Two controlled studies [5,6] suggested that the use of systemic corticosteroids during the acute episode of herpes zoster might reduce the risk of developing post-herpetic neuralgia, and in neither was generalized herpes zoster a problem. However, a recent systematic review [7] concluded steroids not to be of proven efficacy, and this was borne out in a recent randomized open trial [8]. Given its immunosuppressive effects, and potential for serious complications, systemic corticosteroids are not recommended.

In older adults with localized herpes zoster, oral aciclovir (800 mg five times daily for 7 days) reduces acute pain and healing times if treatment is initiated within 72 h of the onset of the eruption [9]. A reduction in ocular complications, particularly keratitis and anterior uveitis, occurs with treatment of herpes zoster ophthalmicus [10]. A recent systematic review of four placebo-controlled trials of oral aciclovir showed only marginal evidence for pain reduction after herpes zoster. Famciclovir and valaciclovir significantly reduced the duration but not the incidence of post-herpetic neuralgia, in one placebo-controlled trial for each agent. Famciclovir (500 mg three times daily for 7 days) or valaciclovir (1000 mg three times daily for 7 days) may provide more prompt relief of zoster-associated pain than aciclovir in acute herpes zoster in older adults (over 50 years of age) [11].

In immunocompromised patients with herpes zoster, intravenous aciclovir (500 mg/m^2/8 h for 7 days) reduces viral shedding, healing times, the risks of cutaneous dissemination and visceral complications, as well as the length of hospital stay in disseminated zoster [12].

Management of established post-herpetic neuralgia [13]

In mild and moderate cases of established post-herpetic neuralgia, simple analgesics help, but in severe cases they may have little effect. Opioids should probably be prescribed for resistant pain not coming under control with other drugs (below). Controlled-release oxycodone at a dose of 10–30 mg 12-hourly was shown to be effective in a randomized placebo-controlled study for steady-state, paroxysmal spontaneous pain and allodynia [14]. Tramadol, a centrally acting analgesic with both opioid and non-opioid activities, seemed to work well in a pilot study up to a maximum dose of 600 mg daily [15].

The most effective drugs include antidepressants and anticonvulsants (membrane-stabilizing drugs). In a placebo-controlled trial, amitriptyline was shown to be superior to placebo, with about 60% of patients experiencing a good response to the active drug [16]. Pain relief was achieved with a relatively low dose. At a dose of around 70 mg/day, some 60% of patients experienced a good

result with reduction of pain from severe to mild, and 14% had no pain. Most patients complained of side effects including dry mouth, drowsiness, constipation or urinary hesitancy. Other antidepressants recommended for post-herpetic neuralgia include desipramine, nortriptyline and maprotiline. Of these, nortriptyline [17] and desipramine [18] were shown to be effective in randomized controlled trials, whereas a controlled trial showed no advantage of maprotiline over amitriptyline [19]. While anticonvulsants such as sodium valproate, phenytoin, carbamazepine and clonazepam are frequently advocated for shooting or lancinating pain, others have claimed that these drugs are unproven and relatively ineffective [20]. The new anticonvulsant drug, gabapentin, has been shown in a randomized, double-blind placebo-controlled trial to reduce post-herpetic neuralgia pain [20]. The mechanism of action of gabapentin is unknown, but it does not interact with any known neurotransmitter receptors and specifically it is not a γ-aminobutyric acid (GABA) agonist, unlike its close relative, baclofen. To date, there are no studies directly comparing gabapentin with antidepressants, but it is considered as least as effective and safe as the antidepressants but with fewer side effects [3]. The results of these studies support the use of gabapentin as a first-line medication in the treatment of chronic neuropathic pain syndromes such as post-herpetic neuralgia. Other drugs reported to be of help are clonidine and lamotrigine, although, as yet, no controlled trials have been carried out on these drugs [3]. Randomized controlled trials of capsaicin, at either 0.025 or 0.077% applied 3–4 times per day, have been shown to be effective [21]. The use of topical 5% lidocaine (lignocaine) patches either worn for around 12 h/day [22], or applied up to four times per day [23], has been shown to be efficacious, well tolerated and associated with low systemic absorption. Other treatments that have been reported to produce benefit in some patients include baclofen [24] and weekly lumbar intrathecal injections of methylprednisolone and lidocaine [25].

Surgical treatments have been tried in the past, including division of the dorsal root or tractotomy, or ablation by injection of the ganglion or sensory root, but these are not advocated due to limited efficacy and the high rate of morbidity [3]. Spinal cord stimulators have been used with variable results and transcutaneous stimulation (TENS) may be helpful, but proper trials seem lacking [26]. There seems to be no good evidence to support a role for acupuncture in treating post-herpetic neuralgia [27].

Neuropathic ulcers

Neuropathic ulcer is a form of chronic ulceration, also known as 'perforating ulcer', which develops in anaesthetic skin. Characteristically neuropathic ulcers are painless, persistent and uninflamed, appearing on areas subject to trauma or pressure.

Aetiology. While a number of neurological disorders may cause neurotrophic ulcers, the vast majority occur in

Fig. 60.5 Clawing of feet occurring in neuropathic foot with painless damage to skin on great toe.

patients with type II diabetes [1,2]. Other causes include leprosy, peripheral neuropathy, alcoholism, vitamin deficiencies, pernicious anaemia, syringomyelia, tabes dorsalis, spinal dysraphism, spinal cord injury and hereditary sensory and autonomic neuropathies [3,4].

Neuropathic ulcers result from a distal polyneuropathy encompassing motor, sensory and autonomic components.

Motor involvement leads to weakness of the intrinsic muscles of the feet and an imbalance between the long flexor and extensor tendons, leading to a typical cavus or high arched foot along with clawing of the toes (Fig. 60.5) [5]. This combined with arch collapse, leads to the 'rocker-bottom foot', which is prone to tissue break down and ulceration. The plantar aspect of the foot is protected by fat pads, which anticipate weight-bearing forces in all directions. Increased pressure under the metatarsal heads and heel, the sites of around 90% of such ulcers, results in high pressure with initial callosity leading to ulceration. In the majority of patients, a palpable pulse in the affected foot is an indication of good vascular supply. However, the presence of rest pain, diminished or absent pulses, pallor on elevation and sluggish refilling of toe capillaries, together with trophic signs in the skin, are highly indicative of ischaemic ulcers. The associated sensory neuropathy allows the patient to injure the foot, either suddenly by standing on sharp objects such as pins or glass, or gradually, for example from pressure within a poorly fitting shoe, without the patient being aware of the damage. Autonomic neuropathy leads to a foot with loss of sweating, leading to dryness with fissuring and cracking and changes in the normal microcirculation autoregulation. Such cracks or fissures allow a portal of entry of infection. In the diabetic foot there is an impairment of the neurogenic vasodilator response, or flare, which correlates with the clinical diminution in pain sensation. It is likely that loss of both components of the nociceptive C-fibre function, both neurological inflammation and pain sensation, is an important factor in the development of foot complications in diabetes. Diabetics have been demonstrated as having a defect of unmyelinated nociceptive C fibres on the soles of their feet, leading to loss of nociceptive function and the development of both neuropathic plantar ulcers and neuroarthropathy. As sympathetic tone is lost, increased peripheral blood flow leads to arterial venous shunting, with blood bypassing the capillary bed, thereby reducing nutritive skin blood flow [6].

Clinical features. Primary neuropathic limbs tend to be warm, insensitive and prone to ulceration on the sole of the foot, while neuroischaemic limbs are usually cool, discoloured and prone to ulceration on the foot margins [2]. Neuropathic ulcers typically occur under the metatarsal heads or heel, surrounded by thick, hyperkeratosis, and have a pink punched out base that bleeds easily and is painless (Figs 60.6 & 60.7). The foot is warm with palpable

Fig. 60.6 Typical neuropathic ulcers with surrounding hyperkeratosis under metatarsal heads.

Fig. 60.7 Neuropathic ulcer with hyperkeratosis removed.

Fig. 60.8 Bailey® nylon monofilament assessing sensory loss on neuropathic foot.

pulses and the changes include pes cavus, warm, dry and insensitive foot with dilated veins, clawed toes and hyperkeratosis under the forefoot and heel [2]. In diabetic patients, there may be a complex interplay of neuropathy and ischaemia, and when the latter is present, the foot may be cold with absent pulses, hyperkeratosis and a dark fibrotic base that does not bleed easily and is painful to touch. In the neuropathic ulcer, the sensations of light touch and vibration and sharp–blunt discrimination are reduced, which can be demonstrated using a Bailey® nylon monofilament (Fig. 60.8), which buckles in response to 10 g force, neurotheissometer and Neurotip® [7], respectively. Absent pulses suggest ischaemia. Falsely high ankle–brachial pressure indices may occur, especially in diabetics, as a result of non-compressible calcified vessels.

A frequent complication is the presence of cellulitis or deep infection with abscess formation or osteomyelitis. One study found that Gram-positive aerobic bacterial colonization predominates (84%), with *Staphylococcus aureus* being the commonest organism (79%). Methicillin-resistant *S. aureus* (MRSA) was isolated in 30% of patients, which was almost double the proportion of MRSA-infected patients 3 years previously [8]. Bacterial colonization of the ulcer does not necessarily indicate infection. By contrast, infection may be present, especially in diabetics, without a very apparent pyrexia; leukocytosis, elevation of erythrocyte sedimentation rate and local signs may be less than expected. Cellulitis should alert one to the possibility of underlying osteomyelitis; plain X-rays may exhibit periosteal reactions or osteolysis. Probing a wound to find palpable bone at the base of an ulcer is an excellent predictor of osteomyelitis [9] (Fig. 60.9). A plain X-ray of the foot should be done to check for foreign bodies, tissue gas or bony abnormalities. A sinogram may be required to show communication of the sinus with a joint or a subfascial plantar abscess. A radioisotope bone scan, or magnetic resonance imaging (MRI) scan, may help to establish the diagnosis [10].

Treatment. The prevention of ulceration in neuropathic patients is of the utmost importance [10]. Persons at risk should receive instruction on basic foot care, preferably from a podiatrist, with education on regular self-inspection of feet and correct nail-cutting techniques. Shoes should accommodate any deformity, have broad rounded or square toes, adequate toe depth and a low heel to avoid excessive pressure on the forefoot [11,12]. They should fasten securely to prevent movement within the shoe. Orthotic devices such as cushioned insoles may also be beneficial in preventing ulceration. Patients should be discouraged from removing callus themselves; this

Fig. 60.10 Aircast Walkers® boot.

should be done by a podiatrist. Control of hypertension, cessation of smoking, prescription of aspirin in patients with atherosclerosis and meticulous control of hyperglycaemia can slow or even reverse the signs of peripheral neuropathy [13].

In the treatment of a neuropathic foot ulcer, a multidisciplinary approach is most effective, and has been shown to significantly reduce amputation [14]. Typically, the ulcer is debrided surgically or treated using a hydrogel followed by the application of a hydrocolloid dressing. Randomized controlled trials have shown benefit from the use of the platelet-derived growth factor becaplermin [15], cultured dermis (Dermograft®) [16] and hyaluronic acid dressings (Hyalofill®) [16,17] in promoting wound healing in clean wounds.

An essential part of treatment is the offloading of areas of abnormal pressure on the foot [14]. Contact casting is useful for healing ulceration over metatarsal heads but requires expertise in application and should not be used in patients whose ulcers are infected, or where there is a significant ischaemic component [14]. An example of such a casting is the Aircast Walkers® foam boot (Fig. 60.10). A modified non-weight-bearing boot made out of layers of adhesive foam padding may achieve complete removal of pressure points [18]. Boots made of Plaster of Paris (with a rocker base) seems popular in some centres, especially with orthopaedic practitioners. The plaster boot is applied, initially weekly, and every 3 weeks, until ulceration is healed [19].

Peripheral neuropathy

Peripheral neuropathy may be sensory, motor or mixed [1]. In most types of peripheral neuropathy, the involvement is symmetrical and symptoms begin in the extremities with sensory loss in a glove and stocking distribution. In contrast to this, is the patchy involvement of peripheral nerves in mononeuritis multiplex seen, for example, in polyarteriitis nodosa, or sarcoidosis (Chapter 58). The causes of peripheral neuropathy are numerous and include diabetes mellitus, carcinomatous neuropathy, vitamin B group deficiency and drugs or chemicals (Table 60.1).

The typical picture of polyneuropathy occurs with acquired, toxic or metabolic neuropathic states, and it is these that will usually be seen by a dermatologist. The first symptoms tend to be sensory, consisting of tingling, prickling, burning or band-like dysaesthesia in the balls of the feet or tips of the toes, or in a general distribution over the soles. Symptoms and findings are usually symmetrical and graded distally. If the polyneuropathy remains mild,

Table 60.1 List of causes of peripheral neuropathy.

Metabolic	Diabetes mellitus, alcohol, porphyria, myxoedema, acromegaly, uraemia, POEMS syndrome, hypoglycaemia
Neoplastic	Paraneoplastic neuropathy, lymphoma, Hodgkin's disease, multiple myeloma
Nutritional	Deficiencies of vitamins B_1, B_{12} or E and malabsorption syndromes including coeliac disease
Toxic	Alcohol, heavy metals (e.g. lead, mercury, gold, thallium), drugs (e.g. amiodarone, cisplatin, hydralazine isoniazid, dapsone, nitrofurantoin, disulfiram, phenytoin, vincristine, metronidazole, antiretroviral nucleoside analogues), other toxic agents (e.g. organophosphates, diphtheria, acrylamide)
Trauma	Pressure neuropathy, ischaemia, pressure from tumours, electrical shock
Infective	Diphtheria, leprosy, mumps, Guillain–Barré syndrome, HIV infection, Lyme disease
Inflammatory	Rheumatoid arthritis, polyarteritis nodosa, sarcoidosis, systemic lupus erythematosus, primary biliary cirrhosis, primary systemic amyloidosis, chronic obstructive airways disease, Churg–Strauss syndrome, critical illness
Genetic	Charcot–Marie–Tooth disease, Refsum's disease, HSANs, Fabry's disease, Roussy–Levy syndrome, metachromatic leukodystrophy

HIV, human immunodeficiency virus; HSANs, hereditary sensory autonomic neuropathies; POEMS, polyneuropathy, organomegaly, endocrinopathy, M-protein, skin changes.

Table 60.2 Investigation of peripheral neuropathy [1].

Urine	Glucose, protein, Bence Jones protein
Haematology	Full blood count, erythrocyte sedimentation rate, vitamin B_{12} and folate
Biochemistry	Fasting blood glucose, renal function, liver function, thyroid function, glucose tolerance test, serum protein electrophoresis, serum angiotensin-converting enzyme, prostate-specific antigen
Radiology	Chest X-ray, abdominal or pelvic ultrasound, chest and abdominal computed tomography, mammography, PET
Immunology	Antinuclear factor, antibodies to extractable nuclear antigen (Ro, La), neutrophilic cytoplasmic antigen, HIV, gliadin, neuronal (Hu, Yo)
Neurophysiology	Proximal and distal nerve conduction studies
Cerebrospinal fluid	Cells, protein, immunoglobulin oligoclonal bands

HIV, human immunodeficiency virus; PET, positron emission tomography.

objective motor or sensory signs may not be detectable. With progression, the dysaesthesia spreads up the legs, pan-sensory loss is found over the feet and the ankle reflexes are lost. Sensory loss moves centripetally in a graded 'stocking' fashion. The patient may complain that the feet have a numb or 'wooden' feeling. Neuropathy is usually less severe in the arms, and spreads in a centripetal, symmetrically graded manner with palmar sensory loss and areflexia. Overall, nerve fibres are affected according to axon length, without regard to the root or nerve trunk distribution, giving rise to the term 'stocking and glove' distribution to describe the pattern of the sensory deficit. Mononeuritis multiplex refers to sequential involvement of individual non-contiguous nerve trunks. This leads to a patchy multifocal neurological defect, and is often caused by an immunological or toxin-mediated disease process. Lightning pains may be a feature of tabes dorsalis and angiokeratoma corporis diffusum (Fabry's disease).

Autonomic neuropathies can be a manifestation of a more generalized polyneuropathy, but may also occur in isolation, when structural changes in the pre- and post-ganglionic neurones occur. Autonomic neuropathy is characterized by symptoms of postural hypotension, anhidrosis, hypothermia, bladder atonia, constipation, dry mouth and eyes, failure of salivary and lacrimal glands to secrete, blurring of vision from lack of pupillary and ciliary regulation, and sexual impotence in males [1].

Carpal tunnel syndrome is caused by an entrapment mononeuropathy of the median nerve at the wrist. It may be secondary to excessive use of the wrist, tenosynovitis, or local infiltration with connective tissue such as in acromegaly, amyloid or mucopolysaccharidosis. The main symptoms are nocturnal paraesthesiae of the thumb, index and middle fingers.

Investigations. The investigations appropriate in peripheral neuropathy are shown in Table 60.2 [1].

Treatment. Treatment of neuropathic pain and neuropathic foot, sexual dysfunction and bowel or bladder control are dealt with in the relevant sections in this chapter.

Human immunodeficiency (HIV) neuropathy

With the effectiveness of antiretroviral treatment and the decline in opportunistic infections and HIV-induced dementia, HIV-associated neuropathies have become the most common neurological disorder associated with acquired immune deficiency syndrome (AIDS). They present as acute or chronic demyelinating neuropathies, mononeuritis multiplex, cytomegalovirus (CMV)-related

polyradiculoneuropathy, autonomic neuropathy or distal painful sensory neuropathy [2–4]. They are multifactorial in aetiology, occurring in all stages of the illness, and take a variety of courses. Early in the course of HIV infection, acute inflammatory demyelinating polyneuropathy resembles Guillan–Barré syndrome. In other patients, a progressive or relapsing inflammatory neuropathy, resembling chronic inflammatory demyelinating polyneuropathy and mononeuritis multiplex, occurs. The most common peripheral neuropathy in patients with HIV infection is distal sensory polyneuropathy (DSP), which may be either a direct consequence of HIV infection, or a side effect of antiretroviral therapy, antiretroviral toxic neuropathy (ATN), or both [2,4].

Aetiology. DSP is characterized by axonal degeneration of long nerves in the extremities. The virus, which is not found within ganglionic neurones or Schwann cells but only within the endoneurial macrophages, may generate a tissue-specific autoimmune attack by secretion of cytokines that promote trafficking of activated T cells and macrophages within the endoneurial parenchyma [5–7].

Studies of skin biopsies of patients with HIV-associated sensory neuropathy, developing during treatment with didanosine or zalcitabine, have shown a reduction in the density of epidermal fibres in distal lower extremities, with an inverse correlation between reduced nerve density and neuropathic pain [7,8]. Mononeuritis multiplex in AIDS may be due to immune complex necrotizing vasculitis, resulting from associated hepatitis B or C infection or cryoglobulinaemia [9,10]. In patients with opportunistic infection and AIDS, extension of CMV cytopathic effects may involve endothelial cells and Schwann cells in the nerve roots, dorsal root ganglia or spinal cord [2].

Clinical features. Distal sensory neuropathy and ATN lead to sensory loss and neuropathic pain in the extremities. Presenting symptoms are usually painful burning sensations in the feet and lower extremities. When due to antiretroviral therapy, patients may complain of a sensation that they are walking on ice. Findings on examination would include a stocking type sensory loss of pin prick, temperature and touch sensation and loss of ankle reflexes. Patients may develop a progressive weakness in the distal muscle groups in limbs [2–4]. Two-thirds of patients with AIDS may have electrophysiological studies showing some evidence of peripheral nerve disease. Progressive, relapsing inflammatory neuropathy, mononeuritis multiplex and CMV-related neuronal damage give rise to sensorimotor neuropathies. Xerosis is common in HIV infection, occurring in around 20% of seropositive patients. This may be related to a decrease in immunoreactive substance P and CGRP fibres occurring around the tubules of the eccrine sweat glands [11].

Treatment. In the acute stage of demyelination, plasma exchange or intravenous immunoglobulins may have been tried with variable success. Gabapentin [12], carbamazepine [13], tricyclic antidepressants or analgesics may be effective for dysaesthesia [2–4].

A multicentre placebo-controlled randomized trial has been carried out using recombinant human NGF, which is trophic for small sensory neurones and stimulates the regeneration of damaged nerve fibres [14,15]. The treatment was shown to be efficacious in reduction of neuropathic pain and increase in pin prick sensitivity. Side effects of treatment included pain at the site of injection and transient myalgic pain.

Trigeminal trophic syndrome

This is an uncommon disorder in which trophic ulceration follows minor, repetitive trauma to anaesthetic skin within the trigeminal area. Neurotrophic changes in the trigeminal area may follow the destruction of fibres conveying pain and temperature sensation [1]. Causes of this disorder include central sensory neuronal damage (post-encephalitic parkinsonism, syringobulbia, posterior fossa tumour or occlusion of the posterior inferior cerebellar

Fig. 60.11 Trigeminal trophic syndrome resembling basal cell carcinoma of the right ala nasi.

artery [2,3], leprous neuritis and brain stem infarcts [4]) or damage to the trigeminal nerve by attempts to relieve intractable trigeminal neuralgia (by surgery or alcohol injections into the gasserian ganglion [5]) or herpes zoster [6] or simplex-related neuritis [7]. Trigeminal trophic syndrome is usually a disease of adults, although recently a case has been described in a 14-year-old child secondary to herpes simplex trigeminal neuritis [8].

