions excised in the first decade of life lies with the lesion being a true Spitz naevus rather than a spitzoid melanoma. This is particularly true if the cell type is predominantly spindle. In the case of lesions removed from adults, the pathological differential becomes very much more difficult, and it may be necessary to admit uncertainty and recommend a period of follow-up after complete scalpel excision. It is worth remembering that one of the original 12 cases identified by the late Sophie Spitz as Spitz naevus rather than melanoma did in fact later metastasize [1].

The concept of a Spitz naevus with a capacity for metastasis to the draining regional lymph nodes but not beyond has been proposed. Six patients who had an initial diagnosis of malignant melanoma later modified to Spitz

naevus had elective lymph node dissection. In all six cases Spitz-type naevus cells were found in the nodes with no evidence of metastasizing malignant melanoma beyond these nodes on short-term follow-up [18].

Treatment. Local excision with a narrow margin of 1–2 mm of normal skin is usually required to confirm the clinical diagnosis. Local recurrence has been recorded in both isolated and agminate lesions [19].

Pigmented spindle cell naevus of Reed [1]

Definition. A heavily pigmented, predominantly junctional naevus. This naevus is considered by some to be a variant of a Spitz naevus rather than an entity in its own right.

Spindle cell naevus of Reed was first described in 1975 [2] and it is important to be aware of its existence when considering a possible diagnosis of malignant melanoma, as it may cause confusion on both clinical and pathological grounds.

Fig. 38.10 Pigmented spindle cell naevus of Reed. A deeply pigmented but regular lesion on the thigh of a young female.

Clinical features. The majority of patients reported are young females, and the lesions are most commonly seen on the thighs [2]. They are densely pigmented, irregularly shaped dark-brown or black nodules and are usually isolated (Fig. 38.10).

Pathology [3,4]**.** The lesions show well-demarcated junctional melanocytic activity with large quantities of melanin pigment. Spindle-shaped melanocytes proliferate downwards towards the dermis, but there is no upward movement of naevus cells through the epidermis, and usually very little, if any, intradermal component. Some naevus cells may be seen in the papillary dermis, but these naevi do not involve the reticular dermis. A sparse lymphocytic infiltrate is seen at the base of the naevus cells, but the lesion is relatively small and circumscribed. As with Spitz naevi, symmetry is an important feature.

Treatment. This lesion should be narrowly excised for pathological diagnosis.

Desmoplastic naevus [1,2]

Definition. A firm, predominantly intradermal naevus with a characteristic thick, collagenous stroma surrounding melanocytic naevus cells.

As with spindle cell naevi of Reed, these naevi may be considered as a subset of Spitz naevi.

The age of affected patients and the body site suggests that these lesions are not precursors to the desmoplastic melanoma (p. 38.31).

Clinical features. Desmoplastic naevi may show little or no clinically visible melanocytic pigmentation, and may appear as pink or red, firm, raised nodules. The lesions may be woody hard, and the clinical differential may include a keloid, although there is no history of injury (Fig. 38.11).

Pathology. This lesion was well described by Barr *et al*. in 1980 [1] and has a very striking and characteristic pathological appearance. The lesions are predominantly intradermal, and a relatively small number of naevus cells will be found embedded in thick collagen fibres. The naevus cells are usually distributed singly through the stroma rather than in clumps, and may be very large and bizarre, with copious cytoplasm, which may contain inclusions. The nuclei look unusual but not frankly malignant, and mitotic figures are rare. Mitotic figures if present are normal [2] (Fig. 38.12).

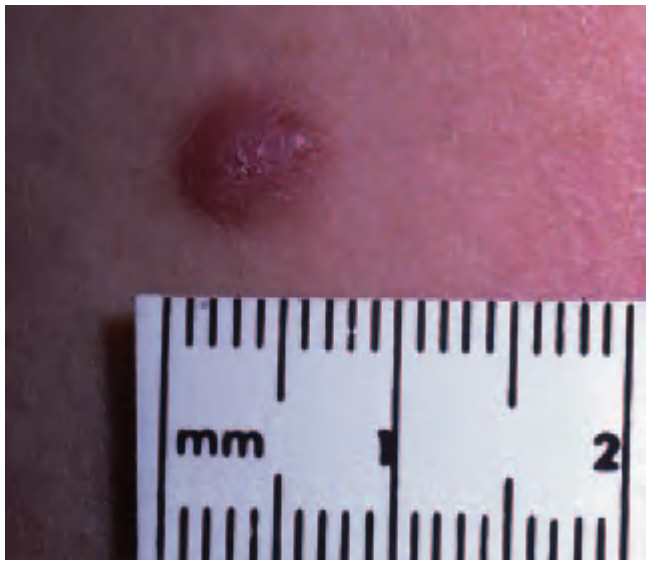

Fig. 38.11 Clinical appearance of desmoplastic naevus. Note the red, keloid-like appearance.

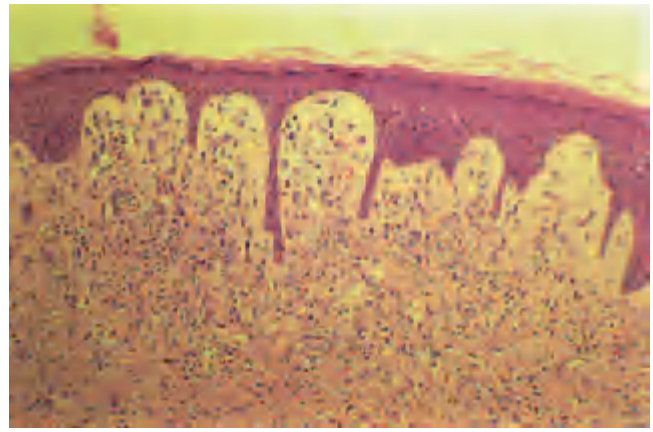

Fig. 38.12 Histology of desmoplastic naevus. Note the presence of cytologically unusual naevus cells set in a dense collagenous stroma.

Treatment. Excision is usually required to establish a diagnosis. Incomplete excision is common due to the unexpected extent of the dermal infiltration of the naevus cells.

Halo naevus [1]

SYN. SUTTON'S NAEVUS

Definition. A melanocytic naevus surrounded by a depigmented halo of otherwise normal skin.

Incidence and epidemiology. Halo naevi are relatively common, particularly in older children and young teenagers. They are frequently multiple. Circulating anti-melanoma antibodies [2] have been detected in a proportion of patients with these lesions, but their role in the development of the halo and the subsequent disappearance of the naevus is not established.

Clinical features [3–5]**.** These lesions have a characteristic appearance and progression. A halo of depigmentation will appear around a pre-existing melanocytic naevus, and on white skin this will usually be seen during the summer months when the rest of the epidermis has acquired a tan, showing the non-tanned halo in sharp contrast (Fig. 38.13). The back is the commonest site and several naevi may develop haloes simultaneously, while other adjacent naevi remain unchanged. Over the next

Fig. 38.13 Clinical appearance of a halo naevus.

few months, the central naevus will gradually disappear leaving a macular area of non-pigmented skin. This depigmented area may persist for years and only gradually return to a normal colour. On biopsy, all traces of the original naevus will be found to have disappeared.

Pathology [6]**.** These lesions are variants of compound melanocytic naevi, and at the time of appearance of the halo they show a very striking lymphocytic infiltrate admixed with the intradermal naevus cells. The use of the antibodies to S 100 protein and NKIC3 will reveal a loss of epidermal melanocytes in the halo area.

Management. Reassurance rather than excision is recommended in young people, particularly if the lesions are multiple. The patient should be warned that the depigmented areas will burn badly in sunlight because of the lack of melanocytes and should be advised to use a sunscreen.

In older patients, the differential diagnosis may include an early superficial spreading melanoma with surrounding depigmentation. In this case the surrounding area of depigmentation is usually irregular, and the central pigmented area may also be irregular in both shape and pigmentation. Obviously if there is any clinical doubt, excision biopsy and pathological confirmation must be obtained.

Cockade naevus

SYN. KOKARDENNAEVUS; NAEVUS EN COCARDE

This rare variant of the pigmented naevus was first described by Mehregan and King in 1972 [1]. Since then, several further cases have been described [2,3]. The lesion is named because of its resemblance to a rosette. All cases so far reported are in young patients with multiple target-like naevi with concentric circles of increased melanin pigmentation. The central lesion in all cases would appear to be a junctional naevus (Fig. 38.14).

Meyerson's naevus [1]

This name is used to describe a melanocytic naevus that

has developed a surrounding inflammatory reaction. The naevus may be pruritic, and there may be overlying scaling.

Clinical features. These lesions present as melanocytic naevi with associated epidermal scaling and a halo of inflammation. The original report was of multiple naevi developing this associated inflammatory reaction simultaneously. Four cases have recently been described of this inflammatory reaction developing around atypical naevi [2]. The central naevus may disappear, leaving a depigmented area [3].

Pathology. The pathology is usually that of a banal, usually compound, naevus with associated spongiotic dermatitis in the overlying dermis.

Treatment. These lesions are frequently excised as the appearance of inflammation in a pre-existing naevus gives rise to concern that the naevus is undergoing malignant change. If this is not a concern, they will settle to a normal naevus appearance after 1–2 week's application of a moderately potent topical steroid.

Speckled and lentiginous naevus

This term is recommended in preference to the term naevus spilus, which is frequently confused with Becker's naevus, a non-melanocytic proliferation (Chapter 39).

Clinical features. Speckled and lentiginous naevus is a relatively rare entity [1]. The lesion may be several centimetres in diameter and is clinically a combination of a flat, macular, lentiginous component, often of a darker shade than the surrounding skin, with even darker central lentigo-like lesions. In addition to these features there are elevated darker-brown areas (Fig. 38.15). It may also coexist with a blue naevus [2].

Pathology. Pathological examination shows, as the clinical appearance suggests, a large lentiginous area with superimposed individual compound naevi.

Management. There have been reports of malignant change in these lesions [3–6]. In view of this and the relative rarity of the lesions, and of their cosmetic appearance, local excision should be considered if this is feasible. This is often not practical as the area involved would require grafting and it may be more practical to photograph the lesion for future reference, and to only excise it if there are subsequent signs of growth or change.

Fig. 38.15 Speckled and lentiginous naevus. Note the variation in colour of this lesion.

Dermal melanocytic naevi

All the melanocytic naevi described in the preceeding pages are believed, on the basis of biopsies from multiple lesions in patients at varying ages, to have developed from epidermal melanocytes that completed their migration from the neural crest to the dermal–epidermal junction in fetal life—the so-called 'abtropfung' (dropping down) theory.

The lesions described below differ in that they are believed to arise from dermal melanocytes that have become arrested in the dermis during fetal life and tissue modelling and have never reached their normal site in the basal layer of the epidermis. Many mammals have a physiologically normal population of dermal melanocytes but

these are not commonly observed in human dermis, with the possible exception of the Mongolian spot [1].

Experimentally induced melanocytic tumours in animals frequently have a morphological resemblance to these dermal naevi [2,3].

Mongolian spot

Definition. Macular blue-grey pigmentation present at birth on the sacral area in normal infants of darker-skinned races.

Incidence. These are present in over 90% of infants of Mongoloid race, and have been found in about 1% of white European infants, the incidence being highest in the Mediterranean region. The incidence in other races lies between these extremes. It has been found in some 80% of East African infants [4].