Clinical features. The patient complains of paraesthesiae or a sensation of itch on the ala nasi. This is then picked, rubbed or scratched and, because the trauma is painless, the erosion increases in size and may extend to destroy the nasal cartilage [1,9]. The patients freely admit to traumatizing the area in an attempt to relieve the uncomfortable sensation. A clinical similarity to a basal cell carcinoma may be striking, often requiring a biopsy, which in trigeminal trophic syndrome simply shows inflammatory reaction [9] (Fig. 60.11). The pattern of ulceration may be sufficiently bizarre to suggest dermatitis artefacta. The ulcer spreads towards the cheek and the upper lip and, apart from the problems of control of secondary infection, subsequent scar formation in the area of the ala can result in the elevation of the lip resulting in a disfiguring sneer [9]. Characteristically, the alar rim is involved and the tip of the nose spared. Sites less frequently involved include the forehead, scalp and cheeks. Neurological examination should reveal decreased perception of light touch and pain over the area, and sometimes an absent corneal reflex on the same side [9].

Treatment. Surgical approaches in the past have included cervical sympathectomy [10], transcutaneous electrical stimulation [11] and grafting or the use of innervated transposition flaps [12], although these can fail if trauma to the area continues. Protection through occlusive dressings and wearing gloves can be of some help, but the ulceration commonly persists, particularly in the elderly or in confused patients who compulsively pick at the skin. Treatments which have resulted in improvement have included amitriptyline [5], diazepam [5], chlorpromazine [1] and pimozide, presumably through influencing the paraesthesiae and behavioural factors involved in the syndrome. Carbamazepine was found to be very effective in one reported case [9], although less so in others [1].

Peripheral nerve injury

Lesions of the peripheral nerve may cause permanent denervation with paralysis and disability, and represent a challenging problem in neurosurgery. The slow rate of nerve regeneration conspires together with atrophy and degeneration of the denervated organs to increase the risk of permanent disability after peripheral nerve injury, emphasizing the importance of rapid and timely intervention [1,2]. Neurotrophic factors are secreted polypeptides that control the survival, differentiation and maintenance of neurones. Sectioning of peripheral nerves results in the almost total loss of immunoreactivity for both low

(p75) and high affinity (TrkA-like) receptors for NGF [3]. Meissner's and pacinian corpuscles, after nerve section, lose immunohistochemical antigens such as S100 protein, epithelial membrane antigen and vimentin, strongly suggesting that the structure and integrity of the nerve axis is essential in maintaining some immunohistochemical characteristics of the human sensory corpuscles [4].

Section or severe contusion of a peripheral nerve has been held responsible for a variety of cutaneous changes. Skin manifestations are found in some 20% of patients with the carpal tunnel syndrome [5], and include a reddish discoloration of the fingers with bullae, small foci of necrosis and nail dystrophy [6]. Nail dystrophy and other trophic changes are also sometimes caused by a cervical rib [7]. In one report, injury to the lateral femoral cutaneous nerve during appendicectomy [8] was followed 6 days later by the development of bullae on the outer aspect of the right lower leg, with subsequent ulceration and scarring.

Cooling also affects conduction in peripheral nerves. Loss of sensation in the feet has been reported after prolonged immersion in cold seawater [9]. Areas of skin looking like partial thickness burns and blistering were found on the feet of 25 out of 160 participants in a barefoot run: a temporary cold-induced neuropathy of the feet had allowed subjects to continue running despite these injuries [10]. Neuropathy may be induced by cryotherapy, and in one series of 183 lesions treated in this way, some subsequent sensory loss was demonstrated in 28%. This was usually mild and transient, although rarely long lasting [11].

Syringomyelia

This is a rare disorder characterized by a longitudinal cyst in the cervical cord and/or medulla (syringobulbia) immediately anterior to the central canal, which spreads, usually asymmetrically, to each side. The majority of lesions occur in association with type 1 Chiari's syndrome where there is a congenital extension of the cerebellar tonsils below the foramen magnum [1]. Other causes include trauma and tumours [1]. MRI scanning of the hindbrain and upper spinal cord is best for delineation of the syrinx [1–3]. An association with other abnormalities, such as a short neck and a low hairline, suggests a developmental origin. Symptoms usually appear in young adults and the disease is generally slowly progressive over 20–30 years, although limited resolution of symptoms has occurred in adults [1] and children [2,3].

Early involvement of pain and temperature fibres, where they cross the midline anteriorly, leads to a characteristic dissociated sensory loss, in which pain and temperature sensation is lost early in the upper limbs, while other sensory modalities carried in the posterior columns (e.g. touch, vibration and position sense) may remain relatively intact. These changes are responsible for the earliest manifestation of the disease, a tendency to sustain painless burns and cuts on the hands and forearms. Later, upper motor neurone signs in the legs may accompany weakness, wasting and loss of reflexes in the arms. Occasionally a combination of progressive pain loss, resultant skin ulceration, loss of soft tissue, resorption of the phalanges and muscular atrophy (Morvan's syndrome) occurs.

Body asymmetry or hemi-hypertrophy is known to occur in syringomyelia and can occur on the head and face. Hypertrophy of the hands and feet, together with hypertrophy of the bones and muscles in the same limb (especially in the upper limbs), has been described with syringomyelia [4].

Many of the skin changes accompanying syringomyelia are the result of repeated burns or other injuries, particularly of the hands, where the skin over the fingers and knuckles may become thickened, swollen, cyanotic and keratotic. Analgesia renders the patient liable to minor injuries, which heal slowly. Gangrene rarely occurs, but damage to, or loss of, terminal phalanges or nails is not uncommon. The French term '*la main succulente*' refers to the swollen and oedematous hands of syringomyelia sufferers. Syringomyelia is responsible for dyshidrosis with hyperhidrosis or hypohidrosis, this being more common than previously recognized, with one series showing dyshidrosis in 60% of patients [5]. The dyshidrosis, usually occurring over the face and upper arms, may be spontaneous or occur reflexly, when the patient consumes hot or highly seasoned food. Its distribution, which can be studied by thermography, correlates with the location

of the syrinx and other neurological manifestations [5]. Hyperhidrosis is probably caused by stimulation of the sympathetic preganglionic neurones and, as the disease progresses, hyperreactivity gradually decreases and is replaced by hypoactivity. This may be important, as focal hyperhidrosis can be regarded as a hallmark of a relatively intact, even though slightly damaged, spinal cord [5]. Asymmetry of scalp hair can also occur in syringomyelia, with the denervated areas having less abundant hair, which grows more slowly [6].

Extension of the syrinx into the medulla may disrupt the vestibular pathways, the descending root of the trigeminal nerve, the sympathetic and taste pathways, and the hypoglossal nerve. The symptoms and signs may then include vertigo with nystagmus, dissociated sensory loss over the face, loss of taste, a wasted tongue, Horner's syndrome and sometimes paralysis of the vocal cords. Facial oedema confined to areas of sensory loss has been described [7].

Tabes dorsalis

This is still the most common form of neurosyphilis and is the one with the longest incubation period (usually 10–20 years: range 5–50 years), affecting men more often than women. The main symptoms are due to degeneration of the afferent fibres of the dorsal roots. It is characterized by a triad of symptoms (lightning pains, dysuria and ataxia) and a triad of signs (Argyll Robertson pupils, areflexia and loss of proprioceptive sense) [1].

Usually, sensory symptoms precede ataxia by months or years. Lightning pains are the most characteristic early symptom, and occur in 90% of cases at some stage, most often affecting the legs. Pain sensibility is also impaired early, the deep tissues becoming insensitive before the skin does. This may be demonstrated by squeezing the Achilles tendon. Argyll Robertson pupils, miotic pupils that fail to react to direct light, are found in about half of the patients. Originally associated with tabes dorsalis, the sign is now recognized as being common to a number of conditions causing lesions in the area of the nucleus of Edinger–Westphal. Thus, MRI studies have localized lesions to this region in patients with sarcoidosis and multiple sclerosis [2]. With the declining incidence of neurosyphilis, the sign is increasingly likely to indicate another cause, although an assiduous search for syphilis should also be undertaken.

Later features may include ataxia, with a wide-based gait, made worse by the elimination of visual clues, dribbling overflow incontinence, visceral crises, optic atrophy and a painless distortion of the hips, knees or ankles (Charcot's joints).

The commonest trophic change in the skin is a neuropathic ulcer. Symptomatic herpes zoster may occur, as in other conditions affecting dorsal roots.

The clinical features and laboratory findings may be modified by the widespread use of antibiotics and corticosteroids for treating unrelated diseases [3]. This sometimes leads to difficulty in deciding whether tabes dorsalis is active or 'burned-out', with a neurological deficit due to fixed structural damage. Penicillin treatment will arrest the course of the disease, but residual lightning pains, gastric crises and urinary incontinence are likely to persist.

Spinal dysraphism

Spinal cord development occurs between weeks 2 and 6 of embryonic life. A raphe is a line of junction between symmetrical embryological structures: dysraphism is a failure of this type of fusion [1]. Spinal dysraphism leads to malformations of midline dorsal structures [2]. Defects in the early embryonic stages produce spinal dysraphisms, which can be categorized clinically into two subsets. Open spinal dysraphisms are exposed to the environment (e.g. spina bifida, myelomeningocoele), while closed spinal dysraphisms are covered by intact skin.

A review of 200 published cases of spinal dysraphism [3] included 102 with cutaneous abnormalities, often in combination. A dermatologist may be the first physician to see such patients, and should be aware of possible associations with underlying neurological abnormalities.

Patients with giant congenital melanocytic naevi overlying the scalp or dorsal spine can, on MRI, have abnormalities of the leptomeninges, the amygdala, cerebellum and pons [4].

Many skin abnormalities overlying the lumbosacral region have been reported to be associated with spinal dysraphism and cord tethering, including lipomas [5], port-wine stains, haemangiomas [6], 'faun tail' (hypertrichosis)

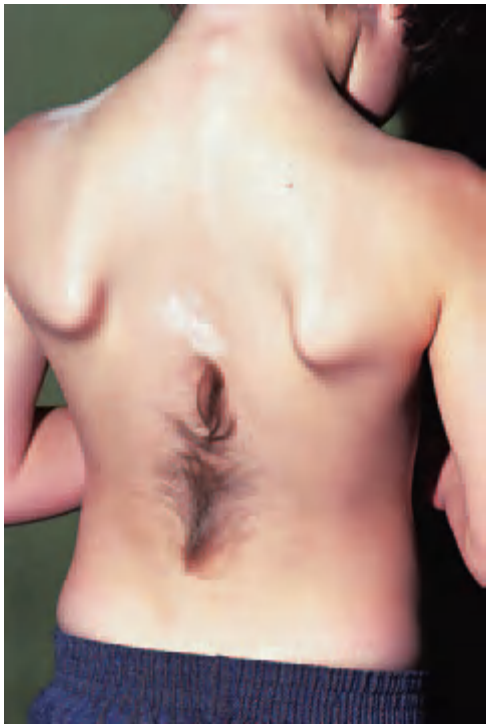

Fig. 60.12 Tuft of hair in association with spina bifida.

[7], pigmented macules and pits or dimples. Because tethered spinal cord is a treatable condition and, if left untreated, can lead to progressive neurological degeneration, spinal MRI scanning of infants with giant melanocytic naevi involving the lumbosacral area is advocated [8,9]. Approximately 20% of patients with large congenital naevi in this region will have associated neurological or developmental abnormalities on MRI scanning [10].

Spina bifida

Several varieties of spina bifida are described, differing in the nature and severity of the spinal defect. In the severe form, a sac protrudes through the vertebral opening and transmits an impulse on crying or coughing. In the least severe cases (spina bifida occulta) there is no such protrusion, but a defect in the vertebral lamina may be felt as a depression, and is sometimes covered by a tuft of hair or a dimple (Fig. 60.12). Spina bifida occulta may give rise to no symptoms, and be a chance finding in the course of a routine examination. However, lesions preventing the ascent of the spinal cord, which occurs during normal growth, can lead to undue traction on the lower end of the cord and cauda equina.

The neurological changes will then be those of a chronic lesion of the cauda equina. Such patients may have been slow to learn to walk. Sensation may be impaired over the areas innervated by the lowest sacral segments, leading to a characteristic saddle-shaped area of analgesia over the buttocks and dorsa of the thighs. Trophic changes are conspicuous in some cases, and are rarely lacking altogether. In milder cases, the feet are usually cold and cyanosed: cutaneous injuries are slow to heal and tend to ulcerate, not only on the feet but also in the analgesic skin of the buttocks and thighs. The most severe neurological abnormality is a flaccid paraparesis with sphincter paralysis.

The diagnosis is confirmed by radiography, showing defective fusion of the laminae in the affected region, usually the first sacral and fifth lumbar vertebrae. An MRI scan or myelography may be helpful. Estimation of α-fetoprotein in the amniotic fluid or in the maternal serum may successfully identify a fetus with a severe malformation of the CNS such as spina bifida cystica or anencephaly.

Patients with spina bifida are at risk of latex sensitivity [11] due to exposure to latex products, both at the time of surgery and also with indwelling catheters, etc. Such patients should be assessed using latex-specific serum IgE, radioallergosorbent test (RAST), skin prick testing to latex suspension and latex glove usage test [12,13]. Patients allergic to latex may display urticaria, conjunctivitis, angio-oedema, rhinitis and bronchial asthma. They are at risk of anaphylaxis during procedures when health care workers are using latex gloves during bladder catheterization and, because of cross-sensitivity to food allergens, can be allergic to fresh foods including kiwi, pear, orange, pineapple, tomato and banana.

The treatment of spina bifida lies in the domain of the paediatrician or neurologist, but the dermatologist may be asked for advice on the trophic ulcers.

Congenital dermal sinuses

These lie close to the midline and may be no more than 1 or 2 mm in diameter [1]. Hairs may protrude from the opening, but these sinuses differ from pilonidal sinuses in that they connect directly to the contents of the spinal canal and so serve as a portal of entry for infection. Probing is therefore unwise. Such sinuses may expand into cysts deeply, and these may press on the spinal cord.

Spinal cord injury

The spinal cord may be injured directly by penetrating wounds or, more frequently, it suffers indirectly as a result of dislocations or fracture dislocations of the vertebral column. Damage may not necessarily be as a result of direct trauma but because of surrounding tissue damage, causing the spinal cord to swell and occupy the entire diameter of the spinal cord at the level of the injury. Causes include motor vehicle accidents (36–48%), violence (5–29%), falls (17–21%) and recreational activities (7–16%) [1]. Conventional radiography on its own should not be depended on to define the damage, and dynamic views in flexion–extension movement may provide additional information; where these are not deemed safe, MRI is necessary [1]. Rare dermatological causes of spinal cord injury have included a neglected basal cell carcinoma on the back [2], an adenocystic carcinoma in overlying skin [3] and multiple myeloma in a man presenting with primary cutaneous plasmacytomas, resulting in spinal cord compression [4].

Seborrhoea and seborrhoeic dermatitis have been reported in quadriplegia patients [5,6]. In one study [6] of 20 patients with spinal injury but no seborrhoeic dermatitis on admission, 13 developed the condition on the face and trunk within a few weeks. Nummular eczema may also occur below the level of the lesion [5]. Twenty-one patients with complete paralysis below levels varying from C5 to T12 were investigated for sebum excretion rate, skin temperature and the presence of acne [7]. An increased incidence of acne was found on the back and buttocks, often occurring for the first time after the onset of paralysis. Sebum excretion on the forehead did not differ from that of normal, but was significantly increased below the neurological lesion. This could not be explained by changes in skin temperature.

The changes in eccrine sweating after spinal cord injuries are complex [8]. Episodes of profuse sweating on the face, neck and upper trunk in patients with lesions at or above T6 may occur as an exaggerated response to stimuli such as bowel or bladder distension (autonomic dysreflexia). Facial flushing and headache may be associated with these episodes. Other patients develop sweating of the face and arms after dizziness due to postural hypotension. Finally, post-traumatic syringomyelia can lead to hyperhidrosis [9]. Dryness of the skin, particularly noticeable on the soles, is an effect of anhidrosis.

Chronic decubitus ulceration can be a problem, and local osteomyelitis rarely leads to secondary amyloidosis. Excellent nursing, prevention of pressure and attention to the patient's general health are essential. There should be frequent review of pressure ulcer prevention and management strategies, and patients should be supplied with aids such as ripple mattresses to help reduce localized pressure. Pressure sore closure is frequently a reconstructive challenge and in itself can be deforming. The use of an inferiorly based vertical rectus abdominis myocutaneous flap for both recalcitrant ischial and trochanteric pressure sores has been shown to be useful [10].

Early decompression and high-dose methylprednisolone may reduce further spinal cord damage following injury. Small gains in neurological regeneration can lead to a disproportionate gain in function, since, for example, fewer than 10% functional long-tract connections are needed to enable good locomotor action. Adequate rehabilitation will prevent many complications and improve outcome [1]. Tendon transfer can improve hand grip and transcutaneous electrical stimulation can help muscles, including the diaphragm, facilitate erection and ejaculation and control pain. Bladder and bowel control may be helped with implantable electrical stimulators or botulinum toxin [11]. Sexual dysfunction can be treated by mechanical (vacuum pumps, penile implants, electrical stimulation) or pharmacological interventions (sildenafil, intracavernosus injection) [1,12], the latter depending on the sparing of either the sacral (S2–S4) or thoraco–lumbar (T10–L2) spinal segments. Exciting new treatment opportunities emerged through the use of NGFs, creation of neuronal 'bridges' using peripheral nerves and the use of stem cells [1], and future development is likely through collaboration between scientists and clinical specialists [1].

Disorders associated with autonomic abnormalities

Hereditary sensory autonomic neuropathies (HSANs)

The classification of HSAN was modified by Dyck [1] into five main groups of syndromes with common clinical, pathophysiological and genetic phenotypes.

Hereditary sensory autonomic neuropathy type I (HSAN I)

HSAN type I differs from all other HSANs in that its symptoms appear late, rather than congenitally. It is an autosomal dominant disorder, mapping to chromosome 9q22.1–q22.3 [2,3]. It is the most common HSAN, resulting in progressive degeneration of sensory dorsal root ganglia, with loss of both small myelinated and unmyelinated nerves leading to a distal sensory and motor loss, particularly in the lower limbs [2,4]. HSAN type I presents in late childhood or adolescence with progressive loss of all modalities of sensation in the lower extremities, particularly pain and temperature. This often results in chronic trophic ulceration on weight-bearing areas of the feet, associated osteomyelitis and mutilating deformity [4,5]. Later manifestations include muscle wasting, weakness and lancinating pain in the lower limbs and extension of sensory symptoms to the upper limbs. Neural deafness is frequent, and congenital cataracts and mental retardation have been reported [4].

Treatment is supportive, with good fitting shoes and alleviation of weight bearing if ulcers form [5].

Hereditary sensory autonomic neuropathy type II (HSAN II)

HSAN type II is an autosomal recessive disorder with a congenital or early onset, with marked loss of sensory, motor and autonomic motor neurones and marked loss of unmyelinated nerves [1,6–8]. No chromosomal linkage has been identified. A high urinary excretion of sphingomyelin and lecithin suggest that the primary mechanism may be a disorder of phospholipid metabolism [7].

Infantile hypotonia is common. Unlike HSAN I, which primarily affects the feet, HSAN II results in loss of sensation equally in hands and feet, leading to ulceration at sites such as the forehead, trunk, tongue and lips as a result of repeated injury. Fingers can show ainhum-like constriction bands and spontaneous amputations. Loss of deep sensation results in deep ulceration, osteomyelitis, stress fractures and injury to long bones [6–8]. Tendon reflexes and anhidrosis occur in areas of decreased sensation, although anhidrosis is less prominent than in HSAN IV.

Associated features include mental retardation, neural deafness, impaired taste and smell, retinitis pigmentosa and cataracts.

Hereditary sensory autonomic neuropathy type III (HSAN III) (familial dysautonomia)

HSAN type III (previously familial dysautonomia; Riley–Day syndrome) is the most common of the sensory and autonomic neuropathies [9–13]. The disorder is transmitted as an autosomal recessive trait, mapping to 9q31–q33 [14–16], and is prevalent in Ashkenazi Jews, in whom the frequency is 1 : 10 000. Scattered cases in non-Jewish patients have been reported. Prenatal diagnosis is now possible [15].

Onset is congenital, and hypotonia, sucking difficulties, a poor cry and vomiting are present at birth. Autonomic features are prominent, with impaired production of tears, unstable temperature control, postural hypotension and excessive sweating, especially during infection, all being major features. Impaired oesophageal motility, with resultant pneumonia, together with bouts of apnoea, are causes of death in childhood. Blotchy erythema occurs during overheating, and erythematous macules 2–5 cm in diameter may occur on the trunk and limbs in response to emotional upsets [13].

A diagnosis is sometimes made in infancy because the child cries without producing tears. Other diagnostic criteria include absent fungiform papillae on the tongue, absent tendon and corneal reflexes, lack of axon flare after intradermal histamine, and miosis following instillation of methacholine. Later, the child may show delayed growth and invariably displays postural hypotension. Intelligence remains normal, but emotional lability is common. Progressive abnormalities of cutaneous temperature discrimination and nociception are found in most patients [11]. Mortality rates remain high but have improved with better supportive measures, and 50% of patients now survive to adulthood [17]. Death may follow inhalation during attacks of vomiting, and hypotension and cardiac arrest are risks with a general anaesthetic [18].

Treatment is symptomatic. Attention to feeding must be meticulous and gastrostomy may be required. Diazepam and chlorpromazine can be used to treat acute autonomic crises and intranasal midazolam can be used for patients at home [19].

Hereditary sensory autonomic neuropathy type IV (HSAN IV)

HSAN type IV probably comprises a heterogeneous group of patients and is transmitted by autosomal dominant inheritance [20]. Defects in the human *TRKA* (*NTRKI*) gene located on chromosome 1 (1q21–q22) which encodes a receptor tyrosine kinase (RTK) have been shown [21].

Clinically, the boundary between HSAN II and IV can be difficult to delineate. HSAN IV is an autosomal recessive disorder characterized by recurrent episodic fevers, anhidrosis, absence of reaction to noxious stimuli, self-mutilating behaviour and mental retardation [20,21]. Infants are hypotonic and areflexic. High fever related to an inability to sweat, especially in the summer, can be associated with seizures [20–22]. Insensitivity to pain with self-inflicted injury results in multiple scars and bone fractures, autoextraction of teeth and ulceration of tongue, lips and buccal mucosal [23].

The anomalous pain and temperature sensation and anhidrosis in HSAN V are due to the absence of afferent neurones activated by tissue-damaging stimuli and a loss of innervation of eccrine sweat glands, respectively [22]. These patients have recently been shown to have a decrease in skin nerve fibres positive for PGP 9.5, CGRP, substance P, NPY, nitric oxide and VIP [22,23], and innervation is almost completely absent around eccrine sweat glands [22].

Treatment is limited; oral shields may prevent damage to the oral tissues [24].

Hereditary sensory autonomic neuropathy type V (HSAN V)

SYN. CONGENITAL INSENSITIVITY TO PAIN

HSAN type V is a rare autosomal recessive hereditary sensory autonomic neuropathy characterized by insensitivity to pain, self-mutilating behaviour, anhidrosis with recurrent hyperpyrexia and mental retardation [25,26].

This autosomal recessive condition results in a defect in the development of sensory and autonomic peripheral nerves [26]. It is caused by mutations of the human *TRKA* (*NTRK1*) gene located on chromosome 1q21–q22, which codes for the receptor for NGF and tyrosine kinase [27–30]. Nociceptive and sympathetic Aδ-fibre and C-fibre nerve activity is reduced or absent in the skin, S100 protein and neurone-specific enolase are reduced or absent in the vicinity of eccrine sweat glands, and substance P receptors are absent from nerve fibres and the epidermis [31]. This is consistent with the loss of unmyelinated and small myelinated fibres, as seen in sural nerve biopsies [32].

Patients present in early childhood when they start to crawl; they fail to learn the consequences of injury and do not cry with soft-tissue injury. There is associated heat intolerance due to anhidrosis, with episodes of hyperpyrexia. Death from hyperpyrexia has been recorded in up to 10% of patients in the first 3 years of life. Sunburn and frostbite may occur. There is a striking absence of the SSR. Congenital insensitivity to pain with anhidrosis is characterized by multisystem involvement. Skin ulcerations on the fingers and toes are common from self-biting, and neurological examination often reveals complete analgesia, although tactile discrimination, sensation of cold, head and vibration may be normal. Corneal reflexes are usually present but deep tendon reflexes are abolished. Neonatal hypotonia and psychomotor retardation are common, as are slow healing fractures, joint deformities, osteomyelitis, avascular necrosis and acro-osteolysis of fingers [33].

Sympathetic nerve injury [1]

When the sympathetic supply of the skin is interrupted, loss of vasoconstrictor impulses leads to erythema. There is passive vasodilatation and the denervated area is anhidrotic. The skin may become noticeably dry with scaliness and fine fissures. The affected area heals only slowly following minor trauma, and some patients complain that it is hyperaesthetic. It has been shown that after sympathetic ganglionectomy there can be dissociation of sudomotor and pilomotor activity [2]. In the denervated areas, there is no loss of cutaneous sensation, and the phenomenon may be due to the regeneration of post-ganglionic cholinergic fibres. In general, the areas of vasodilatation correspond to the areas of anhidrosis, suggesting a close correspondence of sudomotor and vasoconstrictor fibres [3]. Measurements of sweating and vasomotor responses can help to determine the extent of autonomic denervation.

As discussed earlier in this chapter, when sympathetic denervation is combined with a loss of somatic sensation, as, for instance, in peripheral nerve injury or severe peripheral neuropathy, neurotrophic ulcers may be encountered. These result from local minor trauma and are characteristically painless and slow to heal. Sympathetic denervation may also slow or prevent the normal greying of hair that takes place with increasing age [4,5], and in one case it seemed to cause hyperpigmentation of the skin in the affected area [6].

Complex regional pain syndrome (CRPS)

Complex regional pain syndrome (previously known as reflex sympathetic dystrophy or causalgia) is a heterogeneous group of conditions resulting in neuropathic pain that is characterized by pain and dysfunction of the sympathetic nervous system [1–3]. It has been recommended that the diagnostic criteria include at least one event from each of four groups: (i) a syndrome that develops after a noxious event; (ii) spontaneous pain or allodynia/hyperalgesia not limited to the territory of a single nerve and disproportionate to the initiating stimulus; (iii) past or present oedema, abnormal skin blood flow or sudomotor activity; and (iv) absence of conditions that might otherwise account for pain and dysfunction [1,2].

Aetiology. Complex regional pain syndrome commonly develops after trauma, with at least 50% of cases involving a fracture (most often a Colles' fracture), but it can be induced by sprains, contusion or lacerations. It usually involves a distal limb site. Other antecedent factors have included injury to the central or peripheral nervous system, stroke, myocardial infarction, tuberculosis and

certain drugs [1]. Dermatologically associated causes of CRPS are listed in Table 60.3 [1,4–7].

The pathogenesis of CRPS is not well understood, and hypotheses include neuropeptide release causing pain and vasodilation, enhanced α-adrenergic receptor activity, and up-regulation of afferent nocioreceptors in response to norepinephrine release from sympathetic efferents. Other theories suggest excessive inflammation at the site of injury and involvement of the immune system or the CNS [1].

Symptoms. It is common to divide the symptoms of CRPS into three stages [1].

The first stage begins several days or weeks after the injury and lasts about a month. During this first stage, the symptoms are those of spontaneous burning and stinging pain, or shooting pain precipitated by mechanical stimuli such as bathing, clothing resting on the skin or drafts blowing on a limb [2].

The second stage occurs from 1 to 7 months after injury and lasts 3–6 months. The symptoms relate to sympathetic hyperactivity and include cool, oedematous skin, hyperhydrosis and cyanosis or livedo-like changes. Hair may show decreased growth and nails become brittle. Pain is variable and the neuralgia may either spread or decrease.

In the third stage, starting some 8 months after injury there is progressive tissue damage, which can become permanent. The skin becomes shiny, atrophic and dry and fingertips may diminish in size. When pain is made worse by a variety of stimuli, the patient may protect the limb, leading to trophic changes of thin, shiny skin with muscle wasting and bone demineralization (Sudeck's atrophy).

Dermatological manifestations of CRPS are listed in Table 60.4 [1].

Diagnosis. Diagnostic tests include: pain relief on α_1-adrenergic blockade with intravenous phentolamine; pain exacerbation on α_2 stimulation by clonidine; and elicitation of severe pain on cold stimulation, induced by evaporation of a drop of acetone or ethyl chloride on the skin.

Treatment. Interdisciplinary pain management techniques should include the use of occupational therapy and physiotherapy to aid active movement and allow graded increase in activity. Early mobilization of 'at risk' extremities or joints, for example the wrist after Colles' fracture or surgery, can be preventative. This can be accomplished by a series of exercises using devices; for example, in the case of Colles' fracture a rubber ball progressing to spring grip strengtheners and mat exercises [2,8]. Desensitization techniques such as rubbing the skin with silk, then cotton, then towelling, or baths of contrasting temperature, can be particularly useful [2,8].

Drug treatment may include tricyclic antidepressants, or newer antidepressants such as venlafaxine and mirtazapine, especially in the setting of associated depression [2]. Gabapentin [9], lamotrigine and carbamazepine have proved useful, although randomized control trials in CRPS are lacking [2]. Both α- (phentolamine) and β- (propranolol) blockers have been found useful in some patients [1]. An eutectic mixture of local anaesthetics (EMLA) or capsaicin creams have not generally proved beneficial [2,10]. Where inflammation is considered to have an aetiological role, ketoprofen or even a short course of oral steroids may be of help [2]. Interestingly, calcitonin is one of the best-studied drugs in the management of CRPS and produced significant pain relief in almost 60% of patients in a randomized clinical trial [11].

There has been a recent report of resolution of CRPS with thalidomide therapy [12]. Although sympathectomy has been a traditional first line of treatment in CRPS, there is little evidence to support its use, and it does not seem to have a long-term effect [13,14]. Intravenous regional sympathetic blockade using guanethidine [2] or bretylium [2,15], use of a spinal cord stimulator [16] and subcutaneous lidocaine infusions [17] may be helpful.

Horner's syndrome [1]

This follows partial or complete interruption of the sympathetic pathways of the face. It is characterized by ptosis, miosis and anhidrosis.

Aetiology. The fibres responsible for the sympathetic nerve supply to the skin of the face travel from the hypothalamus via the spinal cord, to relay at the level of the first and second thoracic segments in the lateral column of the spinal grey matter. The preganglionic fibres emerge from the cord in the anterior rami of the first and second thoracic spinal nerves, and pass up the cervical sympathetic chain to relay in the superior cervical ganglion. From here, post-ganglionic fibres pass to supply the eye and the skin of a small central area of the face via the internal carotid sympathetic plexus. Other fibres pass along the external carotid artery and its branches to innervate the greater part of the facial skin with vasomotor and sudomotor fibres.

This pathway can be interrupted centrally in the spinal cord; for example, by medullary infarction, syringomyelia, multiple sclerosis or intraspinal tumours. The peripheral fibres can be damaged by an aortic aneurysm, cervical lymphadenopathy, surgery, regional anaesthetic procedures or tumours. Horner's syndrome may follow sympathectomy for the treatment of palmar and axillary hyperhidrosis, and occurs in up to 40% of patients having cervical sympathectomy by conventional open surgery and in up to 8% of those having transthoracic endoscopic sympathectomy [2]. In such cases, there may be resolution of long-standing pompholyx-type hand eczema on the ipsilateral side, suggesting a neurological pathogenesis for endogenous pompholyx in some patients [3,4].

Clinical features. An irritative phase is described, but rarely seen, in which there is transient unilateral hyperhidrosis and vasoconstriction. The paralytic phase is characterized by drooping of the eyelid (ptosis) with narrowing of the palpebral fissure. The pupil is small, but shows normal reflex constriction to light and accommodation, and sweating is absent on the ipsilateral side of the face. There may be slight retraction of the globe of the eye into the orbit (enophthalmos). Cases of bilateral Horner's syndrome are rarely encountered. Sweat glands on the medial and lateral parts of the forehead are innervated separately, with the medial forehead being supplied by nerve fibres from the sympathetic plexus of the internal carotid artery, while the lateral forehead derives its sympathetic nerve supply from the plexus surrounding the external carotid artery [5]. This accounts for the findings in Raeder's syndrome, where damage involving the perivascular plexus of the internal carotid artery leads to anhidrosis medially but not laterally on the forehead [6].

Treatment. This should be directed to the underlying cause; usually, however, this is not amenable to therapy.

Gustatory hyperhidrosis

The autonomic nervous system has a propensity for regrowth [1]. Damage to adjacent preganglionic parasympathetic fibres and post-ganglionic sympathetic fibres

may be followed by parasympathetic fibres regrowing into the sympathetic nerves, thereby directly controlling sweat gland function. In the neck, for example, following damage to the sympathetic cervical trunk and the vagus (parasympathetic) at the time of thyroidectomy or after trauma, such reinnervation may result in gustatory hyperhidrosis even after eating bland foods [2]. A similar event may occur on the cheeks or chin following surgery to the parotid or submandibular glands—the so-called auriculotemporal syndrome (Frey's syndrome) [3]. Secretory sweating is now more frequently seen after endoscopic trans-thoracic sympathectomy [4,5].

Treatment. Fortunately, topical preparations such as those containing aluminium chloride hexahydrate often control these symptoms well, but may themselves produce an irritant dermatitis. Botulinum toxin has been shown to be effective and safe in gustatory sweating [6]. A further option is the use of a 0.5% aqueous solution of glycopyrronium bromide topically, which has been shown to be effective, safe, well tolerated and convenient in diabetes-associated gustatory sweating [7].

Chronic skin pain

The diagnosis of dysmorphophobia or dermatological non-disease [1,2] should always be considered when patients present with chronic skin pain, especially when areas important to body image are involved. These include the burning vulva syndrome (vulvodynia) and the burning scrotum syndrome (Chapter 68) as well as orodynia (Chapter 66). However, one should keep an open mind about other entities including notalgia paraesthetica, brachioradial pruritus (BRP) and skin–ache syndrome. Post-herpetic neuralgia is discussed earlier in this chapter.

Notalgia paraesthetica

Notalgia paraesthetica was first described in 1934 by Astwazaturow [3]. It is characterized by episodes of itch and skin pain, usually close to the medial border of the scapula, corresponding to the posterior primary rami of the thoracic nerves T2–T6. The condition may be caused by entrapment of the posterior rami of these spinal nerves as they pass through muscle, and may be predisposed to by back injury or back trauma from prolonged sitting [4]. Patients present with localized discomfort or pruritus on the back; the condition runs a chronic course, and is probably more frequent than previously thought. Examination often reveals a speckled or uniform area of pigmentation, which may be associated with lichenification. There may be hypoaesthesia or hyperaesthesia to pin prick, often localized to the centre of the area [5]. Histopathology characteristically shows intraepithelial necrotic keratinocytes with melanin and macrophages in the papillary dermis [6]. One study found increased substance P immunoreactive fibres in the skin [7].

The relationship of this condition to primary localized cutaneous amyloidosis of macular type [5] is unclear; but in most cases amyloid has been found to be absent, although it may have been missed because deposits were sparse [3,8]. Cases with classical features of notalgia paraesthetica have been reported in which macular amyloid was present on skin biopsy [3]. It is well known that prolonged scratching and rubbing can give rise to friction-related amyloid deposits (Chapter 57); the intractable pruritus characteristic of notalgia paraesthetica may thus explain the association with localized cutaneous amyloidosis.

In one study, 70% of patients treated with topical capsaicin, and 30% of patients receiving vehicle, reported some degree of improvement, but it was difficult to maintain the double-blind design of the study because of the symptoms produced by capsaicin itself [9]. In a series of three patients, all patients were reported as improved by application of topical EMLA (2.5% lidocaine and 2.5% prilocaine) [6].

Brachioradial pruritus

BRP is a localized itch in a dermatomal distribution, which usually occurs on the lateral aspect of the arm and elbow, or less commonly on the shoulders, neck or upper thorax [10]. It was originally described in patients from Florida, USA, and the Transvaal, South Africa. A strong seasonal variation, with symptoms being worse in summer months, improvement with photoprotection and the fact that case reports have come mainly from tropical areas, have all been cited as evidence that BRP is a photodermatosis [10–14]. In other cases, cervical root damage (C5–C8) from degenerative arthropathy, cervical rib or spinal tumours may have been important aetiological factors [15]. It is likely that both cervical spine disease and sunlight-induced damage to cutaneous nerve endings are important underlying contributors and triggering factors [13]. Dermal pin prick hyperaesthesia may be present in a

cervical nerve distribution [14]. MRI scanning should be performed to define cervical nerve-root compression [16].

Unlike normal itch, which tends to be relieved by scratching, in BRP scratching seems to potentiate the sensation of itch transmitted by the C fibres [10,17]. BRP is often refractory to topical or oral steroids and antihistamines [15]. Reports of response to topical capsaicin have been variable [9,17,18]. Gabapentin may be useful for BRP [19].

Skin-ache syndrome

Bassoe [20] suggested the term 'skin-ache syndrome' for a situation in which patients experience pain of unknown aetiology characterized by cutaneous trigger points, although this is not widely used. Relief of symptoms was reported after injection of lidocaine or surgical removal of the skin trigger point. This is in contrast to fibromyalgia, from which it must be distinguished, and where pain is more refractory.

Restless leg syndrome (RLS)

RLS is a common sleep and movement disorder with a population prevalence of around 2–5% [1]. RLS is a clinically pleomorphic syndrome, probably reflecting multiple genetic and acquired factors. A significant linkage was established to chromosome 12q [2], and it has long been felt that it represented a subclinical sensory neuropathy [3]. Others have related it to a dopamine imbalance, due to the presence of dyskinetic movements and response to levodopa [4]. Studies of the basal ganglia using positron emission tomography (PET) scanning techniques have shown a decreased binding of dopamine to its receptor [1]. Up to 30% of patients have iron deficiency, with consequent reduced levels in brain tissue and cerebrospinal fluid [1]. RLS is a common disorder in haemodialysis patients [5].

Clinical features. Two subtypes are recognized. The first, with an early onset, accounts for some 25% of cases, is more commonly familial and is associated with a history of 'growing pains' in childhood [6]. Those with a late on-set (idiopathic RLS) have less painful paraesthesiae or dysesthesias, insomnia and lack a family history of the condition. RLS is characterized by leg paraesthesiae, associated with an irresistible urge, occurring at rest, to move the legs, which is relieved by movement [3,7,8]. These symptoms are worse at night and often lead to disruption of life and chronic sleep deprivation. Sensory symptoms include painful legs and arms, and pain at 'internal' sites. Many patients will have a previous diagnosis of a musculoskeletal disorder, such as joint and back pains, and there is a significant association with depression and other neuropsychiatric symptoms [6,7]. Headache on awakening and daytime headache occurs frequently, while in men, hypertension and heart problems have been reported [8].

Treatment. Some believe the first choice of treatment for RLS should be dopaminergic agents such as levodopa [3] or the longer acting cabergoline [3]. Other dopaminergic drugs that show promising results are pramipexole and ropinirole, although double-blind trials are not available, and the associated daytime somnolence probably makes these a second-line treatment [9]. In recent randomized, double-blind studies of gabapentin, significant improvement occurred in both idiopathic RLS [10] and haemodialysis patients [5]. Ferrous sulphate, which had been felt to be effective as an empirical treatment, was not shown to have an effect in a randomized double-blind placebo-controlled trial [11].

Burning feet syndrome (BFS)

BFS is a poorly recognized and often underdiagnosed condition [12,13]. It may occur as a result of diabetic neuro-

pathy, but in most cases it is idiopathic. Families with an autosomal dominant inheritance for BFS have been described [14]. A kindred of 21 patients with familial BFS has been described; BFS was often associated with minor foot abnormalities such as high arches or reduced toe fanning [14]. Loss of small fibre sensory nerves has been found in both in type 2 diabetics [12] and idiopathic cases. Tests on the autonomic system have shown predominantly cholinergic defects, unlike other autonomic neuropathies. There is a close correlation between quantitative abnormalities in the sudomotor axon reflex test and the loss of small nerve fibres in the skin [12].

Clinical features. The main clinical features are of a burning sensation on the feet with accentuation by heat or cold. Other autonomic associated features may include dry skin, eyes and mouth, vasomotor symptoms with peripheral coldness, burning or flushing, hypertension and impotence. Orthostatic hypotension does not appear to be an association [12,13].

Treatment. Treatment options for BFS appear less defined than for RLS, but treatments efficacious for the latter would probably also help in the BFS.

Chapter 61

Psychocutaneous Disorders

L.G. Millard & J.A. Cotterill

Introduction

An essential component of dermatological illness is the relationship that somatic dermatology has with the psychological status of the patient at the time. The influence that these psychological, psychosocial and sometimes psychiatric factors have can be conveniently assessed as:

1 Multifactorial dermatological disorders that can be substantially influenced by psychological factors (e.g. psoriasis)

2 Dermatological disorders as a result of psychiatric illness (e.g. factitious dermatoses, body dysmorphic disorder)

3 Psychiatric illness developing as a result of skin disease (e.g. reactive depression, adjustment disorder)

4 Comorbidity with other psychiatric disorder (e.g. alcoholism).

In large centres, this work can be refined and developed in specific clinics for psychosomatic dermatology [1]. Ideally, liaison psychiatry should be available together with help from clinical psychologists and social workers [2]. Research and dissemination of further knowledge in psychosomatic dermatology is supported in Europe by the European Society for Dermatology and Psychiatry (ESDaP) and in North America by the Association for Psychodermatological Medicine of North America (APMNA).

The dermatological consultation is substantially different from the psychiatric one. However, for those who feel intimidated, the consultation process and descriptive psychopathology of psychological medicine is well described for non-psychiatrists [3,4].

Emotional factors in diseases of the skin [1–4]

The narrative of clinical anecdote and experience held for a long time that emotional stress could be counted as an integral cause of skin disease or at least an exacerbating factor leading to increased disease morbidity [1].