Clinical features. The pigmentation is macular, diffuse and more or less uniform, slate blue to grey and usually relatively faint. The patches are usually rounded or oval in shape, up to 10 cm or so in diameter, and usually single but occasionally multiple. The lumbosacral region is the common site, and the buttocks, flanks or even shoulders may be affected in extensive lesions. The pigmentation develops in fetal life, increases in depth for a period after birth and then diminishes. It usually disappears during the first decade, but has occasionally persisted into adult life.

Pathology. Melanocytes are dispersed in a ribbon-like pattern between the collagen fibres and around the neurovascular bundles of the dermis. They run parallel to the skin surface and contain very fine granules of melanin. There is no disturbance of the pattern of collagen and elastic fibres. Melanophages are not found. The last two characteristics enable it to be differentiated from blue naevus.

Management. No treatment is needed.

Blue naevus and cellular blue naevus [5]

Definition. An area of blue or blue-black dermal pigmentation produced by aberrant collections of pigment-producing but benign melanocytes.

Incidence and aetiology. Blue naevi are relatively common. A ratio of 2.5 : 1.0 of female to male patients in a recent series probably reflects the relative degree of either anxiety or wish for removal. Blue naevi are thought to arise because of arrested migration of melanocytes migrating towards the dermal–epidermal junction.

Clinical features. There is an area of diffuse blue pigmentation, usually slightly raised and smooth surfaced. Blue naevi may be found on any site but patients with facial naevi most often request excision for cosmetic reasons.

Fig. 38.16 Clinical appearance of cellular blue naevus on the dorsum of the foot.

The cellular blue naevus is seen most often on the extremities, particularly the dorsa of the hands and feet (Fig. 38.16), the buttocks and the face. The onset may be before birth, but lesions frequently first appear around puberty. Progressive growth is rare, and malignant transformation very rare [5,6] (p. 38.17).

Pathology. In the common or classic variety, bipolar and dendritic melanocytes lie singly or in masses in the dermis (Fig. 38.17). They tend to be profuse in the lower dermis and are often concentrated around appendages or in the perivascular and perineural areas. Deeper tissues may be involved. The melanocytes are relatively inconspicuous, containing fine granules of melanin dispersed through their cytoplasm. There are varying numbers of melanophages in which the melanin granules are coarse and more closely clumped.

The cellular blue naevus is composed of the same elements as the common blue naevus, but in addition possesses islands of larger cells arranged in a neuroid ('pigmented neurofibroma') or sarcomatoid fashion. The appearance may raise suspicions of malignant melanoma, but the lack of mitotic activity, vascularity or inflammatory reaction, the regularity of the cells and the absence of junctional proliferation in continuity with the cellular masses enable the distinction to be made [7–9].

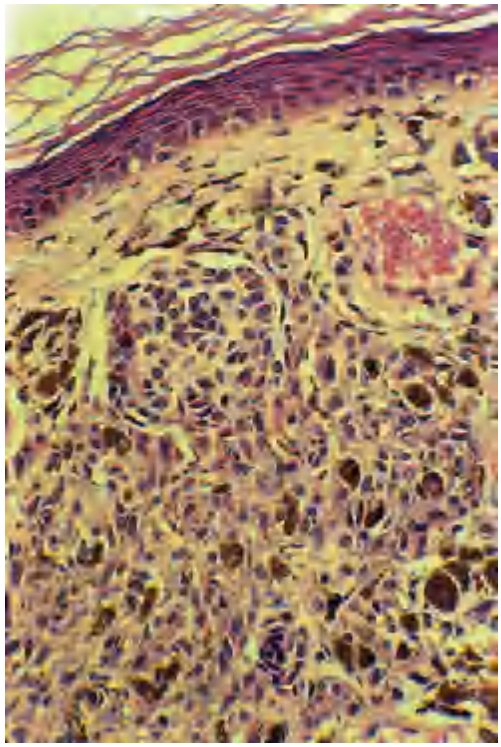

Fig. 38.17 Histology of blue naevus. Note the normal overlying epidermis with spindle cells and dense pigmentation in underlying dermis.

The compound blue naevus is a more recently described entity [10,11] with additional dendritic cells in the overlying epidermis. This lesion may clinically be very similar to early malignant melanoma.

Multiple epithelioid blue naevi may be associated with the Carney complex (Chapter 59). This is a genetically transmitted multitumour syndrome involving both blue naevi and lentigines, and also cardiac myxomas, endocrine tumours and schwannomas [12].

A blue naevus may be present in association with a compound naevus, and the resulting lesion is then called a *combined naevus* (see below).

Malignant blue naevus is a very rare entity, and in some cases it is not possible to differentiate between classic malignant melanoma and malignant change within a blue naevus. Malignant blue naevus appears to develop more often on the scalp, and pathologically have a sheet-like growth pattern. Necrosis and atypical mitotic figures are diagnostic features which will distinguish these lesions from benign classic or cellular blue naevi [13].

Diagnosis. The condition is characterized by its colour and must be differentiated from other dermal melanoses. It is a relatively static, non-progressive lesion.

Treatment. None is needed. Excision may be justified on cosmetic grounds. Rare malignant blue naevi should be widely excised as these tumours are aggressive and have a high recurrence rate

Naevus of Ota [14,15]

SYN. NAEVUS FUSCOCAERULEUS OPHTHALMOMAXILLARIS

Definition. An extensive, blue, patch-like area of dermal melanocytic pigmentation of the sclera and the skin adjacent to the eye due to the presence of dermal melanocytes [16].

Incidence. This disorder is not uncommon in Asian people but is comparatively rare in other races. Unlike the Mongolian spot, it is not usually visible at birth, becomes progressively darker in childhood and persists in adult life.

Clinical features. The pigmentation is often speckled and is composed of deeper bluish and more superficial brownish elements, which do not always coincide. The two colours are perhaps best seen in the eye, where the affected sclera is blue and the conjunctiva brown. The brown pigmentation is patchy and may be patterned in a reticular or geographical way; the blue pigmentation is more diffuse. The areas involved are the eyelids, the bulbar and palpebral conjunctiva and the sclera, and the cheeks, forehead, scalp, alae nasi and ears. The mucosa of the palate and cheeks may also be affected. The distribution is usually restricted to the first and second divisions of the trigeminal nerve, but rarely patches may occur on the trunk [1].

The pigmented spots usually appear in childhood and increase in number and extent to become confluent in some areas [17]. There is one report of the onset following trauma, and in another the ocular pigmentation became much more pronounced after an attack of conjunctivitis. The distribution is usually, but not always, unilateral.

In very rare instances malignant melanoma has developed in naevus of Ota [5].

Pathology [18,19]. The features are the same as those of Mongolian spot.

Treatment. Laser therapy may be of value, and cosmetic camouflage may also be useful.

Naevus of Ito [20]

This type of dermal melanocytosis involves the acromioclavicular region and the upper chest and, like the naevus of Ota, is largely confined to the Japanese (Fig. 38.18).

Naevus fusco-caeruleus zygomaticus

A number of cases of this entity have been described from China and Japan [1]. The lesions are speckled naevi on the upper cheek, and microscopy shows bipolar pigment-bearing cells in the upper dermis only, in contrast to the naevus of Ota in which pigment-bearing cells are seen throughout the dermis.

Malignant blue naevus [1]

Definition. A rare malignancy often confused with melanoma.

Pathology. Malignant cells of melanocytic origin are seen in the deeper dermis with no overlying abnormality of epidermal melanocytes. Mitotic figures are rare [2], but the presence of any at all should suggest the diagnosis. Necrosis within the lesion is another important diagnostic sign, which is not seen in benign blue naevi.

Clinical features. Malignant blue naevus usually arises in a cellular blue naevus, and the scalp is the commonest site (Fig. 38.19). Expansion of a previously identified blue naevus should suggest the diagnosis. Metastases do occur and can cause death [3].

Treatment. Wide surgical excision is required.

Fig. 38.19 Malignant blue naevus which has arisen in a previous cellular blue naevus. This lesion subsequently metastasized to lymph nodes.

Fig. 38.20 Combined naevus showing typical combination of pale-brown and deeper blue-black pigmentation.

Combined naevus [1]

Definition. A melanocytic naevus formed by a combination of epidermally and dermally derived naevus cells.

Clinical features. Combined naevi show clinical evidence of their dual origin in that they are multicoloured, having both a sandy brown component and a blue-black component. They are frequently relatively large and may have an irregular border (Fig. 38.20). This trio of features means that they are frequently mistaken for early melanoma.

Pathology [2]**.** The essential pathological feature of a combined naevus is the combination of some degree, usually slight, of junctional activity at the dermal–epidermal junction together with the presence in the dermis of the heavily pigmented bipolar dendritic cells characteristic of a blue naevus.

Treatment. Excision biopsy and pathological examination is usually necessary to confirm the clinical diagnosis and exclude the possibility of melanoma.

Deep penetrating naevus

Clinical features. This naevus variant is rare. Clinically it may be a deep blue or black colour with a diffuse irregular lateral margin. The clinical differential diagnosis is therefore frequently melanoma.

Pathology. This naevus frequently has features of both a compound and a blue naevus, making it a variant of the so-called combined naevus, but with minimal junctional activity. The diagnostic feature is the presence of clusters of widely separated but deep naevus cells throughout the dermis. Frequently these clusters are around the skin appendages. The cytology is of a spindle cell population and mitotic figures are rare [1].

Congenital melanocytic naevus

Incidence and epidemiology [1,2]**.** One to three per cent of all newborns have a pathologically confirmed congenital melanocytic naevus [3], although clinical studies have suggested that twice as many infants have pigmented lesions clinically compatible with this diagnosis [4]. In addition, there is a subsection of naevi that develop in the first 5 years of life but that were not present at birth which have clinical and pathological features much more compatible with congenital naevi than with acquired naevi. These naevi are frequently referred to as congenital-type or early-onset naevi.

Congenital pigmented naevi have been arbitrarily divided into three size ranges. Small lesions have maximum diameters of less than 1.5 cm, intermediate-sized lesions have maximum diameters between 1.5 and 20.0 cm and giant lesions have diameters of over 20 cm. The great majority of congenital naevi are small, although the published studies in the literature, particularly in relation to the malignant potential of congenital naevi, mainly relate to the giant, or garment, type [5–8].

Clinical features. At birth, congenital naevi may be very pale macular lesions, which may enlarge, darken and develop terminal hair over a period of years (Figs 38.21 & 38.22). Early-onset or congenital-type naevi may first become visible in the 5 years after birth.

Small and medium-sized congenital naevi usually grow less rapidly than the infant so that their surface area relative to the whole body surface area is reduced, but they frequently darken with age and may develop outgrowths of coarse terminal hair. There is frequently a striking increase both in pigmentation and hair growth at puberty.

Fig. 38.21 Small congenital naevus on the leg of a neonate.

Fig. 38.22 Medium-sized congenital naevus on the cheek of a toddler.

Fig. 38.23 Giant or garment congenital naevus on the lower back area of a child.

The rare giant, garment or bathing-trunk naevus is obvious at birth and distressing to parents. The common site is the lower back and thigh area and a very large proportion of the infant's surface area may be involved. There may also be large numbers of smaller congenital naevi present on the infant's skin. As the infant grows the surface may become rugose or warty and nodules can develop within a large naevus. The hairy component, which occurs in 95% of lesions, tends to become more prominent in late childhood, but at this stage the naevus itself ceases to thicken and may become paler. The hair growth pattern may have a 'vortex' distribution, often centred on the midline in giant naevi of the back (Fig. 38.23).