It has been estimated that the effective management of at least one-third of patients attending skin departments depends upon the recognition and treatment of emotional factors [5]. While in disease such as dermatitis artefacta this influence is primary and pathogenic, the relationships between the mind and the skin are usually more complex than this. This intricate interaction may reveal that chronic insult hand dermatitis is the result of the hand-washing rituals of those with obsessive compulsive disorders [6], or that the intractability of atopic dermatitis is a response to an impaired parent–child relationship [7]. The narrative has been supported by an increasing evidence base showing, for example, that stressed patients with psoriasis have more prolonged disease and that simple counselling support can be an effective way of reducing disease severity [3].

The burgeoning science of psychoneuroimmunology has contributed enormously to an understanding of altered immune mechanisms in depression and anxiety. This knowledge might help to explain why pemphigus might be triggered by stress [8] or viral skin infections prolonged [9]. The concepts of the relationship between mind and body and mind and skin may have seemed rather nebulous in the past but measurement and analysis of these interconnections is established. Although the intricacies of the neuro-immuno-cutaneous–endocrine (NICE) network [10] remains rudimentary and science lags behind practice, practical applications in dermatology are effective using hypnosis or biofeedback [11]. Similarly, work on the relationship between mental activity and peripheral blood flow [12] may shed light on the exacerbation of some inflammatory dermatoses by stress, and perhaps on the effect of stress on itching. The influence of psyche upon the skin implies that there are chemical mediators that translate an emotion to a cutaneous lesion. These mediators are neurotransmitters and hormones that can be produced directly in skin by nerve fibres or by other cells such as keratinocytes, Langerhans' cells and perhaps Merkel cells [13]. Neuropeptides, substance P (SP), substance Y, vasoactive intestinal peptide (VIP), calcitonin gene-related peptide (CGRP), and melanocyte stimulating hormone (MSH) all bind to cell surface receptors.

Nevertheless, many of the conditions mentioned in this chapter form obvious groups, shading from one into another. One such spectrum ranges from natural anxiety over disfiguring skin lesions, through disproportionate worry over minor blemishes, to disturbances of body image that lead patients to become obsessed with their skin in the absence of any abnormality, and, finally, to psychotic delusions about their skin (e.g. of parasitosis), which may occasionally be caused by organic brain pathology [14]. These are dealt with in more detail on p. 61.8.

In any patient-centred medical specialty, physical symptoms often present as a manifestation of emotional distress. Somatization is defined as physical symptoms suggesting physical disorder for which there are no demonstrable organic findings and for which there are positive evidence that symptoms are linked to psychological factors or conflicts (Diagnostic and Statistical Manual of Mental Disorders, fourth edition; DSM-IV). In primary care practice, an emotionally distressed patient is more likely to present with physical symptoms than to complain about psychological or social problems [15]. Many studies confirm that this type of patient, with unrecognized psychiatric morbidity, is often passed on to medical and surgical clinics [16]. Surgeons see patients with somatic abdominal pain, physicians those with chest pain and breathlessness, and neurologists those with somatic or 'functional' headache. Dermatologists see a spectrum of those who, for example, may have symptoms as varied as psychogenic itch to those with intractable burning genitalia. Indeed, dermatology in-patients are known to have a higher prevalence of psychiatric disorders than general medical in-patients and dermatology outpatients a higher prevalence than the general population [17].

Somatizing patients may recognize psychological symptoms as part of their illness, but these are overshadowed by intense physical complaints that allow those reluctant to accept the stigma of mental illness still to occupy the 'sick role' [18]. Depression and anxiety are the most common underlying psychological disorders but their mood disturbance and characteristic patterns of thinking are not volunteered. Some somatic symptoms are amplifications of normal physiological sensations (e.g. itching), which tend to worsen under stress [19]; others relate to the physiological accompaniments of anxiety, such as excessive sweating. This type of behaviour merges imperceptibly with hypochondriasis. In some patients, this amplification of physical symptoms with symptom hyperbole is an enduring personality trait [20].

Those areas of overlap between psychiatry and dermatology are important, and a competent dermatologist should be able to pick up any emotional and psychological clues and cues that may be advanced by the patient during consultation. All patients are individual but individual patient personality styles present with recognizable distinctive verbal and body language [21].

Psychological importance of the skin [1–3]

Some cutaneous stimulation is a basic need. Newborn mammals require the stimulus of licking and stroking, and caressing favours emotional development. Massaged babies gain weight as much as 50% faster than unmassaged babies. The functions of swaddling clothes provide an environment of warmth, touch and decreased stress as demonstrated by reduced heart rate, better feeding and longer sleep patterns. Children who live in emotionally destructive homes may show growth arrest as a response to the withdrawal of love and touch. As an organ of touch, temperature and pain sensation, and as an erogenous zone, the skin has great psychological importance at all ages. Many of the alternative medical therapies such as aromatherapy and kinesthesiology show clinical effects related to the the measureable effects of touch. Furthermore, patients who are regularly touched by their carers show quicker improvement than those who do not [3] and this effect is measureable at all ages and intelligences [4]. It is an organ of emotional expression and a site for the discharge of anxiety. Its texture and colour have meaning socially and politically, and its disorders carry with them a disproportionately heavy psychological punishment [5].

Body image [1,2]

Body image can be conceptualized by individuals in many different ways. There are a multiplicity of definitions, but the simplest is that of Critchley [3] who defined body image as 'the physical properties of a person carried into the imagery of himself'. It is important to remember that body image is completely abstract in conceptualization, depending on many factors, including memory, intellect, perception and early life experiences.

Body image may be conceptualized as the internal subjective representation of physical appearance and bodily experience [2]. This develops early, by the age of 3–4 years, with the drawing of the first recognizable figures by children [4]. Body image represents a view of ourselves not only physical but also has always had vital psychological and sociological importance [5]. There is a very significant cutaneous component, the most important areas of which include the face, scalp, hair, breasts in females and genital areas. A child's first recognizable body drawings are 'tadpole' figures, which emphasize the head with spindly legs and an absent body [4]. The nose, which is the central part of the face, is also focal to body-image conceptualization and it is not surprising therefore that skin disease manifesting itself even as a tiny spot on the nose, may produce disparate cosmetic distress, while a much larger lesion on an adjacent cheek may be completely ignored. As the face is both visible and in a very important body-image area, skin disease in this area can produce major distress and lowering of self-esteem. It has been shown that individuals with severe acne, particularly female, have a significant depression of their body image and self-esteem, which was reversible with successful treatment [6]. In addition, individuals with acne are less successful at gaining employment [7]. It may be that potential employers perceive individuals with acne as unattractive,

but also the interviewees themselves may reflect their lower self-esteem and confidence at interviews. Eczema and psoriasis are both likely to produce the same sort of effects, particularly at times of life when the individual would normally be beginning to socialize [8]. Adolescence can be particularly difficult for the teenager with acne, facial psoriasis or eczema. This self-recognition also appears early in child drawings of their disfigurement. The stigmatization induced by a port-wine stain may also deter individuals, particularly males, from making any sort of contact with the opposite sex [9]. The older that patients were before treatment, the higher negative scores for most psychosocial parameters such as self-esteem, supporting the argument for early treatment on psychological grounds [10].

It is important to recognize that individuals with skin problems in important body-image areas may be manifestly depressed. These individuals can be helped both by effective treatment and also by an empathetic medical practitioner. In some instances, a clinical psychologist may help a person to come to terms with his or her problems while, in a minority, depression is severe enough to merit treatment with antidepressants and the help of a psychiatrist. A liaison clinic is particularly helpful in managing this type of patient, where at times there may be a definite risk of suicide or parasuicide [11].

Psychoneuroimmunology [1–3]

The immune system and its relationship to cutaneous reponses is now established as part of the NICE system [1,2]. None of these processes can be be regarded as autonomous because immunoregulatory processes are part of an integrated system of defence [1]. Psychoneuroimmunology is the study of this integrated system and of behavioural–neuroendocrine–immune system interactions in particular.

The brain and immune system are linked by the autonomic nervous system and the neuroendocrine outflow via the hypothalamus and the pituitary gland. Communication between the immune system and the brain is bidirectional and probably largely mediated by neuropeptides [2]. More than 50 neuropeptides have now been identified, the smallest ones containing only two amino acids while the larger peptides contain 40 or more amino acids. Neuropeptides act not only as neurotransmitters, but also as neuromodulators.

Lymphoid tissue is innervated by noradrenergic postganglionic sympathetic nerve fibres, and peptidergic nerve fibres have also been identified in lymph nodes, thymus, spleen and bone marrow [3]. These nerve fibres form close neuroeffective junctions with lymphocytes and macrophages, which also possess receptors for neuropeptides [1].

Neuropeptides in the skin [2] are found not only in cutaneous nerves but also in most skin cells including keratinocytes, fibroblasts and Langerhans' cells. The role of vasoactive petides such as calcitonin gene-related peptide (CGRP), nocioceptive neurotransmitter SP, VIP, neuropeptide Y, and the newer pituitary adenylcyclate-activating peptide are increasingly evident in cutaneous inflammatory disease [3]; SP receptors found on mast cells, neutrophils and macrophages suggest a link between neurogenic stimuli and infiltration of the skin by inflammatory cells. CGRP has crucial immunomodulating effects on disease expression, perhaps by inhibition of antigen presentation by Langerhans' cells.

Moreover, lymphocytes have receptors for corticotrophin-releasing hormone (CRH), adrenocorticotrophic hormone (ACTH) and endogenous opioids, and both endorphins and enkephalins are known to directly influence antigen-specific and non-specific *in vivo* and *in vitro* responses [1].

Mind–body efferent immune interactions

Dermatologists have long recognized the relationship between stress and exacerbations of skin disease. With further knowledge of the psychoneuroimmunology of depression [4] and the further reviews of these effects in psychosomatic medicine [5], the efferent pathway from stress to disease is becoming clearer. Exposure to either naturally occurring or experimentally induced stress affect both humoral and cell-mediated immune responses. Bereavement is often associated with depression and many changes in immune function have been shown in depressed patients. Depression is associated with an increased number of circulating neutrophils, a decreased number of natural killer (NK) cells, T and B lymphocytes, and helper and suppressor cytotoxic T cells [6]. There are

also alterations in B-cell function, manifest by increased antibody titres to herpes simplex and cytomegalovirus [1]. Changes in both humoral and cell-mediated immunity have been found following marital separation and divorce [7] and alterations in immune function may occur during examinations [2]. Slowing of human wound healing has also been shown to be associated with stress, possibly mediated by depression of local production of the cytokine interleukin 1B [8].

Raychaudhuri and Farber [9] have proposed a psychoneuroimmunological basis for psoriasis. Thus, psoriatic skin has been shown to have a significant increase in SP-containing nerves. Psoriatic lesions are rich in neuropeptides such as SP and VIP. Proliferation of keratinocytes, a central feature of psoriasis, could be triggered by release of both SP and VIP, while SP could also induce localized lymphocytic proliferation. Moreover, the initiation and maintenance of the lymphocytic infiltrate characteristic of psoriasis could be in part related to SP, CGRP and VIP; indeed, SP can induce the expression of E-selectin on endothelium. For patients with atopic eczema, both SP and VIP have been demonstrated in lesional skin [10]. Moreover, NPY, a very potent vasoconstrictor, has been detected in the Langerhans' cells of patients with atopic eczema, but not in normal control subjects.

Body–mind afferent immune reactions

The bidirectional communication between the central nervous system (CNS) and the immune system provides the basis not only for behaviourally induced alterations in immune function, but also for immunologically based changes in behaviour [1]. Those patients who present with diseases causing intense afferent stimuli such as scratching, rubbing or traction are probably in a NICE loop where the inflammatory reaction stimulates an immune response which in turn releases cytokines to activate CNS neurotransmitters. Endorphins, for example, modify not only the perception of pain, but also other sensory perceptions [11] such as beauty. The compulsive and irresistible nature of scratching, excoriating and picking may relate to the pleasureable release of endorphins. These pathways may explain how emotional stress influences a wide range of disorders.

Emotional reactions to skin disease [1,2]

Skin disease causes physical problems and distress. The anthropological importance of the skin as an organ of communication both tactile and visual by touch and expression is well recorded [1]. With either real or imagined disfigurement comes shame and reclusiveness. These emotions are part of the arcane folk beliefs that most cutaneous disease is the result of infection with significant imputations of uncleanliness and self-neglect, even in Western cultures. The religious significance of leprosy in many cultures continues to exert an influence where the psychosocial stigma of depigmented skin in vitiligo may operate even in non-endemic populations. A poor self-image and low self-esteem is easily demonstrated by appropriate questionnaires [3]. Patients with psoriasis are aware that other people stare at them, particularly in socially revealing situations such as swimming, and experience much social distress [1,2]. Patients with vitiligo adjust better to their disorder than do those with psoriasis, but also tend to have low self-esteem [4]. There may be a hidden and unbroached difficulty with sexual expression and confidence [5], as skin disease frequently has a negative impact on sexual relationships [6], independent of extent but significantly related to site. The impaired self-image and psychological distress of patients with acne improve with successful treatment of the skin lesions [7].

One of the consistent correlates of the social isolation and low self-esteem is heavy alcohol consumption, which in male psoriatics correlates with both the physical severity of their skin disease and its duration [8]. Ten per cent of patients with psoriasis reported a death wish and 6% reported active suicidal ideation in one study [9]. Acne scarring can lead to profound depression and suicide [10].

Genital skin disease, particularly herpes and chronic candidosis, produces initial shock and emotional numbing at diagnosis followed by a frantic search for a cause, and later by a sense of loneliness and isolation. Some 10–15% of patients with genital herpes never adjust satisfactorily and continue to experience difficulties in all areas of their lives, which become increasingly reclusive and monastic [11].

The concept of stigma [12] is important in this context. It can be defined as a biological or social mark that sets a person apart from others, is discrediting and disrupts interactions with others [13]. In a study of adults with psoriasis, those who were older at the onset of the disease seemed less likely to anticipate rejection, and to be less sensitive to the opinions of others and to feelings of guilt, shame and secrecy [13]. Further, the perceptions of stigmatization were found to be related to psychological distress and degree of disability but not to clinical severity of involvement or anatomical area [14,15].

Atopic dermatitis in children is associated with high levels of psychological morbidity [13]. The disturbance was best predicted by the distribution of the eczema rather than its extent, with facial involvement in children showing particularly high levels of psychological distress. The additional effect of brief, simple, psychotherapy was sufficient to help those patients with high anxiety levels achieve normal remission [16].

With the approach of puberty, a disfiguring skin disease becomes an increasing anxiety to many children and may handicap them in developing easy relationships with the opposite sex [17]. Some children become increasingly introspective and solitary, while others become aggressive and uncooperative. The consultation process in these circumstances is most demanding. The best results are achieved by defusing the anger, which is usually the result of frustration and disappointment, by adopting a planned therapeutic and supportive role. This may be difficult but an organized programme with cooperation from parents, teachers and physicians can maintain optimism through established coping strategies [18]. With sensible and affectionate parents and intelligent teachers, children with disfiguring skin lesions will often adjust extremely well, form satisfactory sexual relationships and establish themselves in successful careers.

Disability and quality of life [1,2]

This aspect of dermatology is covered in more detail in Chapter 71.

Quality of life is defined as an individual's perception of their position in life in the context of the culture and value system in which they live and in relation to their goals, expectations, standards and concerns. It is a broad-ranging concept affected in a complex way by the person's physical heath, psychological state, level of independence, social relationships and relationship to salient features of their environment.

Established dermatological medicine describes skin disorders in relatively enclosed diagnostic terms, which takes little account of the effect of a particular skin disease on the individual patient. The patient with disease needs to be understood not only in terms of mechanistic outcomes of the kind usually assessed in clinical practice but also those composed of the psychosocial (hermaneutic) constructs that are assessed from the patient's self-reports. It is important to try to determine these disparate degrees of disability that a particular skin disease confers because their recognition leads to greater patient compliance and a more positive response [1–3].

The concept of skin failure is just as valid as that of renal, heart or respiratory failure [2]. The effect on quality of life induced by psoriasis, eczema and acne have been assessed using disability indices that are readily accessible [4]. These scales can also be used to quantify reduction in disability before and after treatment. The newer indices of disability have successfully combined the physical and psychological measures to produce a more holistic assessment of disease as exemplified by the Salford Psoriasis Index [3,5]. For instance, the presence of relatively trivial amounts of psoriasis on an individual's face may induce disparate depression. There are other instruments available for atopic eczema [6], acne in adolescence [7] and hair loss [8], which continue this development.

Quality of life assessments are not related to health but to disease and are usually specific to a particular diagnosis. This is very different from the non-medical

connotation of the meaning of the phrase, which is accepted to relate to a well state of contentedness of 'having a good time'. It has been proposed that in future the quality of life of ill people may need to take account of this difference because the patient's pathology involving release of cytokines and other mediators may affect their psychological state and thus response to questionnaires [9].

Classification [1,2]

There are two main internationally recognized classifications of psychiatric disorders. The first is produced by the American Psychiatric Association with disorders defined by diagnostic criteria describing their essential features. The DSM is modified regularly, the current revision dating from 2000 [1]. The current international classification and nomenclature system for medical and psychiatric disorder is published by the World Health Organization [2] and in many respects is similar to DSM. These classifications are part of the essential practice of psychiatry where the language and symptoms of disease and thus its subsequent treatment is to identify, for example, organic syndromes, schizophrenia, bipolar disorders, somatic and personality disorders. This may not be user friendly enough for clinical dermatologists in everyday practice. However, whatever the presenting features to dermatologists, it is signally important to remember that the symptoms are not a diagnosis and therefore should not be assumed to be amenable to the same treatment. For example, dermatitis artefacta may be a symptom of depression, personality disorder or an abnormal psychosocial situation; each requires different treatment. Various other classifications have their merits [3–5] but as our knowledge increases, overlap and clarification make changes inevitable. This classification is therefore pragmatic with an emphasis on usefulness for dermatologists.

Conditions that are primarily psychiatric but which commonly present to dermatologists

Delusional beliefs of skin
(i) Parasitosis (Ekbom's disease)
(ii) Smell
(iii) Impregnation and contamination
(iv) Folie à deux
Disorders of body image
(i) Body dysmorphic disorder (BDD) (syn. dysmorphophobia, dermatological non-disease)
(ii) Atypical pain disorders such as glossodynia and essential vulvodynia
(iii) Dermatological hypochondriasis
(iv) Cyberchondria
(v) Anorexia nervosa
(vi) Bigorexia
(vii) Tanorexia
Phobic states
(i) Venereophobia and acquired immune deficiency syndrome (AIDS) phobia
(ii) Mole phobia
(iii) Wart phobia
(iv) Erythrophobia
(v) Age phobia and botoxophilia
(vi) Ateroidphobia
Obsessive compulsive hand washing

Group and mass population reactions

Sick building syndrome
Epidemic hysteria

Dermatoses primarily factitious in origin

Dermatitis artefacta
Artefact by proxy
Witchcraft syndrome
Dermatological pathomimicry
Dermatitis simulata
Malingering
Compensation neurosis
Munchausen's syndrome
Munchausen's syndrome by proxy
Deliberate self-cutting
Self-mutilation
Religious stigmata and psychogenic purpura

Dermatoses aggravated by harmful habits and compulsions

Lichen simplex
Neurotic excoriations
Prurigo nodularis
Acne excoriée

Hair plucking
Trichotillomania
Trichophagia
Nail destruction
Onychotillomania
Lip-licking cheilitis
Knuckle biting
Disorders of neglect of self-care (syn. Diogenes syndrome)

Dermatoses caused by accentuated physiological responses

Hyperhidrosis
Blushing

Dermatoses in which emotional precipitating or perpetuating factors may be important

Vesicular eczema of the palms and soles
Atopic dermatitis in the adult
Seborrhoeic dermatitis
Psoriasis
Some cases of localized or generalized pruritus
Alopecia areata
Aphthosis
Rosacea
Chronic urticaria

This last group produces most debate and significant continuing research. Different views are held by dermatologists but while the early work relating skin disease to stress [6] was greeted with scepticism, the evolving body of evidence (see above) is a significant development to support the link.

Dermatological delusional symptoms [1,2]

A delusion is a disorder of the content of thinking. Delusions are beliefs that are false or not true to fact, cannot be corrected by an appeal to reason of the individual and are out of harmony with his or her educational and cultural background. Furthermore, the delusion can be further subclassified into [1,2]: (a) primary, where the delusion is the only psychological symptom; rather than (b) secondary functional, in which there is an underlying psychiatric condition such as depression; or (c) secondary organic, where there is physical illness such as dementia [3].

The dermatologist is most likely to see patients with delusions of parasitosis, which in itself is rare, rather than other cutaneous delusions. These are delusions of smell [2], of impregnation or of ocular or oral infestation, all of which are exceedingly uncommon. Equally so are patients who have a belief that they are ageing rapidly, the so-called Dorian Gray syndrome.

Delusions of parasitosis [4–6]

Definition. The patient with delusions of parasitosis (DP) has an unshakeable conviction that his or her skin is infested by parasites (this must be differentiated from parasitophobia—the *fear* of becoming infested).

Aetiology. Most patients with DP have a primary disorder defined as a monosymptomatic hypochondriacal psychosis being characterized by a single delusional system, relatively distinct from the remainder of the personality. The term monosymptomatic hypochondriacal psychosis may be applied to patients with a single, fixed, hypochondriacal delusion that is apparently not secondary to another psychiatric disorder [7]. Occasionally, there are associated visual hallucinations.

Secondary DP has been recorded as a feature of depression, bipolar disorder, paranoid states and schizophreniform illnesses [4–7]. It is therefore essential to define the full psychiatric spectrum in each patient. Those seen by psychiatrists are more likely to be labelled schizophrenic or depressed, or both. Such patients are often intelligent, and the professions are well represented, including doctors and even psychiatrists, but they are often rather solitary people and sometimes thought to be eccentric individuals. Lyell [4] has commented that it is hard to know where eccentricity ends and psychiatric illness begins. Moreover, some patients have a rather obsessional premorbid personality. Table 61.1 summarizes the secondary organic causes of DP [5]. Delusions of perception may follow disease in the non-dominant hemisphere, and so DP is sometimes seen in patients after a cerebrovascular accident involving that side of the brain. Similarly, DP may be part of the picture of dementia and should be considered when examining the elderly patient [8]. DP has also been described in pellagra, vitamin B_{12} deficiency, following coronary bypass surgery, as a side effect of phenelzine and in severe renal disease. DP in a young adult suggest illicit exposure to recreational drugs, in particular amphetamine or cocaine [9].

It is particularly important to exclude the possibility of

Table 61.1 Organic medical disorders associated with delusional parasitosis.

Neurological
Cerebrovascular disease
Dementia
Parkinson's disease
CNS tumours
Cardiovascular disorders
Arrhythmias
Heart failure
Coronary artery bypass
Endocrine disease
Diabetes mellitus
Hyperthyroidism
Hypoparathyroidism
Acromegaly
Nutritional disorders
Pellagra
Vitamin B_{12} deficiency
Anorexia nervosa
Infectious diseases
Syphilis
AIDS
Tuberculosis (pulmonary)
Leprosy
Malignancy
Breast cancer
Lung cancer
Lymphoma
Chronic lymphatic leukaemia
Substance abuse
Amphetamines
Cocaine
Medicines
Corticosteroids
Phenelzine pargyline

a real infestation. In 6% of one series, patients developed DP following real infestation [4] and 12% had a delusion shared with another member of the family (folie à deux; see below).

Incidence. Patients with DP are rare but the true prevalence is unknown. The condition affects both sexes equally below the age of 50 years, but after that age three times as many women are affected as men [3,10]. Although patients with DP are relatively easily recognized, it is possible to spend a lifetime as a dermatologist and never see such a patient. The young patient with DP should be regarded with the utmost concern for they may be drug abusers or the symptom may be the early signs of a major psychotic illness [9].

Clinical features. The presenting features of DP may be extremely variable. It can be as dramatic as an appeal from the primary care practitioner to see urgently a patient with an established delusion of infestation because they are disrupting everyone's life with constant demands, to an apparently benign, ill-defined, persistent itching with no immediate obvious delusional thoughts.

Fig. 61.1 Neurotic exoriations.

In the most established case, the patient may have consulted a series of specialist services to eradicate the imagined infestation. The family doctor is consulted repeatedly for even 'stronger' medicines to treat the 'bugs', the public health authorities called on many occasions to disinfest the home and the veterinary services recruited to scrutinize and treat pets. Eminent university personnel may have been consulted, both medical in infectious disease departments or scientific in zoology specialties. Specimens are sent to international institutions such as the British Museum for the ultimate examination. By the time the patient reaches the clinic there is always an inevitable degree of frustration, anger and impatience which makes the first consultation both difficult and vital.

The presenting symptoms may often be surprisingly ill-defined. Some speak of a sensation in their skin as though an insect or worm is crawling around, followed by a prolonged and elaborate description of the pathway the organism is taking. This agent may not be confined to the skin but also involve the genital, oral [11] or ocular [12] areas. They may describe and draw the insect or worm concerned but not uncommonly describe the infestation as invisible or dissolved in orificial secretions.

No obvious skin disease may be present, but excoriations are common and can be both extensive and very destructive (Fig. 61.1). These follow attempts by the patient to extract the 'parasites' and are therefore not artefactual lesions but produced in an apparently legitimate attempt at cure. Usually, the patient will bring samples to the clinic. Commonly, they proffer a small container, such as a matchbox or pill container, enclosing their 'insects' (Fig. 61.2). Some samples may be described as 'seeds', a guarded interpretation particularly in the patient who is

Fig. 61.2 Container of imaginary insects—from a patient with delusional parasitosis.

now cautious after seeing many doctors. Other samples that have been brought are collections of sweat, sellotape strippings of skin, folded elastoplast impregnated with debris and liquid samples collected from orifices. On microscopy these offerings are usually found to be fragments of skin and hair, samples of fabric and coagulated elements of serum, dust and detritus. The samples may include actual organisms such as ants, flies and sundry isolated fleas. The purification rituals that rapidly become established compel the patients to cleanse the skin and their environment with ever-increasing zeal. Their skin may smell of organic solvents such as benzyl benzoate or horticultural insecticide spray, the hands of bleach and disinfectant. A secondary general or localized chemically induced dermatitis is a feature. This irritant dermatitis is a further reinforcement of the delusional belief.

In 12% of cases, delusions are shared [2,7,13,14]: so-called folie à deux. This is defined in DSM-IV as a delusion developing in an individual in the context of a close relationship with another person, who has an established delusion. Once again this phenomenon is reported more often in women [14] and therefore the relationship between subjects is more often between sisters (34%), wife and husband (20%) and mother and child (20%). This contrasts with that reported between brothers (9%) and fathers and sons (2%). Rarely, the disorder can involve whole families [14].

Diagnosis. Although it is unlikely, the first task is to be certain there is no infestation; primarily scabies, rarely onchocerciasis. In most cases, the history, clinic behaviour, physical examination and presentation of specimens makes the diagnosis of DP obvious. It is also important to rule out underlying secondary organic disease, although this is rare. However, presentations in patients with secondary delusions as part of a depression or dementia may present in a more subtle fashion. The nature of depression may make the patient less communicative and more guilt-ridden. There may be a need to enquire actively about beliefs of infestation in a patient who complains of itching alone. Clinically, there may be a distinction between a true delusion and an overvalued idea [15]. The latter is an acceptable comprehensible idea carried on beyond the bounds of reason. It becomes so dominant that all other ideas are secondary. The patient's life becomes to revolve around this one idea. For example, a depressed bereaved widow who suddenly becomes a social isolate may come to believe that her itching is caused by insects. The nature of depression with feelings of unworthiness and guilt is part of this psychopathology.

Management. Musalek *et al.* [3] have emphasized the importance of establishing a psychiatric diagnosis before instituting treatment. Some patients with DP are depressed, and have been treated with conventional tricyclic antidepressants or serotonin reuptake inhibitors (SSRIs), often with pimozide. It should be remembered that suicide is an ever-attendant risk in these patients [1,4]. The management of patients with DP is always difficult. The basis of the consultation is to change the agenda from one of dermatological infestation as seen by the patient to one of psychiatric intervention. It is therefore essential to maintain a cohesive doctor–patient relationship. The full consultation process should be pursued, with adequate time given for the history, and proper care taken in the physical examination. All samples should be examined at the time and under the microscope. If you are perfunctory about this the patient will be less likely to continue with the same cooperation. Neither should you collude with the patient; it is better to say, 'I can't see any of the parasites today' than to tell the patient that you will treat 'them just in case' to get them out of the room. Neither is it helpful to say directly on the first visit that he or she has a mental problem. Sometimes, patients can be persuaded to accept the medication if told that it has helped previous patients with similar problems. Initially, it is often best to admit the patient to hospital. This reduces pressure at home on other family members and ensures compliance with medication. A psychiatric colleague can more easily be asked to see the patient in the dermatology ward. The further management is ideally a joint consultation with liaison psychiatry but the inevitable difficulty is to convince the patient that this is a psychiatric problem [16].

The response to pimozide is often good in these patients and the initial dose (2 mg) is increased weekly by 2-mg increments as necessary to a maximum of 12 mg/day [16,17]. On higher doses, patients may develop extrapyramidal symptoms which require addition of benzatropine 1–2 mg up to four times daily. With higher doses of pimozide there is a definite risk of ventricular arrhythmias and other electrocardiogram (ECG) abnormalities such as prolongation of the Q–T interval and T-wave changes. An ECG should be performed before pimozide therapy, and the drug should not be given to patients with a prolonged Q–T interval or to patients with a history of cardiac arrhythmia. Patients taking long-term pimozide should have a regular ECG at least once a year and if the Q–T interval is prolonged, treatment should be reviewed or withdrawn [10]. Moreover, concurrent treatment with other antipsychotics, tricyclic antidepressants and other drugs that prolong the Q–T interval, such as the antihistamines terfenadine and astemizole, antimalarials or drugs such as diuretics that alter the electrolyte status, should be avoided [17]. Hypokalaemia may predispose to the cardiotoxic effects of pimozide and care should be taken in patients with hepatic or renal dysfunction [16]. For most patients, pimozide is slightly stimulant so is best given in the morning. However, some find it hypnotic and this minority should take the drug in the evening.

Alternative effective therapy with a better side effect profile includes sulpiride 200–400 mg/day [18]. While this too may produce extrapyramidal side effects, there is no risk of arrhythmias. More recently, the antipsychotic risperidone has proved of use at a dosage of 4–8 mg/day [18,19]. When compliance is a problem, depot neuroleptics may be used [18].

Patients frequently defect from follow-up clinics with the risk of relapse and therefore strenuous efforts should be made to maintain contact either via the general practitioner or community psychiatric services.

Delusions of smell [1,2]

In these cases, there is no actual olfactory hallucination but the patient 'knows' that they are emitting a foul odour. This is because they believe that other people avoid them and talk about them with evident disgust [1]. They believe that the origin of the smell is usually flatus and may see a gastroenterologist, or possibly foul sweat usually produced in excess from body folds and orifices. A subgroup complain of unbearable halitosis and seek dental advice. This delusion is commonly related to a chronic avoidant paranoid personality trait [2].

Two organic syndromes should be noted. First, delusions of smell have been associated with cerebral tumours and, secondly, the fish odour syndrome [3] where patients have suffered social exclusion because of the pungent smell. Occasionally, people who sweat excessively are made to feel unwanted, particularly if they are in an enclosed work environment. This form of social phobia may precipitate a more paranoid response.

Body dysmorphic disorder [1–4]

SYN. DERMATOLOGICAL NON-DISEASE; DYSMORPHOPHOBIA

The terms 'dysmorphophobia'and more recently 'dermatological non-disease' have been in use for over a century to describe patients who are rich in symptoms (especially in areas important in the body image) but poor in signs of

organic skin disease [1]. All dermatology clinics contain these distressed patients whose chronic attendance is a reflection of their impaired family, social and occupational functioning. This somatoform disorder is defined in DSM-IV as body dysmorphic disorder (BDD), a preoccupation with an imagined defect in appearance; if a slight defect is present the person's concern is markedly excessive. Although BDD is classified as a somatoform disorder, there is a delusional variant which is recognized as a psychotic disorder.

Prevalence. This condition was originally thought to be uncommon, but screening research over the last decade has revealed a prevalence of 12% [2]. A point prevalence study of a community sample of women in the USA showed a frequency of 0.75% [5], while a study of German students revealed a prevalence of 5.3% [6]. Patients who present for plastic surgery show rates of up to 15% [7]. Subclinical BDD (patients who keep their beliefs covert) are found in approximately one-fifth of patients presenting to aesthetic medicine; there is an equal gender frequency [8].

Aetiology. The aetiology is unknown. Some patients may be examples of monosymptomatic hypochondriacal psychosis [9] in that they have an isolated delusion. Affected individuals are often solitary, unmarried or divorced. As a whole, they socialize poorly and do not like contact with other people [2,10]. Their symptoms may appear after severe emotional, especially marital, problems and perineal symptoms in men may follow imagined or real sexual exposure. The disorder most often comorbid with BDD is major depression; rates of 60% and a lifetime rate of up to 80% have been reported [2,11]. The depressive symptoms may be subclinical but is revealed on direct questioning. An obsessional premorbid personality is not unusual [10] and comorbidity with obsessional compulsive disorder may be found in 30% [10,12]. Dysmorphophobic symptoms in a teenager or adult may be the presentation of schizophrenia, while in an elderly patient dementia should be considered. Comorbid psychiatric conditions have also included social phobia, trichotillomania, substance abuse and avoidant personality disorder [12,13]. In a study of patients with anorexia nervosa, 39% were diagnosed with comorbid BDD unrelated to weight concerns. These individuals had higher levels of delusionality and lower levels of social functioning than those with eating disorders alone [14]. There is usually no evidence of any underlying organic disease.

Clinical features. Most patients are in their third decade although reported ages are from 5 to 80 years. In one study, the average age of onset was 15 years and the average duration of symptoms was 18 years [12]. Opinions differ whether BDD is more common in men or women [2,10], although referral sources may affect the statistics. Many patients are unmarried and unemployed [15]. Dermatological non-disease presents with symptoms particularly in the face and head including the mouth and scalp. Facial symptoms include complaints of excessive redness, blushing, a burning feeling, scarring, large pores, excessive facial hair and facial greasiness. Patients with orodynia or glossodynia fit into this group with their defect in pain perception involving the mouth. Scalp symptoms include a feeling of intense burning, unremitting by day or night, and excessive hair loss. Those patients with facial and scalp problems are more often female, but those with perineal symptoms are more likely to be male. Perineal symptoms in males include complaints of an excessively red scrotum, discomfort in the genital area, often spreading on to the anterior thighs and making the wearing of clothes uncomfortable, described rather cumbersomely as the dysthaesic peno-scrotal syndrome [16]. The female equivalent, vulvodynia (the burning vulva syndrome) consists of several different clinical entities, including vulval dermatosis, cyclic vulvitis, vulval papillomatosis, the vulva vestibular syndrome and essential vulvodynia [17]. In essential vulvodynia, the discomfort may be so severe that the patient will neither sit down nor go to bed, and this drives every other member of the family to distraction. Women with essential vulvodynia are more distressed than patients with an identified physical cause of vulval pain [18] (see also Chapter 68).

A consultation with a patient with dermatological non-disease always takes much longer than one with a patient with organic disease. The same ground has to be gone over repeatedly and the patient never appreciates normal non-verbal communication emanating from the doctor. The content of the consultation is dominated by complaints of ugliness, unattractiveness and irreconcilable deformity. Any body part may be involved, although a minority may worry about more than one area. Their thoughts are dominated by the abnormality for up to 8 h daily, the distress is intense, self-esteem poor and insight minimal. They admit to compulsive behaviours with excessive grooming, clothes changes and mirror gazing [2]. Patients are driven by the desire to know what they look like, a desire that is made worse if they resist the urge. BDD patients invariably feel worse after mirror watching but cannot resist looking in other reflective surfaces such as shop windows, cutlery and shiny compact discs. The function of mirror watching may be to practise showing the best face to the public [19]. Other activities and behaviour may be stimulated by these beliefs with diet regimes, the purchase of enormous quantities of beauty products and the seeking of unending aesthetic treatments. Muscle dysmorphia describes the men who use illicit anabolic steroids and obsessive weight training to develop their bodies, so-called 'bigorexia'.

Patients with dermatological non-disease are 'doctor shoppers' and will have often seen many doctors over the years about their many problems. An individual patient is likely to return to the clinic within a few minutes of being seen and may repeatedly telephone the doctor asking questions that have already been answered many times in the immediate past. Uncommonly, the delusional type of BDD gives rise to familial BDD where the parent imposes a delusional idea upon the child who in turn develops BDD [20] or, even more rarely, the patient believes that their child has a bodily defect, BDD by proxy [21].

There is a definite risk of suicide in patients with dermatological non-disease [1,2,22,23] and in a large series of 30 patients with BDD, 29% had made a suicide attempt [24].

Dermatological and plastic-surgical treatment. Most patients with dysmorphophobia perceive the solution to their problems in dermatological or plastic-surgical terms and so come to haunt dermatologists and plastic surgeons rather than psychiatrists. It is interesting that a significant proportion of patients presenting with dysmorphophobia have previously received plastic surgery, most commonly to change the shape of their nose. However, occasionally plastic surgery in carefully selected cases may be helpful, but there is always a risk that the patients themselves may then move to a preoccupation with another part of the body. In a series of 30 patients, it was found that 30% of patients had received previous cosmetic surgery, with a mean of 2.0 ± 1.3 procedures and as many as six procedures had occurred in individual patients [24]. Furthermore, 81% of patients with BDD were either dissatisfied or very dissatisfied with their consultation and results of surgery [12]; therefore, if plastic surgery is planned in this group of patients it is very important to have careful preoperative psychiatric assessment. Those contemplating surgery should remember that some patients with BDD are angry and go to litigation relatively easily. A perfect cosmetic result may be perceived by a depressed dysmorphophobic patient as worse than the situation before surgery. Photography before and after surgery is important to refute such claims objectively.

Diagnosis [2,3]. It may be surprising that BDD is often diagnosed late because patients are reluctant to disclose their distress, shame and embarrassment. The clinical clue may be a persistent return to the clinic for a harmless small lesion. BDD should be asked about and stringent questionnaires are available to expose BDD-related thoughts and behaviours [2,3].

Management. The management of patients with dermatological delusional disease is always difficult. There are two treatments that are shown to be successful; first, pharmacotherapy with SSRIs and latterly with cognitive–behavioural therapy.

Treatment with SSRIs. Early studies showed that nearly 50% of patients may respond completely or partially to fluoxetine or clomipramine, whereas there was only a 5% response to all other medications [24]. Systematic review of trials [25] confirmed that over 60% of patients have significant improvement in symptoms. It is important that the medication be continued long term as discontinuation precipitates relapse in 80%. All SSRIs are equally effective and the choice depends on tolerability. In many patients there is a significant improvement in the social prognosis evidenced by an ability to return to school or work. This is accompanied by a reduction in ritualistic behaviour, such as mirror checking and skin picking. Phillips *et al*. [24] observed that only a small proportion of patients responding to SSRIs experience any change in insight.

It is important to note that the effective dosage of SSRIs is usually higher than the dosage conventionally used to treat depression (e.g. the dosage of fluoxetine and fluvoxamine are 50 and 260 mg/day, respectively). In short, the dosage of SSRI needs to be high and the duration of treatment is long term, with response taking on average 2–4 months. The duration of treatment is usually at least 1 year.

There are several pharmacological options for patients who fail to respond to this type of regimen, and the addition of low-dose clomipramine, buspirone 30–60 mg/day or other antipsychotics have been used by psychiatrists. Venlafaxine 37.5 mg/day can be substituted for the SSRI. The help of liaison psychiatry services can be very helpful at this stage.

Patients with somatic pain (e.g. vulvodynia and scrotodynia) may benefit from tricyclic antidepressants such as amitriptyline 50–150 mg/day or alternatively gabapentin 900–1500 mg/day.

Cognitive–behavioural therapy [2,26]. Simple behavioural treatment, such as encouraging patients to avoid ritualistic behaviour and mirror checking, and urging them to give up unnecessary cosmetic camouflage, while gradually exposing them to the most feared social situations, can be helpful, especially if combined with a cognitive approach involving self-esteem building and modification of distorted thinking, coupled with coping strategies. All these techniques are more likely to be effective when combined with SSRI treatment, and initially some patients may be too ill to benefit from a cognitive–behavioural approach. This needs the help of a skilled clinical psychologist but has the advantage that it is often more acceptable to the patient. Up to 77% response can be measured in stress and symptom reduction [26].

Supportive psychotherapy can be helpful in those patients with overvalued ideas who are not truly deluded, but it is very time-consuming and emotionally demanding. As a generalization, patients with BDD are poor communicators and difficulty with interpersonal relationships

may be one of the central crucial and earliest features of this disorder. The physician therefore undertaking supportive psychotherapy has to be patient and very tolerant. Dysmorphophobic patients are poor attenders at clinics, but the consultation may, in some cases, be the only opportunity that they have to talk to another human being, a reflection of the isolated life these patients often lead.

Habituation to dressings

Liddell and Cotterill [1] described a group of patients who became habituated to occlusive bandages, which had been initially applied many years before as treatment for either gravitational ulcers or eczema of the legs. Although the skin in all patients had returned to complete normality, it was impossible to persuade the patients to abandon their occlusive therapy. The patients tended to be elderly, single, lonely and inadequate, and most were male.

It was thought that the behaviour in this group may be regarded as 'attention seeking' in that they derive some sympathy from others because of their problem. Avoidance of work may have been successfully accomplished by some of these patients.

Some patients seem to enjoy the social contact that regular attendance at the clinic brings and are reluctant to be discharged. Thus, it appears that occlusive dressings may support not only the legs, but in a minority of patients, the psyche too.