There may be associated abnormalities such as meningeal involvement, spina bifida or meningocoele when the naevus is over the vertebral column, or club-foot and hypertrophy or atrophy of the deeper structures of a limb. Other hamartomas, such as vascular naevi, lipomas or von Recklinghausen's disease, may be found in patients with extensive congenital pigmented naevi [9].

Pathology [10–13]**.** The pathological features of a congenital melanocytic naevus are the presence of an increased number of melanocytes in the epidermal basal layer in a lentigo-like pattern, a relatively cell-free papillary dermis approximating to a Grenz zone, and aggregates of dermal naevus cells in the lower areas of the dermis. This contrasts with the intradermal component of acquired melanocytic naevi in which the bulk of the intradermal naevus cells are found in the papillary dermis.

In congenital naevi, naevus cells are found not just around but also infiltrating the skin appendages. The presence of these cells in the skin appendages is a relatively specific feature of congenital naevi [13].

Many congenital melanocytic naevi are hamartomas because of the presence of increased numbers of hair follicles and other skin appendages. Large congenital melanocytic naevi over the posterior midline are frequently associated with intracranial melanosis, and over the lower spine area they may be found in association with spina bifida occulta.

Management. There are two main problems to be considered in managing these lesions. The first is the potential of these lesions for malignant change and the resulting need for prophylactic removal [14–17], the second is the cosmetic concern, particularly in the case of the giant lesions.

There are many case reports in the literature of malignant change in giant pigmented naevi, but these reports are likely to overestimate the true frequency of this occurrence because of the tendency to report positive events. The best study involving a large population of patients followed for many years comes from Scandinavia and reports a lifetime incidence of malignant change of 4–6% [5]. A British study has reported that 50% of the cases of malignant change in congenital naevi occur prior to puberty [7]. Thus, there is a significant risk of malignant change in a giant congenital naevus and prophylactic removal, if practical and feasible, is justified. The time at which malignant change is recorded in giant naevi is in contrast with that seen in the small congenital naevi; in small congenital naevi malignant change has only been reported after puberty [14].

The giant congenital melanocytic naevi are a difficult surgical problem, but shaving of the lesion in the neonatal period, and the use of tissue expanders to create additional normal epidermis to use in grafting are both valuable techniques.

A number of centres have advocated deep curettage or shave in the early neonatal period [18]. The object is to remove as many melanocytic naevus cells as possible, and thus both improve the cosmetic appearance and reduce the risk of development of malignant melanoma by reducing the total number of naevus cells present. Despite the necessary trauma of the procedure, it appears to be well tolerated by the infant and does in many cases reduce the degree of pigmentation, at least temporarily. The shave is rarely deep enough to remove the hair follicles and therefore the hair-bearing element of the lesion is less affected. There is a tendency, however, for the naevi to repigment, and the procedure has not been carried out on a large enough sample, or followed for a long enough period of time, to make any judgement as to whether or not it alters the risk of malignant change. Those who perform the procedure state that the best results are obtained if the procedure is carried out as soon as possible after birth—preferably in the first week of life. Follow-up of 16 children treated in this way as neonates reports that, after a decade of observation, the cosmetic results are good, and that no child has yet developed malignant melanoma [19].

The other valuable technique is the use of tissue expanders [20]. Once the required degree of epidermal expansion is achieved, the normal epidermis is harvested and used as an autologous graft to cover a defect created by the removal of an area of giant melanocytic naevus. This approach has meant that naevi that were previously considered unresectable because of their large surface area can now be removed, frequently by serial excisions, and the resulting defects grafted using the epidermis grown up *in vivo* using the tissue expanders.

Long-term follow-up of children with large congenital naevi that are not excised is essential. The naevus should be examined carefully for malignant change, which is more often detected by palpation than by observation. If the area at the base of the neck is involved, a computed tomography (CT) scan or magnetic resonance imaging (MRI) of this area is wise, as leptomeningeal involvement is particularly common in this site. Any textural change in a giant naevus should be biopsied, but many of these are minor, degenerative, cystic changes rather than the development of malignancy. However, malignant change may also develop in the underlying involved areas of the nervous system and may be impossible to detect at an early stage.

In the case of small and medium-sized congenital naevi, the situation is more confused [14,21]. Available data would suggest that there is a very small risk of malignant change. Current practice in many centres is to remove congenital naevi in children referred as soon as the child can tolerate local anaesthesia.

Clinically atypical naevus

SYN. DYSPLASTIC NAEVUS

Definition. A melanocytic naevus, usually compound, identified on histological examination by the presence of architectural atypia (lentiginous melanocytic hyperplasia, bridging of junctional nests and focal elongation of epidermal rete ridges) and cytological atypia of naevus cells.

These naevi may be seen in patients in a sporadic or a familial setting. In the familial setting, they are a major risk factor for melanoma. In a sporadic setting they appear to be a marker of an individual at some increased risk of developing malignant melanoma, either on the naevus or on normal skin of the affected individual.

Incidence and epidemiology [1–3]**.** The term dysplastic naevus was first used by Elder *et al*. [4,5] as a pathological description of a sporadically occurring melanocytic naevus, which was clinically larger and more irregular than banal naevi and showed a constellation of pathological features that also distinguished it from common or banal naevi. Three years earlier, Clark *et al*. [6] and Lynch *et al*. [7] had separately but almost simultaneously described families in which multiple primary melanomas were much more common than expected and who also had large numbers of unusual naevi—the BK mole syndrome or FAMM syndrome (*f*amilial *a*typical *m*ultiple *m*ole *m*elanoma syndrome). Crutcher and Sagebiel [1] estimate the prevalence of dysplastic naevi in Californians at 8%, and figures of 2–4% are reported from other geographical areas.

Fig. 38.24 Clinical features of dysplastic naevus in a young woman whose father and grandfather both died of melanoma. Note the size, irregular edge and irregular pigmentation.

In 1984, the National Institutes of Health (NIH) Consensus Conference [8] suggested that patients with dysplastic naevi could usefully be divided into four broad categories, A–D, on the basis of personal and family involvement (Table 38.2). This is a useful working classification as the risk of malignant melanoma in individuals in the A and B categories is increased by about ×90, while it is much higher, at ×400–500 in the D category [9].

Clinical features [10–13]**.** The original description of dysplastic naevi indicated that these were lesions larger than 5 mm with an irregular edge, irregular pigmentation and a degree of inflammation (Fig. 38.24). A number of subsequent studies have reported that these features are neither totally specific nor totally sensitive for the pathological features described. Because of this lack of complete

Table 38.2 National Institutes of Health (NIH) Consensus Conference classification of 'dysplastic' naevus patients.

Patient		Personal history of melanoma	Family history of multiple naevi	Family history of melanoma
A	Multiple dysplastic naevi	No	No	No
B	Multiple dysplastic naevi	No	Yes	No
C	Multiple dysplastic naevi	Yes	No	No
D*	Multiple dysplastic naevi	Yes	Yes	Yes

* The number 1, 2, 3, etc., after D denotes the number of affected relatives.

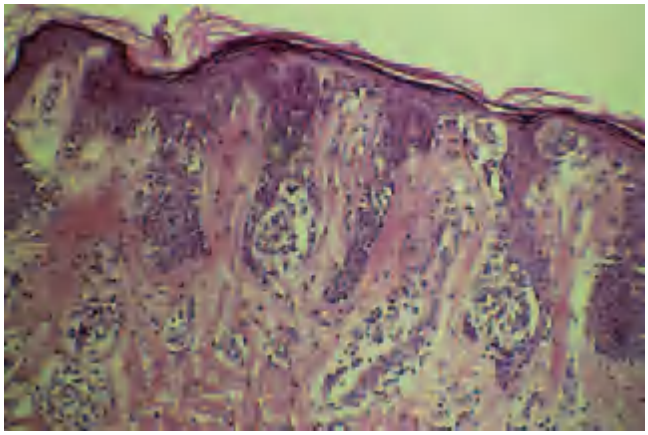

Fig. 38.25 Histological features of dysplastic naevus showing lentiginous melanocytic dysplasia, fibroplasia of the papillary dermis and melanocytic atypia.

correlation, it is suggested that the term 'clinically atypical' naevus be used for the clinical presentation [14] and 'dysplastic' naevus for those that fulfil the pathological criteria.

Pathology [15–21]**.** The great majority of dysplastic naevi are variants of acquired compound melanocytic naevi, although features described in dysplastic lesions may be seen in junctional naevi, in some congenital naevi and, occasionally, in Spitz naevi and variants.

The specific pathological features described in dysplastic naevi can be divided into architectural features, cytological features and features indicative of a host response to the naevus cells [22]. The architectural features are lentiginous melanocytic hyperplasia, fusion of individual nests of naevomelanocytes and associated elongation of epidermal rete ridges (Fig. 38.25). The cytological abnormalities are the increase in the nuclear to cytoplasmic ratio of individual melanocytes, an increase in nuclear staining and occasional normal mitotic figures in melanocytes. Most groups would not make the diagnosis on architectural features alone but consider melanocyte cytological atypia an essential feature for the diagnosis. The three pathological features indicating a host response are the presence of a lymphocytic infiltrate, a degree of fibroplasia of the collagen of the papillary dermis and a relative increase in the vascularity of the underlying dermis [19,22].

Treatment [23–26]**.** Many atypical naevi are difficult to distinguish from early malignant melanoma on clinical grounds, and therefore require an excision biopsy with a 2-mm margin of normal skin and pathological examination. It is essential to establish whether or not the patient has a family history of melanoma as, if this is the case, the risk of melanoma development is very much greater, and the threshold for excision of clinically atypical naevi needs to be lower than for those with no such history. In patients with no family history but large numbers of atypical naevi, a reasonable plan is to excise the most clinically atypical naevus. If this is not melanoma, then the remaining naevi can be recorded either with conventional photography, or with digital imaging, and the patient reviewed at intervals, according to the degree of concern. Changing naevi should be excised to obtain a pathological diagnosis, but static although atypical naevi may be safely observed. This approach results in excision of very thin melanomas. There is no logic in removing all atypical naevi to prevent development of melanomas, as melanoma can develop on clinically normal skin in these individuals.

Melanocytic proliferations associated with lichen sclerosus

A recent paper has recorded the presence of pigmented patches in the genital skin of women affected by lichen sclerosus et atrophicus [1]. Biopsy of these lesions has shown the lesions to be atypical melanocytic naevi. There is no obvious explanation for the development of these naevi in lichen sclerosus et atrophicus, but it is important to be aware of this assocation as clinically the lesions may suggest malignant melanoma.

Malignant melanoma of the skin

Definition. A malignant tumour arising from the epidermal melanocyte.

Incidence and mortality [1]**.** From 1950 to the mid-1990s there was a steady rise in the incidence of malignant melanoma of the skin in Australia, New Zealand, North America and Europe.

In Australia, numbers of new cases rose steadily to over 40 per 100 000 population per annum for males and to 30 per 100 000 population per annum for females in 1995. Since 1995 there has been a stabilization of the annual incidence in women of all ages, and a slight decline in melanoma incidence in younger females. However the incidence continues to increase in males, and is most marked in older males. The most rapid rate of increase by body site is for the head, neck and upper limb in males and the trunk in females. Lesions greater than 1.5 mm thick are increasing in incidence most rapidly in older males [2]. A similar pattern is seen in New Zealand [3].