Cutaneous phobias

A phobic disorder is said to exist when anxiety, often amounting to panic, is evoked only or predominantly in well-defined situations. Patients who are subject to obsessional and ruminative thoughts about contamination and infestation may formalize these specifically into phobias about warts, infestation, dirt or bodily secretions. Patients are afraid to touch anything in the consulting room; indeed, in the hospital occasionally. Such patients will wear gloves when shopping or filling their car with petrol, and even the sight of a wart on another person can induce acute panic. Wart-phobic patients will bring other family members to dermatologists, and attempts will be made to make the dermatologist collude with the phobia and treat a wide variety of minute skin lesions in both the patient and his or her immediate relatives. A sterile pack may be produced so that there is no question of the patient's bare feet coming in contact with anything in the consulting room. Tights and socks are abandoned on the consulting room floor because they are regarded as contaminated by the patient. While relatively few patients with obsessive–compulsive disorder present directly to psychiatrists, it has been claimed that up to 14% of anxious, itchy, dermatological patients have this psychiatric disorder [1]. The typical patient realizes that these persistent ideas are inappropriate, but they continue to engender much distress and anxiety. Attempts are made to ameliorate the anxiety resulting from the obsession by compulsive acts and rituals, which vary from rubbing, lip licking or touching the skin, to more complex rituals involving washing, cleaning, hair pulling, skin excoriation and other cutaneous damaging behaviour.

Patients' phobias about dirt and bacteria may present as hand eczema induced by repeated hand washing. This psychiatric diagnosis should be considered in all patients with refractory hand eczema. The obsessional ideas become heightened during periods of emotional stress.

Mole phobia has also become more common since the recent publicity campaigns about the early diagnosis of malignant melanoma. Affected individuals consult dermatologists repeatedly, along with their unwilling family members. This is often a response to an actual tragic death from malignant melanoma in family, friends or neighbours. Despite reassurances they present repeatedly at clinics [2] and often demand that all the moles are removed and if refused will find a private surgeon to do this [3]. Regularly timed appointments with responsibility given to the physician can be a simple way to defuse panic attacks.

Patients with an overvalued idea about the possibility of venereal disease, including AIDS and herpes simplex, may be anxious or depressed, and a rather obsessional personality trait is not unusual in this group of patients [4].

Although blushing itself is normal under certain circumstances, blushing that is grossly excessive in both frequency and extent is particularly seen in women and may be the cause of considerable embarrassment. The fear of easy and excessive blushing gives rise to erythrophobia [5], which has two components: first, the fear of blushing and, secondly, excessive reactive flushing. Patients with erythrophobia show abnormal autonomic regulation under mental stress [5]. It has also been shown that task training can reduce the phobic behaviour independent of facial coloration [6]. These patients frequently suffer emotional difficulties and inhibitions and can sometimes be helped by a sympathetic clinical psychologist. Flushing may be a manifestation of hyperthyroidism and the distinctive flushing of the carcinoid syndrome must also be excluded (see Chapter 44).

A patient presenting with 'multiple allergies' may have a fear of allergic reactions [7]. All minor skin complaints are misinterpreted by the phobic patient as allergies and the consequent avoidant behaviour may become socially destructive.

An unreasonable fear of topical steroids amounting to an overvalued negative idea prompts patients and parents to refuse treatment. This was based first on real fears of skin thinning but, secondly, in one-quarter of those questioned, on a belief that non-specifically there will be long-term bad effects [8]. Treatment compliance is greatly improved by close surveillance and reassurance.

Anorexia nervosa and bulimia [1–3]

Anorexia nervosa can be looked upon as a phobia about body weight. In the definition of anorexia nervosa in the International Statistical Classification of Diseases 10 (ICD-10), body image distortion is one of the essential features. There is a dread of fatness as an intrusive overvalued idea. There are associations with other psychodermatoses, BDD and self-injurious behaviours. Hair pulling, self-cutting, excoriations and bruising occurred in 44% of 134 female patients [4].

The nutritional consequences of anorexia nervosa are frequent and many dermatological sequelae have been described. The most frequent skin manifestation is xerosis (58%), with a particular form of branny scaling developing on the extensor surfaces of the limbs and flexures. Hair effluvium occurred in 50%, with nail deformities in 45% and cheilitis in 40%. Diffuse hypertrichosis, carotenoderma, poor wound healing and striae distensae were more common in the restrictive type of anorexia as opposed to the bulimic type where hair and nail changes and generalized pruritus were more prominent [3]. Severe perniosis is also seen in individuals with anorexia nervosa [5]. Drenching night sweats during weight recovery, possibly brought about by secondary changes in thermoregulation, which occur with rapid refeeding, have also recently been described in patients with eating disorders [6] as has acne [2].

A minority may develop melasma and seborrhoeic dermatitis. Brittle nails, dry skin and calluses on the fingers are produced by repetitive self-induced vomiting. In the mouth, there may be dental enamel erosion and gingivitis and some patients develop a Sjögren-like syndrome. Other cutaneous features may result from the use of laxatives, such as phenolphthalein, producing a fixed drug reaction, and thiazide diuretics, producing photosensitivity, while the use of the emetic ipecacuanha can be associated with a dermatomyositis-like syndrome [7]. Compulsive hand washing and trichotillomania may result from accompanying psychiatric illness.

The alert dermatologist should suspect anorexia nervosa when presented with these suggestive signs, particularly hair loss and xerosis in an underweight girl. A simple screening questionnaire (SCOFF) [8] is helpful for detecting eating disoders. The patient should be referred to the psychiatrist for specialized care.

Group and mass population reactions [1]

Epidemic hysteria syndrome and occupational mass psychogenic illness

The modern nomenclature for hysteria is conversion or dissociation disorder. The implications of this classification are that the symptoms are psychogenic, that the causation is unconscious, and that symptoms may carry some advantage, either primary such as debilitating symptoms or secondary by being exempted from community responsibility or gaining public attention. Conversion implies the behaviour of physical illness without evidence of organic pathology, the patient being unaware of the psychopathology. The prime examples of this group response are epidemics occurring in the closed communities of workplace and school.

In 1978 there were two separate outbreaks of skin disorders among factory workers in a small town in northern England. In each outbreak, a central female figure with non-industrial dermatological problems fuelled an epidemic of what was thought to be dermatitis among several employees in a ceramics factory and a second epidemic in a textile factory. In the first outbreak 10 employees were affected and 17 in the second. No significant dermatological pathology of industrial origin was found [2]. A similar outbreak occurred in a warehouse, triggered by two severe cases of non-occupational eczema, combined with the idea that incoming aircraft parts to the warehouse from foreign countries might be 'dirty' in some way. This caused a heightened perception of the risk of skin disease, with increased frequency of hand washing. Overfrequent hand washing in a few employees resulted in precisely what the warehouse staff had been trying to avoid [3]. An outbreak in the pottery industry that began as isolated gum arabic sensitivity developed into a more widespread epidemic described as 'epidemic hysteria dermatologica' in eight female workers [4]. There was also a female preponderance in the outbreak at a textile factory where the skin problems were common dermatoses unrelated to work [5]. Most of these mass reactions involve female workers and to try to explain this it has been postulated that in stressful situations in boring, low-paid, repetitive jobs women are more likely to externalize their discontent as a conversion symptom than a direct complaint that may jeopardize their job [1].

Surveys of occupational mass psychogenic illness (OMPI) episodes stress that many outbreaks occur in dehumanizing jobs with poor management communication. Secondary compensation neurosis may follow to prolong the epidemic from those who feel particularly injured. It is clearly important, if possible, to visit a factory very early and examine all the complainants in an outbreak of alleged 'epidemic' industrial dermatitis.

In the other common closed community, schools, epidemic complaints of itch dry skin and transient rash were predominant [6–8]. These outbreaks involved 50–100 children aged 7–12 years. The symptoms lasted 2 weeks and no cause was found. Girls outnumbered boys by 3 to 1. It has been suggested that the precipitating factors may be illness in a favourite teacher or student, rigid teaching regimens and parental pressure for academic success.

Sick building syndrome [1,2]

The concept of building-related illness (BRI) [1] has grown from the rather vague and controversial grouping of symptoms that appear to be caused by a range of supposed allergic, toxic, irritative and possibly infectious causes, to a subject where objective evidence is beginning to define the multifactorial aetiology of this contemporary phenomenon. Both sick building syndrome (SBS) and BRI refer to illnesses related particularly to non-industrial premises such as large blocks of apartments or offices where people spend considerable periods of time in close association. These syndromes consist of a series of heterogeneous complaints such as irritable dry skin, dryness and cracking of mucous membranes of mouth, nose and eyes, recurrent sore throat, headache, fatigue and loss of concentration. In over half of patients the symptoms are

dermatological but the lack of demonstrable biological correlates together with vague aetiological attributes makes precise definition of the problem difficult [2]. Patch testing is negative.

Much of the debate has centred on dampness, smell and ventilation in buildings. In a large review [2], symptoms were significantly associated with signs of dampness, condensation, water leakage, high humidity and mouldy odour. Furthermore, the symptomatology could be related more to mechanical ventilation systems and internal air conditioning than in buildings where there was efficient natural ventilation [3,4]. In addition, changing from artificial ventilation to a natural one reduced skin symptoms by one-third [5].

Workers may feel ill when exposed to odours from xenobiotic sources (cacosmia) [6]. The presence of a strange smell at work may precipitate symptoms in a significant number of previously healthy individuals. Subsequent exposure sets up a classical conditionary loop with somatic amplification of symptoms. Patients develop headache, itchy eyes, transient rash and congested nose or throat followed by sweating, faintness and tachycardia. In most cases, the odour is chemically harmless. A significant psychological component has been postulated, as was the case when 24 workers reported sensitivity to electricity in the workplace, causing itchy whealing of face and limbs [7]. The patients reported increased symptoms not only when they were exposed to an experimental electromagnetic field but also when they believed they were exposed, even though the field was turned off.

Not surprisingly therefore, work stress, manifested by role conflict, work overload, managerial difficulties and workplace building renovations have all been significantly associated with perceptions of poor workplace air quality and increased dermatological symptoms of SBS [8].

Symptoms were more common in those lower down the office hierarchy than in managers, and women had more symptoms than men, irrespective of their status [2].

Self-inflicted and simulated skin disease

It is important to differentiate the dermatological diseases provoked by voluntary, admitted, self-traumatizing behaviour from those induced by covert deception to give the appearance of disease. The former group may range from a normal stress-related activity such as nail biting to a more disease-classifiable problem (e.g. trichotillomania or compulsive hair plucking). At no time is there an intention to falsify the origin of the skin-related damage or to actively obscure the part the patient plays in its production. This does not mean that the shame and self-reproach associated with these activities are not occasionally responsible for a reluctance to primarily volunteer the patient's part. However, this behaviour is significantly different from that of a true factitious disorder, which exhibits the essential elements of the intentional production or feigning of physical or psychological signs or symptoms and the continued denial of the disease origin to the physician. The motivation for this behaviour is assumed to be the sick role and an essential difference from malingering is that there is no external incentive for the behaviour such as economic, legal or employment advantage.

There are normal behaviour habits associated with the skin that appear repetitively at times of stress and anxiety. Picking, plucking, sucking, rubbing, biting and pulling behaviour on skin, nails and hair are stress-relieving activities, which may be reinforced by the release of endorphin-like substances as a neuroendocrine response.

Each of these behaviours is physically brief or spasmodic and, on most occasions, a conscious activity that does not intrude on normal skin function. However, when these habits become entrenched as a repetitive almost compulsive daily routine, or progress beyond the stage where they are an incidental stress-relieving activity, then they are recognizable as a number of dermatological disorders. Nail biting (onychophagia) has been recorded from the age of 15 months [1] but is more common after the age of 3 years and is present in over one-third of children between the ages of 7 and 10 years [2]. Up to half of adolescents continue to bite their nails, and 13.7% of older students and young adults [3,4] show continued body-focused repetitive behaviours (BFRBs), of which nail biting was the most frequent. In addition, those patients who continue with BFRBs also exhibit frequent somatizing activity in other illness. Obsessive onychophagia is well recorded [5]. Studies of college students [5,6] showed 1.5% of males and 3.4% of females continued hair pulling, but only 0.5% satisfied the DSM-IV-R criteria for trichotillomania.

Scratching and rubbing behaviour may progress to lichen simplex or nodular prurigo. Destructive picking activity may develop into neurotic excoriations or acne excoriée. Nose picking (rhinotillexomania) greater than

20 times per day may persist in 8% of adolescents [7] and while this may be a culture-bound syndrome, it is associated with multiple BFRBs in approximately 15% of individuals, usually men. In extreme cases, trigeminal trophic syndrome may follow herpes zoster in the nasal area. Persistent pluckers most commonly abuse their hair and can present with trichotillomania. Perioral dermatitis can be a consequence of chronic lip-licking behaviour and chronic cheilitis the result of lip biting (see Chapter 66). Chronic nail disease such as paronychia follows from nail biting and onychophagia (see Chapter 62).

Lichen simplex and neurodermatitis

(see Chapter 17)

Lichenification describes the characteristic pattern of response of the predisposed skin to repeated rubbing. In some instances, a minor initiating event, such as trauma, infection or insect bite, precipitates episodic insistent scratching and rubbing. Irresistable itching is the major complaint, scratching the chronic accompaniment. This behaviour takes the form of rubbing with either the hands, back of nails or knuckles and in extreme cases sometimes with the use of a convenient instrument such as a hairbrush, a pen or some other domestic implement. The actions may be subconscious and proceed without continuous conscious control. However, in some cases patients subject themselves to frenetic prolonged spasms of uncontrollable self-damage, which proceeds with increasing rapidity until the pruritus is replaced by soreness and pain. The change from itch to pain is quite sudden and this abrupt cessation has been described as orgasm cutanée. Lichen simplex and neurodermatitis are much less common in the elderly.

Regular rubbing and pressure on the skin produces the characteristic thickened, coarsely grained nodules on the skin with hyperpigmentation. The classic sites of involvement are within easy reach, particularly on the nape and sides of the neck, elbows, thighs, knees and ankles. It is unknown why these areas remain so discrete. These areas may be in varying stages of evolution, from early small violaceous papules with surface excoriations to chronic areas that present as hyperkeratotic plaques with pigment changes, described as 'dermatological worry beads'. Localized patches of lichen simplex presenting as pruritus ani and vulvae are described in Chapters 17 and 68. These lesions are more often found in females and occur predominantly after puberty. They are found, very rarely, as isolated phenomena in children, even in atopics. They are more often seen in Afro-Caribbean patients.

Most authors have commented on the relationship of emotional tension to bouts of scratching [1]. Patients are usually described as stable but anxious individuals, whose reactions to stress are relieved by ritualized behaviour such as rubbing [2]. Aggression and hostility related to anxiety [3] caused by emotional disturbance may lead to itching. This maladaptive response has been treated successfully with behaviour therapy [3] to break the itch–scratch cycle.

Treatment with antihistamines is helpful, but antidepressants, particularly tricyclic compounds such as doxepin in dosage as low as 25–50 mg/day, have been shown to be more effective [4]. Non-psychotropic medication is also sometimes effective using thalidomide 50–100 mg/day for up to 2 months at a time.

Psychogenic excoriations

SYN. NEUROTIC EXCORIATIONS; COMPULSIVE SKIN PICKING; DERMATILLOMANIA; ACNE EXCORIÉE [1,2]

The most common of the self-inflicted dermatoses are neurotic excoriations and acne excoriée. The differences between the two are more a matter of distribution than degree of severity of the lesions. The lesions differ from other artefactual disorders as those who suffer readily admit to an urge to pick and gouge at their skin. Both of these clinical syndromes are characterized by the preponderance of females, the destructive scarring nature of the lesions and the relationship to psychological stress. Some patients show features of both conditions and one condition may merge into the other.

Destructive excoriations are seen most frequently in middle-aged women, the average age of onset being between 30 and 50 years of age [1,4], but significantly the average duration of disease before presentation can be up to 10 years. This group make up the most severe cases, where the problem tends to be persistent and unremitting.

The picking and excoriation proceeds in bouts that exceed the bounds of simple habit. These patients are described as rather rigid and obsessional individuals with repressed emotions [3,5]. They have difficulty in verbalizing their problems and are aggressive but also insecure [4]. Depression was a very common feature in one series [2]. These patients describe picking, scratching, gouging and using implements on their skin, producing bleeding and pain during periods of low mood and self-esteem. There is a compulsive quality about the need to continue until pain is produced. The duration of these bouts may last for some hours and can be ritualized to a set time and place. Psychosocial stresses have been reported to precede exacerbations of excoriations in 30–90% of patients [1,4]. Immediately following such behaviour, patients are characteristically unhappy and guilty about the disfigurement.

Patients with psychogenic excoriations frequently have co-morbid disorders in the compulsivity–impulsivity spectrum, including BDD, substance abuse, eating disorders and trichotillomania [2]. The Skin Picking Impact Scale (SPIS) is a self-report instrument developed to assess the psychosocial consequences of repetitive skin picking. SPIS scores were significantly higher for those with self-injurious behaviour than those with reactive scratching from itchy dermatoses and correlated with anxiety and depression inventories [6].

Clinical features. Lesions can be seen in all stages of development. Clinically, the lesions are polymorphic, the newer lesions are angular crusted excoriated erosions with a serosanguinous crust, found predominantly on the sides of the neck, chin, upper chest shoulders and upper arms. The healing lesions are erythematous and depigmented, eventually with chronicity becoming white and atrophic centrally and commonly hyperpigmented at the periphery. They may be quite deep, extending into dermis, and are distributed symmetrically within reach of the hands. Older lesions show pink or red scars, some of which may be hypertrophic. Chronic lesions may also show atrophic scars, which merge and are eventually seen as linear coalescent areas. Lesions appear at all stages of development and may number from a few to several hundred (Fig. 61.1).

Differential diagnosis. It is important to exclude excoriations caused by generalized pruritus, bullous disorders such as pemphigus, and linear excoriated lesions, which may be the presenting signs of lichen planus or lupus erythematosus.

Treatment. Simple, empathic, supportive psychotherapy can produce significant improvement, whereas insight-orientated analysis may exacerbate symptoms [7]. Cognitive–behavioural therapy has improved some patients, although the management of underlying personality difficulties may require the specific skills of a psychotherapist [8,9]. Habit reversal programmes may also help [2]. The compulsive nature of this disorder responds well to antidepressants and in particular to SSRIs, such as fluoxetine, fluvoxamine and citalopram [2,6]. Clomipramine [10] and doxepin [11] have been reported to work well. While the condition eventually resolves, the most difficult cases are middle-aged women with established patterns of excoriation, which may have been present continuing for decades. It may be necessary to continue antidepressants in these patients for some years.

Acne excoriée (see Chapter 43) [1,2]

There is not one patient with acne who can resist squeezing and pinching of lesions. Brocq [3] in 1891 described acne excoriée particularly in adolescent girls under emotional stress who picked and squeezed acne spots. The condition should be considered to be a variant of psychogenic (neurotic) excoriation [2] with the lesions largely confined to the face. Acne excoriée is more common in women [1–4] and seen in an older age group than acne vulgaris, with a mean age of approximately 30 years [1,2,4]. Psychological studies have shown no diagnosable DSM-IV-R disorder [4,5], although associated phobic states [1] and depressive and delusional disorders [6,7] have been described.

The clinical lesions resemble those of excoriations. They are found predominantly around the hairline, forehead, pre-auricular cheek and chin areas. Extension to the neck and occipital hairline is common and with even more extensive lesions producing an overlap clinically with psychogenic pruritus. Chronic lesions characteristically show white atrophic scarring with peripheral hyperpigmentation.

A strong association with atopy has been suggested with resemblances to prurigo mitis.

Although patients with acne excoriée sometimes respond to simple topical acne therapy, most require systemic antibiotics and isotretinoin. The tetracyclines, in particular doxycycline, are better than the other antibiotics [1] and topically the patients prefer antibiotic roll-on preparations to the benzoyl peroxide creams, which are too irritant. While this may arrest the development of new lesions and scarring, the physical course of the disease is poor without psychological support [1]. These patients tend to be psychologically dependent, and the benefits of simple supportive consultation and psychotherapy should not be underestimated [8]. Compulsive behaviour that leads to further scarring may respond to cognitive and habit-reversal therapy [9].

Psychogenic pruritus [1,2]

This subgroup of the psychopruritic disorders represents those with intractable or persistent itch for which no pruritic physical illness or dermatological illness can be found [1]. Musaph [2] pointed out that one mechanism for relieving everyday irritations is to scratch a little. The motorist stopped at a red traffic light almost invariably scratches some accessible site such as the neck and most of us develop a small itch from time to time during the day that is relieved by slight scratching. He called this the 'traffic-light phenomenon' and its function is a common way of relieving minor frustrations. Individuals who develop localized or generalized neurodermatitis may begin in this way, but their itch–scratch cycle gets out of hand. In some individuals, intense scratching can induce an ultimate feeling of pleasure and this may be related to the release of opioids centrally.

Enkephalins and endorphins are important as neurotransmitters in the CNS in mediating the sensation of itch because it has been recognized for many years that, although morphine may alleviate pain, it may aggravate itch. As itch and pain are thought to share common neurological pathways, the central elicitation of itch by morphine may result from binding to opioid receptors and this binding may mimic normal physiological binding of endorphins and enkephalins at these receptor sites [3]. Moreover, naloxone, an opioid antagonist, has been found to reduce or abolish histamine-provoked itch. It has been shown that naloxone can relieve itching experienced by patients with intrahepatic cholestasis and may also be effective in patients with generalized pruritus caused by chronic liver disease. This drug, however, did not produce a uniform reduction in itching in all patients. Patients with generalized pruritus who had responded well to placebo reported greater itching after naloxone, probably because of the abolition of the placebo response. Conversely, the placebo non-responders reported less itch after naloxone than the placebo responders, suggesting that naloxone may be competing with an endorphin system, thus modulating the individual's perception of itch [3,4].