In the USA, the SEER programme reported a trebling of melanoma incidence in males aged 45–64 years over the 30-year period 1969–99, from 13.5 to 40.0 per 100 000 population per annum, and a fivefold increase in older males aged over 65 years, from 18.8 to 91.9 per 100 000 population per annum. Incidence rates for females aged 45–64 years and for those aged over 65 years have also risen but less steeply than for males, while the incidence of melanoma in younger adults of both sexes aged under 45 years has only risen slightly over a 40-year period [4].

In Scotland, the incidence trebled in males of all ages over the 20-year period 1979–98, from 3.5 to 10.6 per 100 000 population per annum, and nearly doubled for females of all ages, from 7.0 to 13.1 per 100 000 population per annum over the same time period [5].

In the Stockholm/Gottland area of Sweden there was an average increase in incidence of 5% per year from 1976 to 1994. In the latter part of the 1990s this rate of increase levelled off in males but not in females [6].

Melanoma mortality has not risen at the same rate as melanoma incidence. In the USA, the increase in melanoma-attributable mortality has only been observed in males aged 65 years and over, in whom it trebled between 1969 and 1999. Over the same time period, melanoma mortality in both sexes aged below 45 years at diagnosis declined slightly [7]. In Scotland, melanoma mortality over the time period 1979–98 remained static in males of all ages at 1.9 per 100 000 population per annum and fell very slightly for females from 1.90 to 1.85 per 100 000 population per annum [5].

The rising incidence suggests continuing effects of past or present exposure to aetiological factors, most marked in older males. Static mortality figures can be attributed to patients presenting for surgery with thinner primary tumours.

Aetiology

Malignant melanoma is an example of a malignancy strongly influenced by environmental factors that develop in a genetically susceptible host. The main identified environmental aetiological agent is UV radiation.

UV radiation

Large case–control studies carried out in different continents all indicate that intense burning sun exposure of unacclimatized white skin is a major risk factor for

cutaneous malignant melanoma [1–3]. However the exact dose of UV irradiation which increases melanoma risk, the timing in life of this excessive UV exposure and the exact wavelengths of the UV spectrum which are most likely to induce melanoma are not yet established. The sun exposure-related risk appears to be greatest for intense intermittent exposure [4–10] of non-sun-acclimatized skin rather than continual, occupational sun exposure. Episodes of severe sunburn appear to be risk factors in 19 of 22 published studies [11,12]. The typical melanoma patient is an indoor office worker [13] who is not exposed to regular daily sunlight but who enjoys one or two holidays each year in an area of high UV intensity. Case–control studies from Denmark [4] and Canada [8,9,14] have confirmed this, and have also incriminated outdoor hobbies such as sailing and swimming as risk factors for melanoma.

Migration. Studies of age at migration from Europe to a sunnier climate such as Israel [15] or Australia [16] indicate that exposure to intense UV at a young age may be particularly important. A comparison of native-born Israelis and Australians with those who arrived in these countries after the age of 5 years indicates that the melanoma incidence is higher in the native-born group.

Use of artificial UV sources. Several studies now incriminate the use of sunbeds and sunlamps as a weak but significant risk factor, suggesting that longer-wave artificial UVA may play a part in the aetiology of melanoma in addition to exposure to natural sunlight [17–21]. However, these studies may be confounded by the fact that those who use sunbeds are also those who spend excessive amounts of time trying to acquire a tan in natural sunlight.

The use of sunscreens and melanoma risk. Studies suggesting that the use of sunscreens or even the wearing of hats are statistically significant risk factors for melanoma require to be interpreted with care. They are likely to be confounding factors in that those likely to use sunscreens and hats are those with a phenotype associated with increased melanoma risk in the form of sun-sensitive skin [6,22].

Hormonal. Studies have been carried out to establish whether or not use of the oral contraceptive is a risk factor for melanoma in women [23]. Two recent large reviews find no significant association with use of the modern low-dose oral contraceptive [24,25]

Socio-economic status. Two studies have now shown that melanoma is more prevalent in those of high socio-economic status, but the converse applies to mortality, in that patients in lower socio-economic groups are more likely to die of melanoma even after controlling for the well-recognized prognostic factors, particularly tumour thickness [26].

Occupational. A number of studies have suggested that the risk of melanoma is slightly increased in pilots and other airline crew members. A recent study of 10 032 pilots showed a relative risk of 2.3 (CI 1.7–3.0) [27]. The explanation for this may be the greater than average opportunity for recreational sun exposure.

Genetic susceptibility to melanoma

Patients with sporadic melanoma are more frequently fair skinned, fair or red haired and blue eyed, with a tendency to burn easily and tan poorly, if at all, on exposure to sunlight [1–6]. They also have large numbers of banal naevi, a tendency to freckle and more atypical or dysplastic naevi than control subjects [7,8]. These phenotypic characteristics are influenced by several genes. The melanocortin 1 receptor gene (*MC1R*) gene on chromosome 17 codes for production of dark eumelanin, found in darker haired, darker skinned white people, or for phaeomelanin, which is the melanin variant found in fair skinned red heads. *MC1R* polymorphisms are very much more common in freckled redheads and it has been suggested that this gene may be a major determinant of the freckling tendency [9].

Familial melanoma and melanoma susceptibility genes

Around 2% of melanoma patients have a proven positive family history of melanoma in one or more first-degree relatives. A higher percentage give a positive family history on first questioning, but this requires to be pathologically confirmed as non-melanoma skin cancer or a benign melanocytic lesion may be confused by patients and their relatives with true melanoma.

The major melanoma susceptibility gene identified to date is the *CDKN2A* gene, which is located on chromosome 9p21. Mutations in this gene are found in 10–30% of melanoma patients with a positive family history, with a higher prevalence of mutations in families with more than two affected members. The function of the wild-type *CDKN2A* gene is to control entry of cells into the G1 phase of the cell cycle and to prevent or delay entry of damaged cells into the cycle to allow time for repair of damaged DNA. It thus acts as a tumour suppressor gene. Mutated *CDKN2A* does not act as a break on the cell cycle in this way, and allows uncontrolled entry into the cycle of cells with damaged DNA, and subsequent proliferation and extension of DNA damage [1–3].

A number of cases of familial melanoma who have abnormalities of chromosome 9p do not have a detectable *CDKN2A* mutation, suggesting that there may be other melanoma susceptibility genes in this area.

A large number of different mutations in the *CDKN2A* gene have been found in familial melanoma patients with certain mutations been more prevalent in different geographical areas, suggesting a founder effect. For example, the 113 insert R *CDKN2A* mutation is preferentially found in Swedish families [4].

There appears to be marked geographical variation in the penetrance of *CDKN2A* mutations worldwide with the greatest penetrance observed in areas of highest UV exposure, implying a genotype–environment interaction. Overall penetrance of *CDKN2A* mutations is 30% at age 50 years, rising to 67% at age 80 years, but analysis of patients in Europe, North America and Australia shows lowest penetration in Europe and highest in Australia, where 90% penetrance is observed at age 80 years [5].

In addition three families worldwide have been found to have mutations in the *CDKN2A* binding domain of *CDK4* [6]. This is an oncogenic mutation.

In addition to *CDKN2A* and *CDK4* mutations, one US group has published evidence that melanoma susceptibility gene(s) are located on chromosome 1 [7], but this has not yet been confirmed outside the USA, and no candidate gene has been identified.

The melanocortin 1 receptor gene (*MC1R*) is a further candidate melanoma susceptibility gene. This gene is highly polymorphic and certain polymorphisms have been reported as being strongly associated with the melanoma susceptible phenotype of red hair. Many redheads have two or more *MC1R* polymorphisms, a phenomenon not observed in non-redheaded subjects [8]. Once hair colour is controlled for, *MC1R* polymorphisms still appear to be associated with increased melanoma risk [9], and may also interact with *CDKN2A* mutations [10].

The *BRAF* gene has also been identified as an oncogene in a proportion of patients with sporadic cutaneous malignant melanoma. *BRAF* encodes a *ras*-regulated kinase that controls cell growth and malignant transformation

mediated by the kinase pathway. Somatic mutations in *BRAF* have been identified in two-thirds of melanoma samples examined [11] and also in other tumour types. *BRAF* mutations are also found in benign melanocytic naevi of the congenital, compound, intradermal and dysplastic varieties in 82% of samples examined, indicating that *BRAF* mutations alone are not sufficient for full transformation to malignant melanoma [12]. Germline *BRAF* mutations are not found in the peripheral blood of patients with familial melanoma, either in those who do or do not have *CDKN2A* mutations [13].

Clinicopathological variants of primary malignant melanoma [1]

In 1969, Clark *et al*. [2] suggested that, using a combination of clinical and pathological features, malignant melanoma could be divided into three main subsets; the superficial spreading melanoma, the nodular melanoma and the lentigo maligna melanoma. In 1975, Reed *et al*. [3] added a fourth group, the acral lentiginous or palmoplantar malignant melanoma.

There is some controversy as to whether or not these subsets are completely discrete entities, and it has been established that the clinico-pathological variant is not an independent determinant of prognosis [4]. However, the four subtypes have distinct clinical features, thus giving rise to a different range of conditions to be considered in the differential diagnosis in the early growth phase.

There are two simple systems devised to aid clinical diagnosis of melanoma by naked-eye inspection. Both apply mainly to the superficial spreading variant of malignant melanoma. These are the American ABCD categories and the Glasgow seven-point check-list. The American ABCD mnemonic is A = asymmetry, B = irregular border, C = irregular colour and D = diameter over 1 cm. The Glasgow seven-point check-list is divided into three major and four minor features. These are:

Major features:
1 Change in size
2 Change in shape
3 Change in colour.

Minor features:
4 Diameter more than 5 mm
5 Inflammation
6 Oozing or bleeding
7 Mild itch or altered sensation.

It is suggested that any lesion with one major feature in an adult be considered for removal, and that the presence of additional minor features should add to clinical suspicion.

Now that the majority of melanomas are recognized and removed at an early growth stage, it is clearly essential that all dermatologists in training learn to recognize such lesions.

Superficial spreading melanoma [5]. This is by far the commonest type of melanoma on white skin. Superficial spreading melanomas present most frequently in a patient in the fourth or fifth decade. The commonest sites are the female leg and the male back (Fig. 38.26), but any body site may be involved. Early presentation is of an irregularly shaped, brown lesion, usually still macular, but with clear colour variation within the lesion. Shades of brown, black, red and grey or white may be present. At this stage the lesion may still be very small—only 4–5 mm in diameter, but there may be a history of growth or change, and of subtle altered sensation, often described as a new awareness of the lesion. At this stage, the lesion will almost certainly be in the early horizontal growth phase, but as growth continues the lesion will become palpable, indicating that the lesion has now progressed to the vertical growth phase. If the melanoma is developing in a pre-existing naevus, which occurs in approximately 50% of lesions, the irregular appearance of the growing melanoma may contrast strikingly with the more regularly pigmented and outlined residual naevus component.

Partial regression may cause central pigment loss while extension continues peripherally. This pattern of growth may result in a crescentic area of dense blue-black pigmentation with some adjacent inflammatory response and a central area of thin grey or white atrophic epidermis. Elevated nodules and a history of bleeding are associated with advanced lesions.

The main differential diagnosis here is between an early melanoma and a benign but atypical melanocytic naevus.

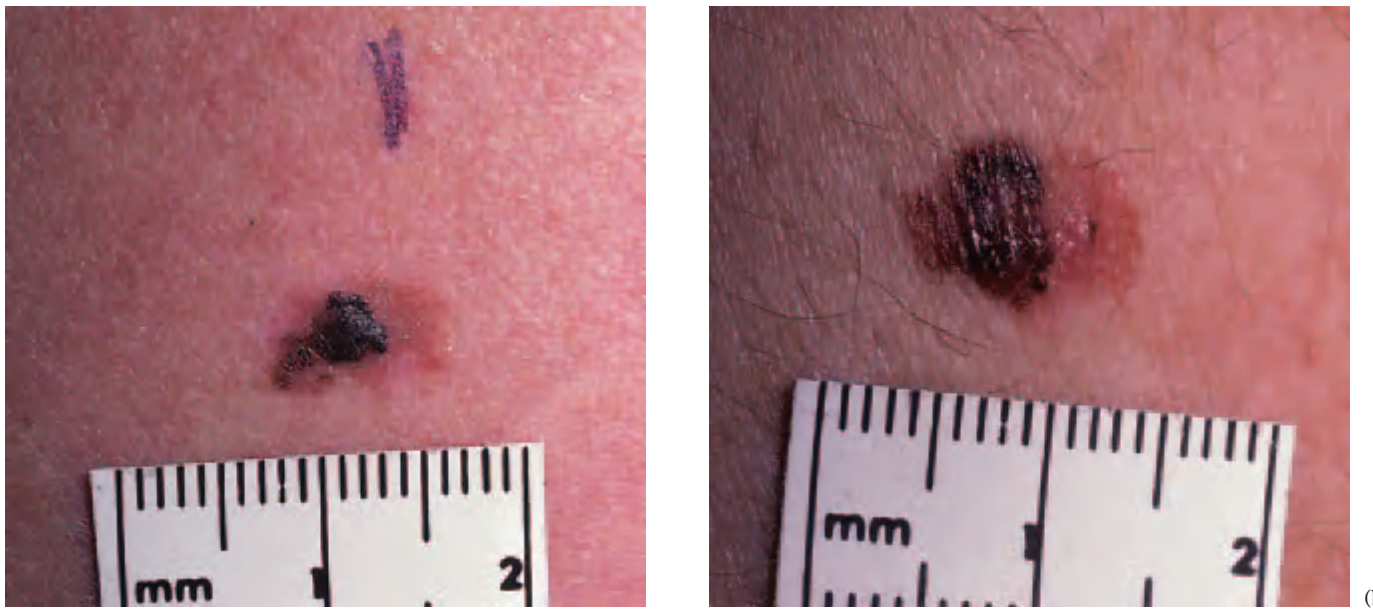

Fig. 38.26 (a,b) Two early superficial spreading malignant melanomas. Note the size, the irregular edge and the irregular pigmentation.

A history of growth or change strongly suggests early melanoma, as does a size of 6 mm or greater, but other clinical features may be very similar in atypical naevi and early melanomas, and an excision biopsy may be needed.

The relatively rare verrucous variant is more difficult to diagnose clinically. It presents as a raised, crusted, changing, pigmented lesion [6]. The differential diagnosis here may be a seborrhoeic keratosis, a pigmented actinic keratosis or a pigmented squamous cell carcinoma.

Nodular melanoma. This variety presents most commonly in the fifth or sixth decade and occurs more frequently in males than in females. The trunk is a common site. These lesions grow rapidly and because of this, and the fact that they are commonly deep tumours by the time they are excised, they have a poor prognosis. This, however, relates to tumour thickness not to the nodular nature of the lesion *per se*.

The lesion presents clinically as an elevated, dome-shaped polypoid or even pedunculated structure and the predominant colour may be reddish brown. (Fig. 38.27) Melanin pigment may be sparse in these lesions and a raised red central area, with only a peripheral brown ring of melanin, is a common clinical pattern. Ulceration and bleeding from the lesion occur frequently. This variety of malignant melanoma is misdiagnosed prior to surgery more frequently than either a superficial spreading melanoma or a lentigo maligna melanoma. The reason for this is probably the rapid growth and relative lack of melanin pigment, which may lead to confusion with vascular lesions.

Lesions to consider in the differential diagnosis are angioma or pigmented basal cell carcinoma. Histiocytoma or sclerosing angioma may also cause clinical confusion. The latter are usually a yellow-brown colour, due to both iron pigment and melanin and are well tethered to the overlying epidermis, giving the so-called dimple sign—if the lesion is compressed laterally, the epidermis is seen to be tethered to the underlying dermis. However, this is not specific, and an excision biopsy should be carried out if there is any clinical concern.

Lentigo maligna melanoma [7]. In this histogenetic variant, the preceding horizontal or *in situ* growth phase is the lentigo maligna (Hutchinson's melanotic freckle; melanosis circumscripta precancerosa of Dubreuilh). By comparison with the horizontal growth phase of the superficial spreading melanoma, this is a much more prolonged period of lateral extension. Most occur on the face, commonly on the upper cheek, temple or forehead. Ocular structures may be involved in the process. A small proportion of lentigo maligna melanomas are observed on extrafacial exposed sites such as the hand or leg. Patients tend to be older than those presenting with the other types of melanoma and many of the risk factors suggest that the aetiology of this variety of melanoma has a greater similarity to squamous cell carcinoma than to the other melanoma variants.

Initially the lentigo maligna is a flat, brown or black, irregularly shaped lesion. These lesions will grow very slowly, over months or years, and there may be central regression while the peripheral margin continues to extend. In time, a raised central nodule will develop (Fig. 38.28) indicating transition to the vertical growth phase.

Two lesions that may require inclusion in the differential diagnosis of early lesions are pigmented actinic

(a)

(b)

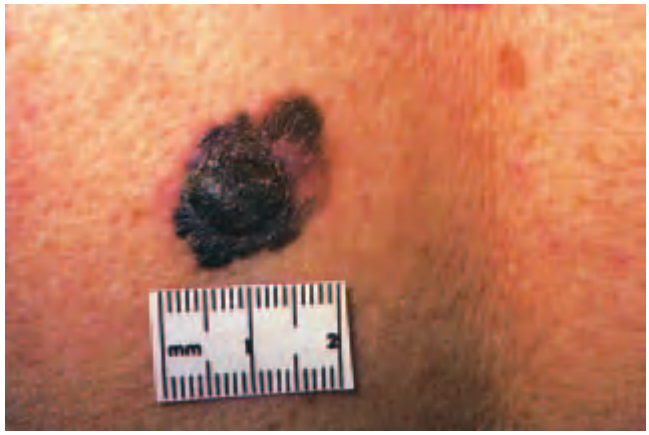

Fig. 38.27 (a) Distant and (b) close-up view of malignant melanoma on the lower back of a male patient. The second large lesion in the distant view is a seborrhoeic keratosis. Note the fact that here a nodule has developed in a pre-existing superficial spreading malignant melanoma.

keratoses and the flatter variant of seborrhoeic keratoses. Both tend to have more surface scaling, lack a visible melanin pigment network and have a dull, non-reflective surface.

Acral lentiginous melanoma (palmoplantar malignant melanoma) [3,8]. This type of melanoma comprises around 10% of all melanomas on white skin but over 50% of all melanomas on darker-skinned races [9]. The lesions are found mainly on the sole of the foot but also on the palm

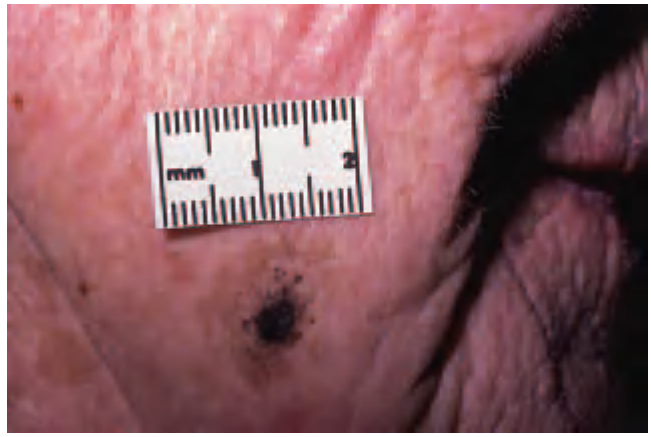

Fig. 38.28 Lentigo maligna melanoma. Note the elevated nodule in the centre of macular pigmented area.

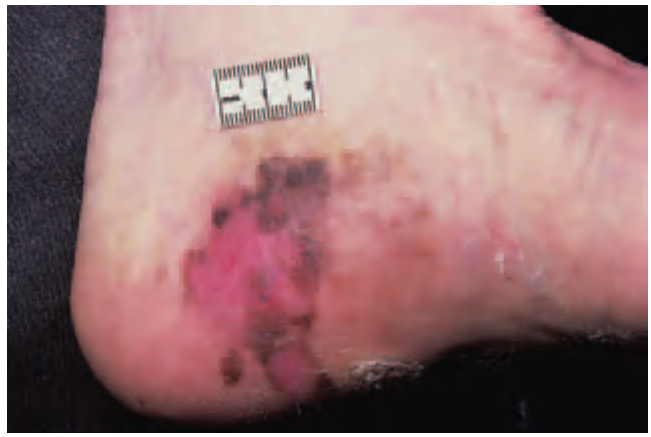

Fig. 38.29 Acral lentiginous melanoma on the sole of the foot.

of the hand, and are characterized, as their name would suggest, by a large, macular, lentiginous pigmented area around an invasive raised tumour. Approximately 50% of all melanomas on the foot come into this category (Fig. 38.29).

The clinical differential diagnosis may include a plantar wart, which is a common cause of delayed diagnosis, and black heel (talon noir) (Chapter 22), due to haemorrhage into the superficial layers of the epidermis. Any tender growing nodule on the sole of the foot should give rise to concern that the lesion is a melanoma and a biopsy considered.

Subungual malignant melanoma [10]. These lesions are commonly diagnosed at a late stage in development because of earlier confusion with a benign melanocytic lesion, a traumatic haemorrhage under the nail, pyogenic granuloma [11], persistent paronychia, a fungal infection or even a subungual wart. Any pigmentation of the nail bed should be examined with great care, particularly if there is

Fig. 38.30 Subungual melanoma causing destruction of the nail. Note the pigmentation on the nail fold.

full-length involvement of the nail and if the nail fold is also affected. This is known as Hutchinson's sign.

As the melanoma continues to grow, the nail is destroyed (Fig. 38.30).

Mucosal melanoma. Mucosal melanomas are rare, but can be seen in the oral cavity, on the genital mucosa and in the perianal area. The most common presenting feature of mucosal melanoma is the presence of extensive, irregular macular pigmentation. This may be extensive but spotty and may extend laterally for years before becoming elevated. Such lesions should be biopsied without delay, although clinically they may look deceptively benign (Fig. 38.31).

Secondary melanoma with no obvious primary site [12]. About 5% of cutaneous melanomas present as an isolated, usually non-pigmented, subcutaneous or dermal nodule with no primary source of the tumour apparent. In such a situation, the possibility of an ocular or mucosal primary tumour should be carefully investigated.

A further possibility in such a situation is that the primary lesion has undergone spontaneous regression, and examination of the skin distal to the secondary nodule may reveal a depigmented area suggestive of regression. In many cases, the site of origin is never identified.