There are more intricate relationships between allergic disease and neural mechanisms, which identify further mechanisms that produce central itch [5] including those selectively responsive to histamine [6].

The psychopruritic disorders have some common features that help to differentiate them from physical diseases. Pruritic episodes may be bizarre in onset and presentation with abrupt and sudden termination. This itching may occur commonly during relaxation or sometimes after nighttime waking [7]. Furthermore, localized itching may lead to generalized body itch within a short time. The episodes are chronic and relapsing and last variable lengths of time from hours to days.

Patients with psychogenic itch tend to be introverted and there may be a history of recent major psychological stress [8]. A psychiatric and psychodynamic investigation of patients with prurigo nodularis demonstrated an extraordinary propensity for these patients to suffer from psychological trauma, and a distinct correlation was claimed between the outbreak of the disease and the preceding loss of a human relationship detrimental to self-esteem [9]. A significant proportion of patients with generalized pruritus may be suffering from depression. Using the Beck depression inventory, significantly more patients with generalized pruritus (32.4%) had depressive symptomatology than controls [10].

Treatment with antihistamines is disappointing, although those that have phenothiazine activity, such as hydroxyzine 50–75 mg/day, may produce more relief. Doxepin used in dosage up to 125 mg/day is more effective, probably because of the combined effect of both antipruritic and antidepressant actions. SSRIs can also afford relief: typical dosage is paroxetine 20–40 mg/day, fluvoximine 100–200 mg/day or citalopram 20–40 mg/day [11].

Behaviour-orientated therapy may give some benefit but relies upon a receptive patient, and success will be limited and disappointing in those with significant mood shift or personality disorder [12].

Trichotillomania [1–3]

Definition. Trichotillomania is defined as the irresistable urge to pull out hair, accompanied by a sense of relief after the hair has been plucked. The term was firstly used by Hallopeau in 1889 and literally means a morbid craving to pull out hair. Originally, DSM-IV [4] listed trichotillomania under impulse–control disorders in company with compulsive gambling and kleptomania, but the broad spectrum of psychopathologies [1] prompted modifications to the definition. The revised DSM-IV-R [5] diagnostic criteria for trichotillomania are:

1 Recurrent pulling out of one's own hair resulting in hair loss

2 An increasing sense of tension immediately before pulling out the hair or when attempting to resist the behaviour

3 Pleasure, gratification or relief when pulling out the hair

4 The disturbance is not better accounted for by another mental disorder

5 The disturbance provokes clinically marked distress and/or impairment in occupational, social or other areas of functioning.

The ICD-10 definition [6] is consistent with this but does not mention distress or loss of functioning.

Aetiology and pathogenesis [1,2]. The epidemiology of this complaint is not absolutely clear, probably for the reason that this physical sign and response is a product of various psychopathologies. Studies of frequency show a wide variation. In an unselected population the incidence has been reported as below 1 in 1000 to as high as 1 in 200 by the age of 18 years [6]. However, there appear to be two distinct populations: those who present in childhood [2,7] and who probably represent the bulk of cases [6,8]; and fewer but more chronic cases who present as adults, who have continued hair-pulling activity from adolescence or developed the disorder in early adult life [2]. There is an estimated lifetime prevalence of 0.6% in college students [9], with equal sex incidence. If the criteria are based on ICD-10 then the prevalence increased to 3.4% in females and 1.5% in men. The number of affected children may be seven times that of adults [10] and preschool children are more likely to be boys (62%) although after this older boys and adolescents are 30% of the group [7]. This early-onset group, usually between the ages of 2 and 10 years, show benign self-limiting behaviour and most are probably suffering from a habit disorder, perhaps as an extension of hair twirling activity and childhood stress [11]. The association with nail biting and thumb sucking, skin picking, nose picking, lip biting and cheek chewing is well documented [12,13]. In children, there is an association with anxiety and dysthymia [12], learning disability and iron deficiency [8]. Emotional problems in the pre-adolescent group tend to be less severe, more a reflection of a stressful life event rather than serious psychopathology [13].

The adolescent age group, more likely to be girls, have more psychopathology related to parent relationships, school difficulties commonly bullying, body image changes and infrequently sexual abuse. It is more likely that there is an accompanying anxiety disorder although depression in children may be missed because the features are of somatic complaints and irritability [14].

The adult age groups are associated with greater psychopathology and show distinct female preponderance [1,2,7,], usually 4 : 1, but 15 : 1 being most evident in the oldest group [15]. This remains true for different racial groups [16–18]. The adult patients show more diverse psychopathology with depression, anxiety disorder, obsessive–compulsive disorder (OCD) and panic attacks prominent. Depression was present in 14% and anxiety in 15% [19]. Substance abuse (6%) and eating disorders may also be evident [2,3]. There is a significant debate about the relationship of trichotillomania to OCD [1]. While it has been proposed that adult chronic trichotillomania is a variant of OCD, with positive correlation in family studies [20], this definition is too narrow for many patients [2] and has not been supported by psychometric testing [21]. OCD compulsions are performed to avoid increased anxiety, are not pleasureable and are performed in full awareness. Patients with OCD have an explanation for their responses, whereas those with trichotillomania rarely justify their actions. In addition, the activity relieves stress

for those with trichotillomania, although a small subset may have the typical disabling compulsive conscious behaviours [22]. A family history is present in 5–8%, which may represent either a genetic predisposition or, more likely, a continuing family psychosocial response [20].

Clinical features [1]. The hair pulling activity is usually not as a response to any skin symptoms but is either a conscious deliberate act or, more often, a subconscious act, in some children being part of a hypnogogic (dream-like) state. Most adult patients describe an increased sense of tension before hair pulling or a sense of relief after the act. Some patients may have incomplete awareness until the pattern has been established [23].

Hair pulling and plucking is most common from the scalp but only occasionally as a response to scalp symptoms. Most pull hair from the vertex, but temporal, occipital and frontal hair loss in children may be more obvious on the side of manual dominance. The hair loss may be minimal, commonly a solitary patch, but visible hair thinning may progress to virtual total depilation, significantly so in adult women. Typically, the hairs are short, irregular, broken and distorted. The hair feels like stubble because of the fractured hair shafts, in contrast to alopecia areata which is much smoother. The patterns of plucking activity are centrifugal from a single starting point or linear, in wave-like activity. In extreme cases, the centrifugal pattern removes all hair except the most difficult to access, namely the occiput. This shows as a 'tonsure pattern' [24] or 'Friar Tuck' [25] distribution. The eyelashes, eyebrows, facial and pubic hair may also be primarily affected. Children will pluck the eyebrows and eyelashes but adults almost exclusively pluck hair on the torso. Two-thirds of adults pulled hair from two or more sites and one-third from three areas [2,3]. Body and pubic hair plucking is more common in males and may become a ritualized activity, either alone or as a conjugal activity.

Younger patients will tend to pick and pluck the hair at times of leisure, when alone or when tired and in the evening. Adults have a more conscious structured activity, initially seeking thicker or distorted hair and then progressing to larger areas, taking longer and longer over the activity. This may become more like a compulsion with elaboration of the rituals using instruments. The more frequent the plucking episodes, the greater the body image dissatisfaction and the more likely the patient will have depression and anxiety.

Patients present in the clinic with bald patches but associated features are the use of wigs, false eyelashes and semi-permanent use of hats and scarves. Occasionally, the psychosocial effects of hair loss (e.g. reluctance to swim, date and do sports) may precipitate referral to clinical psychologists or psychiatrists. Chronic folliculitis of the neck, chin, chest, pubic areas or thighs as a result of plucking activity may also be the presenting complaint.

One of the secretive activities in many patients with trichotillomania is some degree of hair licking, chewing and eating (trichophagia). Children may pluck the hair, stroke or suck the hair root before chewing and swallowing the remainder. Occasionally, hair may be seen stuck between the teeth. Patients may swallow longer strands of hair and a small percentage develop gastrointestinal bezoars. There should be a high index of suspicion in children with trichotillomania who present with abdominal pain, weight loss, nausea, vomiting, anorexia and foul breath [7,8]. Gastric trichobezoars may cause intestinal bleeding, pancreatitis or obstructive jaundice [1,17]. If the hair bolus extends down the small intestine (Rapunzel syndrome), life-threatening intestinal obstruction necessitates a laparotomy [26]. It has been reported in over 10% of adults, who usually report no abdominal symptoms, and patients with learning disability [27].

Investigations. Scalp biopsy has been shown to be most useful [7,10]. The most important findings include multiple catagen hairs, pigment casts and traumatized hair bulbs.

Gastrointestinal bezoars have been investigated by conventional radiography, sonography, and computed tomography (CT) scanning. CT scan diagnosed all cases in both stomach and small intestine, while ultrasound was almost as accurate [28]. Conventional X-ray of bezoar was least helpful.

Differential diagnosis. See Chapter 63.

Treatment. Clinical assessment scales are helpful in the fuller evaluation of treatments but remain largely research tools [29]. For many adolescents and children, identification of stressful episodes with accompanying support and parent education is usually all that is necessary. It is essential to present the harmful habit in an atmosphere of non-blame or fault but to change the agenda to a positive one to negotiate change. Habit reversal [29] is effective as is behaviour therapy. This was effective in children [1,22,30] and reduced symptoms by 90% in 19 adults [29]. It is time consuming and needs expert clinical psychology support to maintain progress.

One study showed that tricyclic antidepressants were effective agents and further that clomipramine was more effective than desipramine [16], although relapse may be common unless treatment is continued for at least 1 year. SSRIs have been of benefit in open studies. In two further studies [31,32], fluoxetine in dosage of up to 80 mg/day decreased severity by 60%. In a double-blind study, citalopram reduced severity by 30% by week 12 [33]. Low-dose pimozide has been shown to augment this response [34] as has risperidone because relapse is common after 1 year if SSRIs are used as monotherapy [35].

Onychotillomania and onychophagia

(see Chapter 62) [1,2]

The compulsive habits of nail picking and nail biting have been shown to be common in children and adolescents [2,3]. The aetiologies suggested include stress, imitation of family members and a transference from the thumb sucking habit. Nail biting is usually confined to the fingernails, but nail picking, especially in adults, may involve all digits. Damage to cuticles and nails causes paronychia, nail dystrophy and longitudinal melanonychia [4]. In chronic cases, there is an association with trichotillomania [1]. Compulsive biting, tearing or picking with instruments such as scissors, knives or razorblades may lead to permanent destruction [5].

Onychotillomania is often denied by the patient but some admit to the habit. Of these, the most common problem is a compulsive action, not always at times of stress. Self-induced anonychia of the toenails was produced by one man who plucked out the nails with pliers rather than suffer recurrent paronychia of previously crushed toes [6]. DP may provoke self-destruction of the nails [7] as can a folie à deux in the confused elderly [8]. Successful response to treatment has been shown with clomipramine [9] and pimozide [8].

Psychogenic purpuras [1,2]

This group of disorders is incompletely understood. The common features are the presence of purpura, bruising or frank bleeding in patients who show severe emotional

disturbance. The patients are predominantly female. For clarification it is helpful to consider the following separate categories, although some overlap is apparent:

1 Autoerythrocyte sensitization syndrome (Gardner–Diamond syndrome) [3]
2 Psychogenic purpura without autoerythrocyte sensitization but with other abnormalities [4,5]
3 Psychogenic purpura with no measurable abnormality [6,7]
4 Purpura factitia [8–10]
5 Religious stigmata [2].

Autoerythrocyte sensitization syndrome [3]

SYN. GARDNER–DIAMOND SYNDROME

In this rare but well-recognized condition (see Chapter 48), exquisitely tender bruises arise after minimal trauma with or without a history of emotional disorders. In the original cases, it was noted there was a preceding history of an injury involving extensive bruising or major surgery. These bizarre tender lesions are most commonly located on the arms and legs [11,12]. Bruising is heralded by a burning or stinging sensation followed after a few hours by oedema and erythema. The bruising appears a day or so later [12]. Abdominal pain, bleeding from internal organs and neurological symptoms may occur [1]. Psychiatric symptoms were present in 21 of 30 cases reported [13]. Severe emotional disturbances are a constant feature and the relationship to religious stigmatization has been discussed [1,2,14]. The possible relationship of stress to altered fibrinolysis is conjectural but measureable effects have been found [2].

Typical bruising can be reproduced by the intradermal injection of the patient's own erythrocytes and in some cases red-cell phosphotidyl-L-serine [15]. Gomi and Miura [16] described a case with associated thrombocytosis where busulfan therapy produced a reduction in attacks. Increased fibrinolytic activity has also been noted at the onset of fresh lesions in some patients [5,17]. One case seemed to have been made worse by a copper-containing intrauterine contraceptive [18]. Psychiatric treatment using psychotherapy [1,11] or psychotropics [15] has been reported.

Psychogenic purpura without autoerythrocyte sensitization but with other abnormalities [4,5]

A very similar clinical syndrome has been reported but with a negative reaction to intradermal red cells. Rowell [5] described two women with painful bleeding and bruises in association with increased fibrinolytic activity and mental stress. A further condition in this group consists of autosensitivity to DNA [4] described as painful itchy eccymoses, which recurred over a number of years.

Psychogenic purpura with no measurable abnormality [6,7]

Sorensen *et al*. [7] considered that patients with psychogenic purpura with no abnormal tests shared the same emotional background and other clinical features and should be regarded as part of the same syndrome. The lesions may be less tender and dramatic [6].

Purpura factitia [8–10]

Bleeding, bruising and purpura have all been reported as artefactual disease. Agle [8] described malingerers who misuse anticoagulants, while aspirin has also been taken to similar effect. Mechanical purpuras are ingenious and well reported [9,10].

Factitious skin disease

The dermatologist, in common with most clinicians, is trained to believe what the patient says. Most physicians will maintain an endearing and undiscerning naivety even in the face of strong evidence of simulated or frau-

dulent illness. Clinical deception refers to a spectrum of illness that lies in a continuum which stretches from the unconscious processes (e.g. conversion and somatization) through the conscious and sporadic (e.g. dermatitis artefacta) to the falsification for deliberate gain (e.g. so-called malingering). The dilemma for the clinician is to determine the degree of voluntariness present in the patient for the consciousness of the action may not equate with the consciousness of the motive.

At a simple and elementary level, patients commonly exaggerate or minimize symptoms, may misattribute causation or have mistaken beliefs. This pattern is common and does not really constitute a fabrication although as a persistent behaviour it can alienate the clinician's objectivity. These distortions are singularly different from the factitious falsification of information (lying), the manufacture of skin lesions, the occult use of others (proxy disease) and disease produced for material profit or retribution.

The definition of factitious behaviour is not completely clear because the level of intention may vary, but for the dermatologist the definition by DSM-IV-TR criteria maintains the difference from malingering [1]. The DSM-IV-TR criteria for factitious disorder include:

1 Intentional feigning of physical or psychological signs or symptoms

2 The motivation is to assume the sick role

3 External incentives for the behaviour (such as economic gain, avoiding legal responsibility or improving physical well-being, as in malingering) are absent.

Dermatologists will encounter the subtype 300.19 presenting with predominantly physical signs and symptoms.

There are a series of recognized skin diseases characterized by the essential features that first are caused by the fully aware patient and, secondly, involve the desire to hide the cause from their doctors. This definition includes dermatitis artefacta, dermatological pathomimicry, dermatitis simulata and dermatitis passivata. These syndromes are additionally distinguishable from others where there is a secondary gain, such as Munchausen's syndrome, Munchausen's by proxy and malingering.

Dermatitis artefacta

Definition. Dermatitis artefacta is an artefactual skin disease caused entirely by the actions of the fully aware (not consciously impaired) patient on the skin, hair, nails or mucosae. These patients hide the responsibility for their actions from their doctors [2].

Epidemiology and aetiology. All studies have shown the preponderance of females, the ratio of female to male varying from 20 : 1 to 4 : 1 [2–6]. Lesions have been found in children from the age of 8 years [6], prepubertal children having an equal sex ratio rising to 3 : 1 female predominance by the early teens. In half of subjects the lesions are on the face, particularly in children [3,6]. While these series confirm that the majority of cases commence in adolescence and in adults under 30 years of age, there is an important subgroup whose age of onset is significantly older. This subgroup is distinguished by being more likely to be male (male to female ratio 1 : 2) to produce more subtle skin lesions [3,4] and to have a past history of somatizing illness [7–9]. These complaints may take the form of pseudoseizures, abdominal pain, syncope, chronic fatigue and backache. Previous work has suggested that dermatitis artefacta is more common in health care workers and their families [5,10,11] because this environment provides not only a ready 'model to copy' but also a social structure where illness is always understood and allowed for. However, this bias may now be less obvious [3] in a well-informed society whose medical symptoms, pathology and disease are more available via the media and the Internet.

Much has been written about the motivation to assume the sick role and the psychopathology underlying the production of artefact [7,12–14]. The idea that the patient *wants* the sickness role is the essential pathology because the primary gain of *being* a patient is usually to be expected of all illness. The main additional gains can be summarized as:

1 Strong masochistic needs (e.g. self-hate and guilt)

2 A sickness that allows inappropriate regression and avoidance of adult (especially sexual) responsibilities (e.g. marital trauma)

3 An illness that symbolizes anger at or conflict with authority figures (e.g. school phobia)

4 Psychiatric or medical care that fulfills massive dependency needs (e.g. inadequate coping strategies)

5 An illness that symbolizes attempts at mastery of past trauma (repetitive compulsion) (e.g. childhood abuse).

In many cases, the psychosocial stress of a major life event may be apparent. Children and adolescents commonly show anxiety and immaturity of coping styles in response to a dysfunctional parent–child relationship, bullying, physical body changes, or sexual and substance abuse. Adults may be neurotic and react to adverse situations in an immature impulsive manner [2,13]. However, there may also be significant depression [2,3]. The more chronic patients tend to have a demonstrable personality disorder, more particularly borderline or hysterical in females and paranoid in males [3,7,11,13]. There is a significant literature on the relationship between factitious disorder and illness falsification in both children and adults and previous factitious disorder by proxy victimization (Munchausen's by proxy; see below).

Clinical features. The nature of the clinical symptomatology in dermatitis artefacta is the 'hollow history' [15]. The patient describes the sudden appearance of complete lesions with little or no prodrome. There is no complete

description of the genesis of individual skin lesions. The signs invariably appear overnight, in a lunch break, on the way home from school or work. Lesions appear at the same identical stage in development in crops or groups, either symmetrically or scattered apparently at random. There is a significant lack of a history of a progression of lesions from an initial lesion to its fully developed state. By contrast, there is a prolonged and elaborate description of complications and failure to heal. Characteristically, established lesions may undergo sudden deterioration at the same time as new areas appear. It has been suggested that the patients show a 'belle indifference' to their predicament as part of a dissociative state and, in the presence of visible disease, manifest a nonchalance and innocence transmitted through an enigmatic 'Mona Lisa' smile. It is probably true to say that the patients are more often passive than aggressive, even though they have a widespread disfigurement. However, this is not always the case and considerable anger may be shown by the patient, but more particularly by parents, carers, husbands or partners, who rail at the incompetence of a succession of doctors. This may extend further to recruiting other doctors, university academics, nurses and social workers to support their case [3]. More than one person may be involved, as in the 'folie à deux' of two patients with factitious ulcers [16].

Fig. 61.3 Dermatitis artefacta: note the straight edges and sharp angulation of some of the lesions.

Clinical signs [5,11,15]. The most common site of involvement is the face, particularly cheeks. The dorsa of the hands rather than the palms are the next most common site then the forearms, most frequently the non-dominant limb. There is a particular covert pattern on covered skin where clothes hide significant mutilation of the breasts, abdominal areas and sometimes the genitalia. Involvement of the back, axillae and external ear is uncommon.

Cutaneous lesions are produced by every known means of damaging the skin. Crude destructive processes are the result of thermal, chemical or instrumental injury. Less commonly, dermal lesions from blunt trauma or injections are found. Oedema of limbs from constricting bands and hysterical dependent posture has been described (Secretan's syndrome) [17]. It is characteristic that one digit, usually a toe, will be constricted at a time while all others are healthy. A series of single ischaemic toes while all others are healthy should raise suspicion of artefact.

Excoriations may be made with nail files, sanding boards, wood or wire brushes to produce raw, crusty, linear or arciform lesions with characteristic angulated edges (Fig. 61.3). Punched out necrotic areas, sometimes with blisters developing into indurated necrotic scars are typical of thermal burns from cigarettes, soldering irons or ovens. These are usually uniform in size and scattered haphazardly. Urticarial lesions are initially produced by chemical damage and progress subsequently to crusting and scarring.

Characteristically, these areas may show the 'drip-sign', where corrosive liquids have been allowed to run over the skin (Fig. 61.4). Bleaches, soaps and household cleaners are most commonly employed by women; industrial acids and automotive fluids by men. These chemicals may produce a persistent detectable smell on the skin. Purpura and bruising are seen after suction, friction or blunt trauma. Children produce purpura on the chin by sucking on cups and on limbs by direct mouth suction or with the use of a toy or tool. Shearing stress also produces purpura, tending to present as linear lesions on the limbs.