Depigmentation in relation to malignant melanomas. Haloes of depigmentation are occasionally seen around primary malignant melanoma. As they may also occur around benign pigmented lesions, their presence is not diagnostic of malignant melanoma. The haloes around benign lesions tend, however, to be more symmetrical, whereas those around a neoplastic lesion may be highly irregular. The significance of this is not yet clear, but they may be

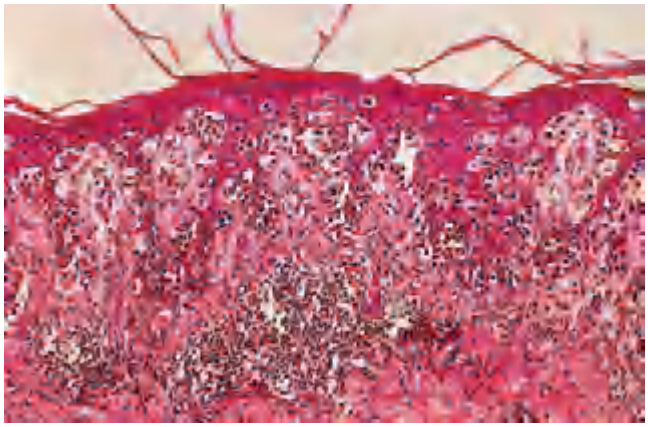
Fig. 38.31 Vulvar melanoma. This lesion is obviously deeply invasive and has a poor prognosis.

related to the immunological mechanisms known to be active, particularly in patients with early disease. It has been suggested but not yet confirmed that depigmentation around a primary tumour may be associated with a good prognosis.

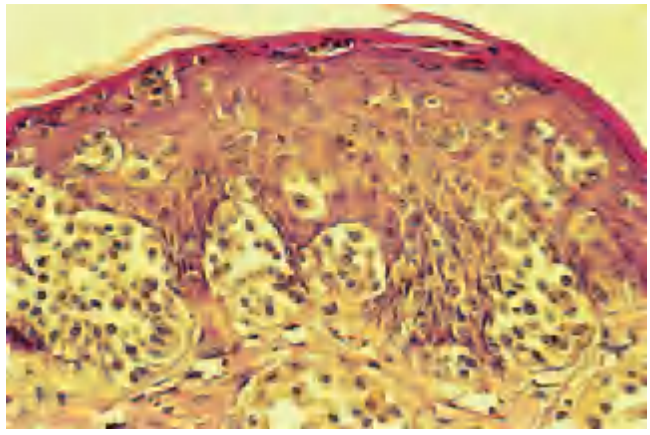
Multiple primary malignant melanomas [13,14]. At present around 5% of patients who have already had one melanoma diagnosed will develop a second and possibly a third or further primary melanoma. For patients who have had a thin melanoma diagnosed, the risk of a second primary melanoma is greater than the risk of the first melanoma metastasizing. Patients who have a family history of melanoma comprise about 50% of those who develop multiple primary melanomas, and a small number will have mutations in the *CDKN2A* gene. An importance consequence of this high incidence of second primary tumours is in follow-up regimes (p. 38.37). It is vital to look for a second primary melanoma on routine follow-up visits with as much if not more suspicion than it is to palpate for enlarged lymph nodes.

Pathology

Essential diagnostic features of malignant melanoma. The essential pathological feature for the diagnosis of primary cutaneous malignant melanoma is the presence of cytologically malignant melanocytes invading the dermis. Similar cells may also be seen in the overlying epidermis



(a)



(b)

Fig. 38.32 (a,b) Histology of superficial spreading melanoma showing striking pagetoid invasion of the overlying epidermis.

and also in the epidermis lateral to the invasive component. Additional supportive microscopic evidence that the lesion is melanoma rather than a benign melanocytic naevus is the presence of ulceration, a lack of maturation of the cells comprising the dermal component, the presence of a lymphocytic infiltrate, the presence of atypical mitoses, particularly in the deeper melanocytic cells, and apparent angiogenesis at the base of the lesion.

Superficial spreading or pagetoid melanoma [5]. The essential pathological features are the presence of a focus of malignant melanoma cells invading the dermis with areas of *in situ* malignant change in the adjacent epidermis. This consists of the presence of cytologically atypical melanocytes in the suprabasal layers of the epidermis, both singly and in clumps (Fig. 38.32). On H&E sections, the pattern may be very similar to that seen in extramammary Paget's disease, and the term pagetoid melanoma may therefore also be used to describe this lesion.

The verrucous variant [6]. This is characterized by gross hyperkeratosis and also epidermal hyperplasia. The significance of this lesion is the fact that it is not usually recognized clinically because of the hyperkeratosis, and it may be confused with both benign and malignant lesions derived from the keratinocyte, such as a seborrhoeic keratosis or a squamous cell carcinoma.

Nodular melanoma. The nodular melanoma has the pathological features of a focus of invasive melanoma cells in the dermis with direct contact with the immediately overlying epidermis, and no morphological abnormality apparent in the adjacent epidermis on either side of the invasive nodule. An alternative term therefore is primary malignant melanoma with no recognizable adjacent *in situ* or horizontal growth phase [1]. These lesions frequently grow relatively rapidly. There is a tendency to use the term nodular melanoma inappropriately for any primary melanoma that has a visible nodule. This is incorrect usage, as superficial spreading, acral and lentigo maligna melanomas can all develop elevated nodular areas in the course of later growth.

Lentigo maligna melanoma [7]. This variant of melanoma is the most distinct. It is found on chronically light-exposed skin, usually the face, and has a long preinvasive or horizontal growth phase during which there is striking lentiginous replacement of the basal keratinocytes by atypical melanocytes, but no downward invasion into the underlying dermis, which will show actinic damage of the dermal collagen. During this phase, the names **lentigo maligna**, Hutchinson's melanotic freckle and premalignant melanosis of Dubreuilh are all appropriate. There is also often extensive colonization of the hair-follicle epithelium by atypical melanocytes. After a variable period of time, invasion into the underlying dermis will take place. The site of such early invasion in its earliest stages may be marked by a lymphocytic infiltrate. Once obvious dermal invasion is present, the name **lentigo maligna melanoma** is appropriate.

Acral lentiginous melanoma [8]. About 50% of melanomas arising on the non-hair-bearing areas of the palms and soles have pathological features that do not allow them to be easily classified into Clark's original three variants. This was recognized by Reed who introduced the term acral lentiginous melanoma in 1975. The essential pathological features are the presence of an extensive area of lentiginous change in the epidermis around the focus of invasive primary melanoma. Very often this lentiginous area is very easy to identify, but the invasive focus is small and difficult to find, requiring cutting of many sections. The basal keratinocytes are replaced by cytologically malignant melanocytes, and there is often an associated inflammatory flare of lymphoid cells in the underlying dermis. An important feature is the presence of skip areas, with foci of relatively normal epidermis in areas of gross lentiginous change. This feature makes it particularly

important to examine the excision specimen thoroughly to determine whether or not the lesion has been completely excised.

Primary melanomas arising on the mucosal surface of the oral cavity, the vulvovaginal and the rectal areas have some features in common with acral lentiginous melanomas, and the term palmoplantar mucosal melanoma is sometimes used to describe the entire group. Extensive lentiginous change is frequently visible, both clinically and pathologically, and the focus of invasion may be very difficult to find, even in the presence of obvious metastases.

Desmoplastic neurotropic and myxoid variants [15–18]. The desmoplastic variant of malignant melanoma is frequently seen in association with chronically sun-damaged skin and overlying lentigo maligna in the epidermis. As the name suggests, this is a combination of malignant melanocytes in association with extremely dense desmoplastic change of the dermis. The stromal change in the dermis is usually much more obvious than the malignant melanocytes, which may be few in number. The pathological importance of this variant is the fact that it can be difficult to be absolutely certain that excision is complete, and local recurrence is a common problem. Two studies have reported that malignant melanocytes in these lesions stain less reliably with the antibodies NKI C3 and HMB 45, both antibodies used commonly to identify melanoma cells on tissue sections. One study suggests that desmoplasia is associated with a statistically significantly better survival [19], while another finds no survival difference [15].

A pathological variant sometimes coexisting with the desmoplastic pattern is the neurotropic melanoma [20]. In this variant, the pattern of metastatic spread is along the cutaneous nerve trunks. This is seen particularly in lesions on the head and neck area, and may cause severe, relentless pain. As with the desmoplastic variant, completeness of excision can be difficult to determine.

Myxoid melanoma is a rare variant in which there is a striking myxoid stroma in the dermis surrounding malignant spindle cells. The morphological features have some features in common with desmoplastic melanoma [21].

Naevoid melanoma (minimal deviation melanoma, small cell melanoma) [22,23]. A further pathological variant is the so-called naevoid, minimal deviation or small cell melanoma. These lesions lack epidermal involvement, are fairly well defined at their lateral margins, and the small naevoid cells in the dermis, which make up the bulk of the tumour, show partial differentiation. However, careful examination will reveal the presence of abnormal mitoses in naevomelanocytes. These lesions may be confused with compound naevi.

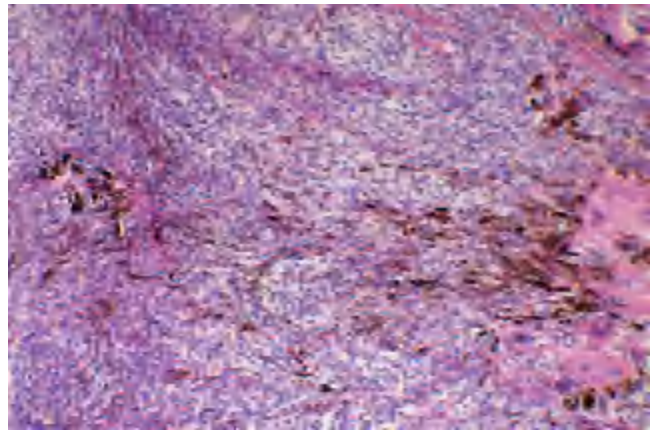


Fig. 38.33 Pathology of melanoma of the soft parts. Note the eosinophilic cytoplasm and also the pigmentation.

Animal-type melanoma. This is a rare pathological variant of melanoma which, as the name suggests, has some morphological similarities to melanoma found in grey horses. Blue-black nodules are the clinical presenting feature, and the pathology shows heavy dermal melanin pigmentation with sheets of atypical spindle cells, which may be difficult to visualize without bleaching because of the quantity of pigment present. The epidermis is usually, but not always, involved and mitotic figures may be difficult to find. Metastases to both regional nodes and to distant organs may occur [24].

Melanoma of the soft parts (clear cell sarcoma). This is a further rare pathological variant of malignant melanoma. The tumours usually arise on the tendons and aponeuroses. The ankle appears to be a relatively common site, and the tumours generally appear in young people. There appears to be no epidermal component, which gives rise to diagnostic confusion with various types of sarcoma, but the malignant cells contain premelanosomes and melanosomes. Plump, pale spindle cells with clear cytoplasm are seen in the tendons (Fig. 38.33). They may be deceptively bland on microscopy as mitotic figures are difficult to find, but both local recurrence and distant metastases are relatively common [25–27].

Wide excision and amputation may be required.

Vulvar and vaginal melanomas. These tumours are also discussed on page 38.29. They are rare variants of melanoma, which usually present late with vaginal bleeding. They are relatively common vulvar tumours, and the average age at presentation is in the seventh decade, significantly older than for cutaneous melanomas. A mass will be present and on biopsy the majority of the tumours are of the nodular type of melanoma. Vascular invasion and nodal involvement are both common at the time of diagnosis.

The prognosis is poor, presumably related to the late stage at presentation [28,29].

Differential diagnosis. There are two quite distinct problems in pathological differential diagnosis of primary malignant melanoma. The first is the benign melanocytic naevus and the second is non-melanocytic but malignant tumours, either primary or secondary. These are more often a problem when a clinically indeterminate large nodule is excised.

The differentiation between benign and malignant melanocytic lesions rests on both the pattern of involvement and the cytological features of individual cells. The association of cytologically atypical melanocytic cells in the upper layers of the epidermis with apparent proliferation at the dermal–epidermal junction and invasion of the underlying dermis by atypical melanocytic cells is a malignant pattern. The cells in the deeper areas of the dermis will show no maturation such as is seen in a benign naevus with dermal involvement. The cytological characteristics of malignancy are a high nuclear to cytoplasmic ratio, intense nuclear staining, size variation between adjacent cells and the presence of abnormal mitotic figures.

Two of the more difficult pathological differential diagnoses in this area lie between the halo naevus [30] or Spitz naevus and malignant melanoma. It is unusual for a melanoma to elicit as intense a lymphocytic response as the halo naevus, but a careful search should be made through the lymphocytic infiltrate for cytologically malignant cells, particularly if the clinical information available does not suggest a halo naevus.

The differentiation between malignant melanoma and Spitz naevus can be extremely difficult. Features suggesting that the lesion is a melanoma and not a Spitz naevus are an asymmetrical lesion with a poorly defined lateral margin, the presence of abnormal mitoses in the melanocytic cells, lack of any maturation or differentiation in the deeper naevus cells, and an epithelioid cell pattern with striking lack of adhesion of one cell to the other. These features are not absolute, and there are times when it may be necessary to state that a firm diagnosis cannot be made on pathological grounds. In such cases excision and a period of follow-up are common practice.

A range of antibodies are currently in routine diagnostic use. They will confirm the melanocytic nature of the lesion, but cannot differentiate between benign and malignant melanocytic lesions. These antibodies include antibody to S 100 protein, HMB 45 and melan A/MART-1 [31].

Pathological prognostic features [1,32]. A large number of pathological features have been suggested as offering prognostic information. Tumour thickness was established by Alexander Breslow as the most valuable prognostic guide [33]. Blocks are cut from the apparently thickest area of the primary melanoma and the slides cut from this block are examined using an ocular micrometer to measure the distance between the overlying epidermal granular layer and the deepest invasive area of the primary lesion (Fig. 38.34). This figure in millimetres is the Breslow or tumour-thickness measurement and should be included in all pathology reports of primary melanoma. Thin primary melanomas are associated with females, a family or personal history of melanoma, large numbers of benign naevi and one or more atypical naevi, suggesting that educating those at greatest risk of developing a melanoma does result in earlier diagnosis [34].

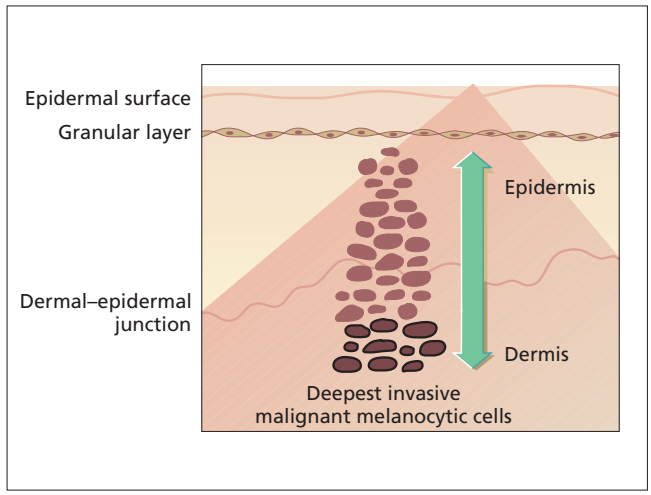

Fig. 38.34 Malignant melanoma thickness measurement (Breslow). The pathologist measures in millimetres the distance between the granular layer in the epidermis and the deepest invasive melanoma cell. (From Breslow [33].)

Ulceration, even if only microscopic, is an additional and independent, poor prognostic sign, and the mitotic count also varies inversely with survival [35]. The presence of tumour cells in vessels is a poor prognostic sign associated with both local and distant recurrence. Prominent tumour vascularity at the base of the primary melanoma has also been recorded as a statistically significant prognostic sign, lesions with increasing tumour vascularization showing a higher incidence of metastatic spread [36].

The levels of invasion into the dermis introduced by Clark *et al*. [2] are a similar way of relating extent of penetration of the primary lesion to prognosis. Clark's levels are as follows:

1 intraepidermal or *in situ*
2 a few cells in the papillary dermis
3 occupation and expansion of the papillary dermis by melanoma cells
4 invasion of the reticular dermis
5 invasion into fat

Five-year survival figures fall steadily with the deeper levels [37].

Regression in and around a primary melanoma is a sign of disputed prognostic value. The first reports associated regression in thin, primary melanomas with a poorer-than-expected 5-year survival [38], but since that time there have been several papers from other parts of the world both confirming and refuting this observation [39,40]. Part of the apparent disagreement may relate to the problem of definition of regression. This should include dermal change similar to either granulation tissue formation or scarring, a lymphocytic response, pigment-filled macrophages and free melanin, and also the presence of at least a few degenerating malignant melanoma cells.

There are currently a number of models available of melanoma prognosis designed to be applied to individual patients to give an accurate indication of the outlook for that patient. The best established and validated of these is the Clark model [41]. As these models are developed on series of patients in very different geographical areas who have varied phenotypic characteristics, it is necessary to validate them in different geographical areas before they are generally applied.

Prepubertal melanomas [1]

Malignant melanoma is extremely rare before puberty, although the incidence rises steadily in the second and third decades. Children with giant congenital naevi are at increased risk of developing melanoma, and approximately half of all the reported cases of prepubertal melanoma appear to have arisen in giant congenital naevi [2].

Very occasionally, melanomas may be present in neonates either spontaneously or as a result of transplacental metastases [3].

For pathologists, the difficult diagnosis is between the true Spitz naevus, commoner in children than adults, and

the spitzoid melanoma. This can be extremely difficult and there are occasions when it is virtually impossible, even if several expert opinions are sought [4]. In such situations, reasonably wide excision and careful follow-up is usually the safest compromise.

American Joint Committee on Cancer (AJCC) tumour node metastasis (TNM) staging system for cutaneous melanoma

The most recent TNM staging system for melanoma published by the AJCC is outlined in Table 38.3.

A provisional review [1] was followed by validation on a sample of over 17 000 patients [2] and the final version then published [3].

The major changes are, firstly, that Clark levels of invasion are not used in primary melanomas thicker than 1 mm. The overriding importance of tumour thickness has firmly established that Clark levels offer no additional information for these thicker tumours. Secondly, the presence of ulceration in patients with stage 1 or 2 disease advances the stage. In the N category, total number of affected nodes and their identification on clinical or pathological grounds replace gross dimensions of these nodes. In this section, data obtained as a result of sentinel lymph-node biopsy is also included (p. 38.36). In the M category, the site of distant metastases is now included, as is the presence of elevated lactic dehydrogenase.

Management of cutaneous malignant melanoma

This can logically be divided into clinical diagnosis, biopsy confirmation, definitive surgical excision, appropriate treatment of draining lymph nodes, routine follow-up of patients with melanoma apparently confined to the

Table 38.3 Current tumour node metastasis (TNM) classification for cutaneous melanoma.

Tumour T classification	
T1: ≤ 1 mm	a, no ulceration b, ulcerated or Clark level 4
T2: 1.01–2.00 mm	a, no ulceration b, ulcerated
T3: 2.01–4.00 mm	a, no ulceration b, ulcerated
T4: > 4 mm	a, no ulceration b, ulcerated
Node N classification	
N1: 1 lymph node	a, micrometastases b, macrometastases
N2: 2–3 nodes	a, micrometastases b, macrometastases c, in transit metastases or satellites without metastatic nodes
N3: > 4 metastatic nodes or combinations of satellites and or in transit lesions	
Metastases M classification	
M1: Distant skin, subcutaneous tissue or nodal metastases	Normal LDH
M2: Lung metastases	Normal LDH
M3: All other visceral metastases	Normal LDH
Any distant metastases with elevated LDH	Elevated LDH

LDH, lactate dehydrogenase.

primary site, management of nodal disease, management of patients with distant metastases and palliative care [1]. Dermatologists will mainly be involved with patients with stages 1 and 2 melanoma, but it is necessary to have a reasonable understanding of the likely further management of these patients by surgeons and oncologists. In the UK there is currently a policy to manage patients with stages 3 and 4 melanoma in specialized melanoma units in cancer treatment centres by a multidisciplinary team as part of a managed clinical network.

UK guidelines are available for the management of all stages of melanoma [2] and similar guidelines have been published for the USA [3] and the Netherlands [4]. Such guidelines are valuable provided they are regularly updated as new information becomes available.

Clinical diagnosis. Risk factors for melanoma are described on p. 38.23. The most likely patient is a white adult with pale skin which burns easily, and who has a history of excessive sun exposure. Males are most likely to have melanoma on the trunk, and females on the lower limbs. A positive family history is a strong risk factor, as is a personal history of a previous primary melanoma. Patients with large numbers of benign melanocytic naevi are also at increased risk. The patient will give a history of a new or pre-existing pigmented lesion that is changing in size, shape or colour. Some early melanomas have slight altered sensation described by patients as a minor itch. The melanoma is likely to be 5–6 mm in diameter and to have an irregular lateral outline. It may be composed of several shades of brown, black, red and blue.

The two commonest clinical differential diagnoses are benign melanocytic naevi in younger adults and seborrhoeic keratoses in older adults. Benign naevi are usually smaller than melanoma, have a regular oval or circular outline, and are a uniform shade of brown. Seborrhoeic keratoses are dull, non-reflective lesions, which have a hyperkeratotic surface and a tendency to crumble. They are usually multiple and found mainly on the trunk.

Dermatoscopy (epiluminescence microscopy). This technique involves the examination of the surface of the pigmented lesion at moderate magnifications using the hand-held dermatoscope, having first 'cleared' the epidermal surface with oil. With this technique it is possible to see the distribution of melanin in the epidermis and superficial dermis in great detail. The technique is currently widely used in certain European countries, such as Germany and Austria, and in Australia. There are now three published atlases giving detailed descriptions of the dermatoscopic appearance of malignant melanoma, of benign melanocytic naevi and of other non-melanocytic pigmented lesions which may require to be included in the differential diagnosis [1–3]. Few dermatoscopic features are totally specific for melanoma but certain are found more frequently in melanoma than in benign naevi. These include peripherally situated black or brown dots and globules, a blue-white 'veil' appearance over the lesion, irregular pseudopods of pigment and asymmetric parallel linear extensions of pigment at the margin referred to as 'radial streaming'. A lace-like melanin pigment network is seen in both benign and malignant melanocytic lesions and is therefore not a useful discriminating feature. This network can, however, be seen to be broadened and irregular in melanoma. Some non-melanocytic lesions have a characteristic appearance on dermatoscopy, including vascular lesions and basal cell carcinomas. Angiomas are relatively easy to identify with the small capillaries being clearly seen through the epidermis. Basal cell carcinomas often have a characteristic clover leaf pattern of bluish pigmentation, which represents dermally situated melanin or altered blood trapped within the basal cell carcinoma cell nests. Seborrhoeic keratoses show clearly the keratin pits, which can be seen with the naked eye on their surface.

The technique of dermatoscopy is simple but interpretation of the patterns visualized requires some training and experience [4]. The best approach is to use the hand-held dermatoscope with a camera attachment (Dermaphot™), and record all lesions to be excised both with a conventional camera and with the Dermaphot™. These two images can then be studied when the pathology of the lesion is established.

There are also currently a number of computerized image analysis systems in development to aid preoperative diagnosis of malignant melanoma. These include the Mole Max system™ and spectrophotometric intracutaneous analysis using the siascope [5]. The absolute value of these machines in increasing both sensitivity and specificity of preoperative diagnosis of melanomas, thus reducing the number of unnecessary removals of benign naevi in routine practice, is not yet established.

Biopsy. All patients with suspected malignant melanoma should have an excision biopsy of the lesion carried out with a narrow surrounding cuff of 1–2 mm of clinically normal skin. This will enable the pathologist both to confirm the diagnosis and also to measure the thickness of the melanoma, which is an essential guide to further management. In rare situations when an excisional biopsy is not practical, such as a large possible melanoma on the face, an incisional biopsy from the area of the lesion which appears to be most invasive is acceptable, provided any necessary definitive surgery follows within 1–2 weeks. Punch biopsies should not be routinely performed in suspected melanoma as a false tumour thickness may be obtained due to biopsy trauma and there is a theoretical risk of displacing melanoma cells deeper into the dermis. The surgeon should measure accurately the clinical excision margins, as biopsy samples shrink by 20–30% during fixation in formalin and the pathologist may report a narrower margin than was excised. It is the clinical rather than the pathologically measured excision margins that should be used in decisions concerning further surgery.

This biopsy should be ribboned by the pathologist and examined in total. Features required in the biopsy report are the diagnosis, the apparent completeness of excision, the tumour thickness, histogenetic type, presence of ulceration, presence of regression and an estimate of the number of mitoses both normal and abnormal in the tumour. Clark levels add little prognostic information for thicker primary melanomas, but should also be included, particularly for melanomas less than 1 mm in thickness, as Clark level 4 lesions in this thickness range appear to have a worse prognosis than level 3 lesions. It is also important to report the presence of regression if observed as this may influence decisions on the width of definitive excision.

In some cases there will be pathological evidence of a pre-existing benign melanocytic naevus on which the melanoma has developed. In these cases the pathologist may feel it necessary to give two tumour thicknesses, one measuring the entire thickness of the lesion and one measuring only to the deepest obvious tumour cell, ignoring any deeper apparent naevus cells.

Definitive surgical treatment to the primary site. Once the diagnosis of primary malignant melanoma is established, and the thickness of the melanoma has been measured, the definitive excision can be planned. The extent of this excision will relate to the tumour thickness. At present, if the diagnosis is of a level 1 or *in situ* melanoma, a margin of only 2–5 mm of surrounding normal skin is considered adequate. This may have been included in the diagnostic biopsy and therefore no further surgery may be necessary [1].

Invasive melanomas up to 1 mm thick require an excision margin of 1 cm, those 1–2 mm deep require a margin of 2 cm of clinically normal skin, and thicker tumours require a maximum margin of 3 cm of clinically normal skin [1]. There is no evidence that a wider margin of clinically normal skin improves survival for patients with thicker tumours. Most melanoma excisions can be closed directly, and skin grafts are nowadays rarely needed. Thus melanoma surgery is commonly a day case procedure carried out under local anaesthesia.

Patients with lesions on the fingers and toes may require amputation through the distal joint to achieve adequate clearance.

Further investigations. There is currently no evidence to support extensive staging investigations other than sentinel node biopsy (see below) for patients with stage 1 or 2 melanoma [1].

Sentinel node biopsy. In the past decade, Morton and his colleagues have initiated large clinical trials to establish whether or not the technique of sentinel lymph-node biopsy, to assess the need for further surgery to the lymph-node basin, confers a survival advantage for patients with primary malignant melanoma still apparently confined to the primary site [1]. The results are awaited.

The principle behind the technique is the observation that a proportion of patients with thicker melanomas will have occult lymph-node metastases that are not clinically detectable on palpation. Studies on animal models have suggested that the drainage of tumour cells into a nodal basin such as the axilla or groin follows an orderly pattern with the most distal node, henceforward referred to as the sentinel node, trapping tumour cells first, prior to spread proximally to the other nodes in the area [2]. Thus, sampling this sentinel node would determine the need for further nodal surgery. A negative sentinel lymph-node biopsy would indicate that the proximal nodes would be clear of tumour and therefore that full node dissection was unnecessary. In contrast, a sentinel node containing tumour cells would indicate that the more proximal nodes might contain tumour and that a full lymph node dissection of the area was justified [3–8].

The technique requires three technical skills. These are lymphoscintigraphy to identify the lymphatic drainage pattern from the site of the primary melanoma, the surgical skills involved in injecting radiolabelled colloid and/or blue dye at the site of the primary melanoma to identify the sentinel node using a hand-held gamma probe (neoprobe), and the pathological skills to identify

what may be very small numbers of melanoma cells within a node biopsy and differentiating these melanoma cells from benign naevus cells which are found in around 10% of lymph nodes. There are detailed recommended protocols available for the handling of sentinel node biopsies to obtain maximum information using both conventional haematoxylin and eosin staining and also relevant antibodies in immunohistochemistry [9].

The technique of sentinel node biopsy is thus labour intensive and therefore expensive.

Careful studies of the frequency of positive sentinel nodes in melanomas of increasing thickness have established that melanomas less than 1 mm thick or of Clark levels 2 and 3 rarely yield positive sentinel nodes so the technique is not justified in these thin tumours. There is an increasing yield of positive sentinel nodes in thicker tumours, with a yield of around 30% positivity in patients with primary melanomas greater than 3 mm thick. In most published series, the yield of non-sentinel nodes containing melanoma following a positive sentinel node is 15–20%. At present sentinel node biopsy is a valuable staging technique in centres that have the trained personnel and resources to perform it. Results of the two large trials currently nearing completion will determine whether or not advancing the time at which the diagnosis of melanoma in the draining nodes is made offers the patient a survival advantage. Until these results are available, sentinel node biopsy should be considered a technique under evaluation rather than the current standard of care. It has, however, become a required investigation for entry into some adjuvant trials.

Follow-up after surgery for stage 1 or 2 melanoma. Patients who have had surgery for primary melanoma with no evidence of spread beyond the primary site have traditionally undergone a period of hospital-based follow-up at varying intervals for a varying number of years. The three main purposes of this follow-up are to detect any local recurrence around the scar of the excised melanoma, to palpate the local draining nodes for any clinically detectable evidence of nodal spread and to examine the rest of the skin surface for a second primary melanoma. Accepted intervals and duration of follow-up are 3-monthly intervals for 3–5 years. As, however, there is no evidence that this routine follow-up examination advances the time of diagnosing metastatic spread, and the majority of recurrences are detected between such visits, these intervals can be interpreted according to the needs of individual patients and the geographical situation. All patients should be taught how to look for local recurrence, how to palpate the relevant area for enlarged nodes, and be made aware of the clinical features which would suggest a second primary melanoma. They should have information about an appropriate contact in case they detect possible recurrence between regular appointments.

Patients with only an *in situ* melanoma do not require to be placed on a follow-up regime but can be discharged after appropriate surgery.

Management of clinically involved lymph nodes. Patients who have palpable regional lymph nodes are highly likely to have metastatic spread in these nodes. Normal practice is to carry out a fine-needle aspirate or an open node biopsy to obtain pathological confirmation. If the pathology shows melanoma cells, a CT scan of the chest, abdomen and pelvis should be arranged to establish whether there is spread beyond the draining nodes. It is not normal practice in the UK to include a routine head and neck scan in asymptomatic patients, although this is a requirement prior to entry into some trials of adjuvant therapy. The patient should then have a full node dissection of the involved nodal basin. The number of nodes involved has been shown to affect prognosis and so this should be reported by the pathologist, as should the total number of nodes excised. Thereafter the patient should be followed up at 3-monthly intervals, or considered for randomization into ongoing trials for stage 3 disease. Appropriate investigations such as chest X-ray and CT scans should be arranged according to signs and symptoms.

Adjuvant therapy for patients with stages 2 and 3 melanoma. At present there is no proven effective adjuvant non-surgical therapy for these patients which has been shown to increase overall survival time. There have been several well-conducted randomized controlled trials using interferons and vaccines. Trials of interferon (IFN) have been in progress for the past decade and results of these trials involving around 5000 patients have been published

[1–7]. The dose of IFN, treatment schedule and duration of therapy is very variable, ranging from 1 million units given subcutaneously thrice weekly for 6 months to high-dose regimes involving megaunits of IFN given daily intravenously for 4 weeks and thereafter high maintenance doses for 11 months. Although some of these trials report early results of an increased disease-free interval in the IFN-treated group, only one trial has shown an effect on overall survival time from diagnosis [2], although the confirmatory study proved negative [5]. At present, patients with stage 2 or 3 melanoma should be considered for entry into available trials of IFN.

Trials of vaccines given as adjuvant therapy have not yet shown any survival benefit. Vaccines used have included an allogeneic tumour vaccine [8] and two vaccinia viral lysates [9,10]. None have shown improved survival, although tests of immune function have indicated an immune response to the virus.

Management of patients with stage 4 disease

This will be mainly carried out by an oncologist who is part of a melanoma management team and who has an interest in melanoma. Even when stage 4 disease is obvious, accurate staging is still worthwhile, as if the disease burden is limited to, for example, one lung or one area of the gastrointestinal tract, further surgery to these isolated lesions may offer worthwhile palliation. This also applies to isolated cerebral metastases, and patients who are otherwise fit with cerebral metastases should be rapidly referred to a neurosurgical unit for evaluation for surgery, usually followed by radiotherapy.

The AJCC TNM staging revision has clearly indicated that patients with metastatic spread to certain areas, including the lungs and soft tissue, have a better outlook than those patients with spread to the liver or central nervous system. Lung and soft tissue lesions tend to be more responsive to chemotherapy, but even for these patients such responses are rarely complete and tend to be of short duration.

No chemotherapeutic agent gives a high proportion of complete responses in melanoma. The current chemotherapeutic agent of choice is dacarbazine (DTIC), which gives around a 20% overall response rate [1–3]. With modern antiemetics DTIC is relatively non-toxic and can be given as a day case, usually at 3-week intervals. Patients should be assessed for response after 4–6 courses. There is no evidence that combination therapy with DTIC and other chemotherapeutic agents or with IFN increases the response rate or the duration of response achieved by DTIC alone [4,5].

Patients with recurrent disease confined to one limb may obtain an extended disease-free interval with arterial perfusion [6–11] or infusion with melphalan or tumour necrosis factor-α, but a large controlled trial has demonstrated no survival benefit for this treatment used in an adjuvant or prophylactic setting for thick, poor-prognosis primaries on a limb.