Subtle artefact [3] is seen as fixed urticaria, vasculitis (Fig. 61.5), dermal nodules, panniculitis-type lesions and boggy fluctuant swellings. Considerable atrophy and pigment change occur with resolution. Careful examination may reveal the presence of a needle track where milk, air, faeces, urine, cooking oil, silicone, grease or engine oil has been injected [18,19].

In other specialties such as ophthalmology, oral medicine and otolaryngology artefact presents as non-healing infected wounds and excoriations [20–22].

The last common group is that presenting as non-healing surgical wounds. Commonly, this may follow a small operation after minor skin trauma, instrumentation such as an arthroscopy or breast biopsy. Unfortunately, further 'wound repairs' exacerbate and ligitimize the continuing wound. It is not unusual to see patients who

Fig. 61.4 Dermatitis artefacta showing the drip sign.

Fig. 61.5 Vasculitic lesions showing acute inflammatory lesions and old monomorphic atrophic scars.

have had up to eight operative revisions before a further referral is made to a dermatologist.

There may be unexpected complications to the artefactual damage leading to severe infection such as cerebral abscess [23] which may be life threatening [24].

Differential diagnosis. The distribution and physical characteristics of the crude dermatitis artefacta are diagnostic. However, blistering crusty lesions may simulate ecthyma, herpes simplex and bullous disorders. More subtle facial blisters may simulate porphyria cutanea tarda. The collagen–vascular diseases including vasculitis and pyoderma gangrenosum must be excluded in non-healing wounds as must atypical mycobacterial infections and imported tropical infections. The curious linear dermatoses such as Nékam's syndrome, cutaneous lymphomas and linear drug eruptions [25] must be excluded. The diverse hereditary sensory neuropathies can show chronic non-healing ulcers and be mistaken for artefact as can the cutaneous changes of reflex sympathetic dystrophy [26]. The purpuras and tissue purpuric reactions such as cutaneous amyloid can be perplexing and should be excluded [27].

Factitious cheilitis (Fig. 61.6)

SYN. LE TIC DES LEVRES

Artefactual lesions of the lips are uncommon. Studies are small but it appears equally in males and females [1,2]. Such lesions manifest particularly as persistent inflammation with crusting and variable haemorrhage. This is caused by picking, biting, rubbing and licking [3]. Occasionally, young adolescents will develop a disuse crusting of the lips because they become dysmorphic about cleaning and washing their mouths [4].

Differential diagnosis includes contact dermatitis, actinic damage, chronic lip-licking habit and causes of granulomatous cheilitis.

Fig. 61.6 Factitial cheilitis—a type of dermatitis artefacta of the lips.

Nail artefact

Chronic paronychia caused by the insertion of nails, pins or splinters has been recorded in soldiers avoiding duty and also in children [1]. The characteristic lesions show purpura and haemorrhage around the nail fold but also subungual haemorrhage and pustules. Similarly, Lyell [2] described a patient who induced haemorrhagic nail loss using a nail file. A significant sign is repeated traumatic nail loss occurring singly or multiply on one hand only. The differential diagnosis is described in Chapter 62.

Hair artefact

A bizarre pattern of hair loss may occur after cutting or shaving. It differs from the plucked appearance of trichotillomania and usually appears acutely, either as rough cropped areas of hair loss or unnatural patterned alopecia of scalp or eyebrows (Fig. 61.7).

Differential diagnosis. See Chapter 63.

Fig. 61.7 Bizarre pattern of alopecia on the scalp with regimented rows of surviving hairs.

Artefact by proxy [1,2]

SYN. WITCHCRAFT SYNDROME

Artefact dermatitis can be provoked on an unknowing and unsuspecting victim by proxy. As an act of revenge, the daughter of a hairdresser applied benzyl ether of nicotinic acid to the customer's skin. This induced hyperaemia with some oedema within 10 min but not on the perpetrator because absorption of the agent is very low on the palm of the hand, so she could easily apply it to the customer's skin without harm to herself.

Dermatitis artefacta with artefact of patch tests [1]

Bullous dermatitis artefacta in a female veterinary assistant healed with occlusive dressings. New bullae on the other arm prompted the parents to demand 'allergy' tests. Ten patch tests to yellow petrolatum were applied to the back, which provoked a non-inflammatory bulla on one of the sites 2 days later. Two other cases are cited.

Investigations

The diagnosis of dermatitis artefacta is based upon major suspicions. In the absence of admission of deceit by the patient, suspicions are aroused by the presence of physiologically impossible symptoms, incompatable lesions, contradictory objective evidence and non-response to reasonable treatment. Other clinical diagnostic clues may be seen such as the sparing of decorative marks and areas of skin on the back [1]. While the diagnosis is based clinically upon a high index of suspicion, litmus paper has been reported as a valuable aid to diagnosis, because it detects strong alkali or acid, particularly in new lesions [2]. Ordinary histopathology will confirm the nature of skin damage in crude artefact, while deeper lesions of vasculitis and panniculitis may show injection tracks and foreign material [3–5]. It has also been shown that serial biopsy may be diagnostically helpful in sophisticated artefact [6].

There are psychometric tests that can be used for the assessment of factitial disorders, but these are essentially research tools [7].

Co-morbidity

There are common overlap syndromes and related disorders that should be investigated. Twenty per cent of patients have a somatization disorder [1] and hypochondriasis. These are co-morbid with anxiety, depression and substance abuse [2]. Borderline personality disorder is a factor for chronicity in both sexes [3].

Treatment. There are three therapeutic aims. The first is to treat the cutaneous damage. There is always significant skin damage, which will be both inflamed and infected. Topical and systemic antibiotics and anti-inflammatories establish the doctor–patient relationship and underlines to the patient that the physician is helpful, non-aggressive and sympathetic.

Secondly, there is a need to identify the nature and extent of the psychological problem. The dilemma has always been whether or not patients should be confronted [1]. In most cases, the urge to confrontation is stimulated by the aggression the physician feels because the doctor–patient relationship has apparently been betrayed. The doctor must avoid personalizing the episode and needs to consider the approach that is likely to change the patient's behaviour. Confrontation is a highly charged strategy and should only be done if the deliberate act is certain (e.g. if the self-damage has been witnessed) and there is sufficient support and advice available at the consultation. This will need the assistance of psychiatric advice and finally to effect a transference to psychiatric care if necessary. This catharsis can be achieved in a manner that allows the patient to express a positive decision to

change without dwelling on the deception and precipitating an aggressive defensive response [2,3].

Not surprisingly, other workers disagree with this approach, citing the high failure rate and the risk that the patient will strive even harder to legitimize the illness and himself by seeing other doctors [4].

For many years, a non-confrontational and non-punitive approach has been favoured. This passive acceptance of 'a cry for help' has the merit of a non-aggressive interview in the short term but may paradoxically give the patient consent to continue in the abnormal sickness role, albeit as a psychiatric patient [5]. This approach has been unsuccessful; although for a dermatologist it is the most comfortable because there are no rows. Unfortunately, many patients usually default the clinic or are referred elsewhere.

Efficient occlusive bandaging will allow most lesions to heal, except for those of the most devious and determined. The psychological problems should be approached in a non-confrontational manner [6–11], allowing the patient to express their difficulties in a passive confidential environment. Children usually respond well to this approach, particularly if a cause of psychosocial pressure is identifiable. However, chronic persistent self-damage is predictive of long-term emotional illness and referral to a child psychiatrist is imperative [6].

For adults, a non-confrontational approach that also displays surprising robustness is the 'narrow escape', 'quasi-confession', 'recovery' or 'face-saving' strategy. This is the suggestion that the patient finds a solution to their illness by offering a rationale for recovery. This may take the form of a self-explanation, however fantastic, as a mechanism to escape without public retribution. The patient may claim that alternative medicine such as hypnosis, homoeopathy or fringe methods such as kinaesthetic manipulation has 'cured' them [12]. One additional technique is the double bind strategy where the physician explains that the treatment carries an expectation for recovery. If this does not occur then they will be forced to conclude that the problem is psychological or factitious [12].

The management and prognosis in adults is that of the primary psychological disorder [6]. Acute stress reaction can be addressed in a series of short consultations at the time when the dressings are changed. Patients with depression responded well in two series to tricyclics or SSRI antidepressants [7,8], even when no precipitating event was identifiable. Tacit acceptance that the cause of the rash has been identified, without further challenge, helps to make the transfer to formal psychiatric care easier if needed [10]. Between one-third and half of patients continue to develop chronic lesions [6,11]. Such cases usually have a personality disorder, commonly hysterical, paranoid or borderline [10,11] and need psychiatric assessment [13]. Unfortunately, this is frequently unacceptable to the patient.

Dermatological pathomimicry [1]

Some patients intentionally aggravate an existing dermatosis as an expression of their distress at the unresolved discomfort they feel towards their skin disease, or equally as a mechanism to recruit an existing sick role into another psychosocial situation. To this extent it is distinguishable from dermatitis artefacta because the disease appears as an exacerbation of established skin disease with none of the bizarre physical signs typical of mechanical, chemical or thermal interference. This is also to be differentiated from self-inflicted delayed healing of surgical and traumatic wounds that is achieved by external damage. However, a group of 13 patients who had deliberately caused recurrence of their existing skin disease by reintroducing the precipitating factor and invoking the original pathogenic mechanism have also been described [1,2]. The most common provocative agents were atopic allergens, contact allergens, drug sensitivities and irritants applied to chronic leg disorders. Other reports have described irritant contact dermatitis [3] and artificial oedema of an arm or leg [4]. Most patients were young women who had lost support from within their family group. More direct confrontational discussion without recrimination proved helpful and follow-up showed only minor recurrence in two patients 5 years later [2]. Since the original description there have been numerous reports of contrived exacerbations of common dermatoses. These include atopic eczema by deliberate exposure to individual known

personal aeroallergens such as pet danders or food allergens such as milk. In one case this was done by proxy by a mother. A patient with psoriasis covertly retook atenolol, which previously had caused problems (Dr L. Stankler, personal communication).

Dermatitis simulata

Apparent skin disease can be represented by patients who are ingenious enough to use external disguise to simulate disease. Make-up has been used to paint on a rash [1], sugar to simulate chronic cheilitis, drugs to induce skin discoloration [2] and topical printing dyes to produce discolored sweat [3]. Red make-up has been used to simulate a port-wine stain on the face. These deceptions were clever enough to confuse doctors for months. Most of these patients were young and immature, but a somatizing illness was recorded in one older patient and previous treated depression in another.

Dermatitis passivata

The cessation of normal skin cleansing will produce an accumulation of keratinous crusts. This is commonly seen in geriatric or demented patients who suffer from self-neglect and has been called the Diogenes syndrome [1]. Lesions are usually found on the upper central chest, over the back both upper and sacral and accumulated as coagulated debris in the groin creases. However, a group of patients were described [2] who showed lesions on the scalp, face or arms. Notably, they were young adults who were invariably accompanied by parents or family. Significant psychopathology such as schizoid thought disorder or hysterical limb palsy was present. Specialist psychological therapy was usually necessary either as day care or community psychiatric support [3].

Munchausen's syndrome [1,2]

Asher [1] used this term to describe the notorious hospital hopper who presents with a dramatic and untruthful story of illness. This is a severe and chronic subtype of factitious disease [2]. The essential elements are the chronicity of the illness, and the frequency and similarity of the repetitive pattern of the complaint in different hospitals (peregrination). The simulated illnesses may be esoteric and rare. While dermatological complaints are uncommon in Munchausen's syndrome, patients with simulated porphyria and connective tissue disease, for example, may present to the dermatologist. The last element in the syndrome is pseudologica fantastica. This describes the telling of lies about past social history and connections, exploits, wealth and invention of an alias [3]. The patients are usually male, and travel widely from hospital to hospital complaining of abdominal pain, haemorrhage or some neurological incapacity. Skin lesions such as non-healing wounds, widespread blistering and multiple excoriations may be part of the syndrome of simulated disease [4]. The secondary gain is prolonged medical attention, although serious consequences such as septicaemia and paraplegia have occurred [5] from induced cutaneous ulceration. The Internet provides access to those interested in health and medicine and is a rich resource for the expansive personality of the Munchausen patient. Because the Internet offers 'virtual support groups', these individuals may offer 'virtual' factitious disorders. Four cases have been reported, showing the facility with which they can attract attention, mobilize sympathy and control others [6].

Munchausen's syndrome by proxy [1,2]

In 1977, Meadow [1] had the clinical acuity and personal courage to described the syndrome of Munchausen's by

proxy where the illness is fabricated by the parent, usually the mother, or someone *in loco parentis*. Since then it is clear that not only do some parents harm their children but other carers may be involved and these may include health professionals. Doctors and others may not only fail to understand the origins of a child's symptoms but also institute further harm by inappropriate investigations, treatment and surgery [3]. The guidelines to identifying cases [2] mirror many of those discussed for dermatitis artefacta. The victims have a persistent or recurrent illness that cannot be readily explained. The diagnosis remains descriptive and not stringent. Symptoms do not respond and laboratory tests are incongruous. The reported symptoms are inconsistent with presenting health and the symptoms fail to appear in the absence of a certain parent (usually the mother). The perpetrator is reluctant to leave the child even for a few minutes, but remains oddly impassive even in an emergency. Characteristically, like patients with dermatitis artefacta, these carers attempt to make close relationships with medical staff with a blurring of the doctor–parent barrier. There may be fabrication of family details and a disturbed marital and social structure. Rarely, the parent exhibits the syndrome herself and produces proxy lesions on the child (Polle's syndrome) [4].

The victims are usually infants or toddlers with a mean age at diagnosis of 40 months [6]. The mean delay between presentation and diagnosis is 15 months. The signs and symptoms of illness were mostly produced in hospital. The most common presentation in one series was bleeding (44%), CNS depression (19%), apnoea (15%), diarrhoea (11%), vomiting (10%), fever (10%) and rash (9%) [6]. Skin lesions are usually crude forms of dermatitis artefacta [6,7] produced by scratching or caustic painting on skin. On one occasion the rash was the result of drug poisoning. A large review of countries outside English-speaking industrialized populations produced similar results in rather older children [8]. The long-term consequences of childhood victimization might contribute to the development of factitious disease in adult life. Elements of the child victim's experience, including feelings of powerlessness, lack of control and disappointment in the physican, are the suggested dynamics for the development of independent illness falsification [9].

Munchausen's by proxy may also rarely be seen in the elderly, mentally handicapped or other dependent persons [10], perpetrated by relatives, nurses and care home personnel.

Malingering [1]

Asher [1] defined malingering as the imitation, production or encouragement of illness for a deliberate end. The American Psychiatric Association DSM-IV definition is 'the intentional production of false or grossly exaggerated physical or psychological symptoms, motivated by external incentives'. However, the taxonomy of the malingering is difficult because of the moralistic overtones of criminality and false compensation litigation [2,3].

Malingering may be co-morbid with conversion disorders, personality disorders and other factitial behaviour. However, usually it differs from most factitial disease in being short term and opportunistic, whereas other illness falsification is chronic and persistent. Fear, desire and escape are the three main motives to produce false or grossly exaggerated physical or psychological symptoms. Soldiers feigning disease and disability hope to avoid duty, suspend transfer or be discharged from the service. Workers can prolong sick leave, delay corporate change of job or seek to obtain early retirement with an apparently extended illness. Some patients may seek compensation for some contrived illness (e.g. alleged burns) or aggravate and continue an existing disease (e.g. industrial dermatitis) out of a sense of grievance or retribution. Prolonged legal cases of supposed medical negligence are common in those with manufactured illness whose dissatisfaction with their doctors or the care they have received may lead to a financial settlement as a reward [4].

Cutaneous lesions are usually crude forms of artefact dermatitis [5]. Chronic non-healing postoperative scars are manipulated with instruments, or even faecal injection to maintain sepsis [6]. Hand dermatitis, both irritant and allergic contact dermatitis, may be perpetuated to seek higher compensation awards [7].

Treatment depends on the underlying psychiatric illness if significant psychopathology can be found, but the opportunist response in patients with an underlying personality disorder is poor [8].

Self-mutilation

There is a transition between some forms of self-decorative behaviour such as piercings and the development of pathological self-mutilation (SM). This will depend upon the psychological state of the individual, the acceptable fashion norms and the peer group pressures to conform [1]. In a study of adolescents, of 14% engaged in SM two-thirds were girls. Self-cutting was most common followed by self-hitting, pinching, scratching and biting. These students with SM showed significantly more anxiety and depressive symptoms than non-mutilators.

Dermatologists are seldom asked to manage patients who admit to SM but it may be seen as an incidental clinical finding. A group of female patients perform delicate self-cutting, which leaves fine linear non-sutured scars on the wrist and forearm [2]. The cutting is a form of emotional release, both immediately physical often accompanied by euphoria and in the longer term as a control of anxiety [3]. The most common mutilators are young women who are wrist slashers [3]. They are described further as usually attractive, unmarried, easily addicted and unable to relate to others. The patient slashes her wrist at the slightest provocation but does not commit suicide. They tend to be depressed and obsessional, attached and dominated by their mothers, often in the absence of a father. Other impulse control disorders may be evident such as anorexia and bulimia [4]. It is suggested that this form of self-harm is a substitute for masturbation, a form of self-purifying catharsis which modulates stress and anger in patients who remain infantile in outlook [5]. Child abuse and family psychiatric history were frequent in some studies where genital mutilation predominated [6,7]. The more severe forms of SM leading to autocastration or enucleation of an eye are usually reported in association with schizophrenia [8,9].

Cutaneous disease and alcohol misuse [1,2]

Alcoholism and alcohol abuse rank among the three most common psychiatric disorders in the community. There are significant medical and economic consequences because of differing effects of alcohol on metabolism, health, treatment, behaviour and motivation [3]. Alcohol abuse can be missed as a diagnosis by experienced physicians even though the problem is common. Mechanisms for screening and brief interventions are well established and show robust stringency. The two-question screen consisting first of enquiry about past alcohol problems and, secondly, the period since the last drink shows 90% accuracy [4].

The psychosocial effects of chronic and disfiguring skin disease commonly produce feelings of stigma and rejection. Recreational substances, such as alcohol, are commonly used by affected patients [5]. A study of a large urban population suggested that male as well as female psoriatics showed an excess rate of alcoholism [6]. However, further studies suggested that while alcohol abuse was not a factor in the onset of psoriasis, it became significant in women after the disease was present and was significantly associated with the area of skin surface involvement [7] and severity, particularly in men [8]. Furthermore, a prospective study [9] showed that a daily intake of alcohol of more than 80 g was more frequently associated with less treatment-induced in-patient improvement in the percentage of the total body surface area affected by psoriasis. In two wide reviews [2,10], it appears that the changed character and distribution of psoriasis make it more difficult to treat. In studies of patients with psoriasis, alcohol abuse was not marked by elevated liver function tests. Alcohol abstinence helped to induce remission, and relapse was induced by reconsumption.

Discoid eczema appears to be more frequent in alcohol abusers and is a more reliable indicator of alcohol dependence, with significantly abnomal biochemistry and immunology related to alcohol excess. Atopic eczema appears to be unaffected by alcohol to the same degree. Seborrhoeic dermatitis is twice as common with alcohol abuse [11] and this may be related to immunosuppression and the effect on cutaneous microflora. The effects of alcohol on immune function and skin vasculature are thought to precipitate exacerbations of rosacea and post-adolescent acne.

Infestations of the skin and superficial skin infections were found more often in alcoholic vagrants than in non-alcoholics and those with other psychiatric disorders. This also suggests that more specific alcohol-related immune factors were active [12].

AIDS, HIV infection and psychological illness (see Chapter 26)

Human immunodeficiency virus (HIV) and AIDS cause cognitive, motor, behavioural and psychiatric symptoms in children and adults [1]. The impact is variable and the progression of disease unpredictable. Poor compliance with retroviral therapy is related to psychiatric morbidity [2] and suicidal ideation, which may be found in 60% of some groups of HIV patients. Most CNS involvement complicating HIV infection occurs in the late phase of the disease. Such patients have been usefully classified first into those with headache or meningitic symptoms; secondly, those with focal CNS symptoms or signs; and, lastly, those with non-focal cerebral and/or motor dysfunction [3]. This latter group present with mental illness where alertness is characteristically impaired because of metabolic or toxic encephalopathy. It refers to a distinct subcortical dementia characterized by retarded and imprecise cognition and motor control. New-onset delusions and hallucinations may be either a result of the metabolic encephalopathy of AIDS or an opportunist cerebral infection, rather than a psychological reaction to having HIV and/or AIDS *per se* [4]. Psychosis develops in patients with late HIV infection and immunosuppression, and has been shown to have a higher incidence in those with CD4 counts of less than 100/μL [5]. A controlled study [6] showed that the neuropsychological deficit as measured by a broad range of cognitive functions was 44% in seropositive patients and up to 87% in those with AIDS.

Progression to AIDS is affected by many factors but significantly so by the effects of stress, lack of social support and depressive symptoms. The presence of all three made the progression to AIDS at least twice as likely [7]. Highly active antiretroviral therapy (HAART) has had a significant impact on patient survival but brings with it the psychosocial aspects of living with a chronic disease. While HAART therapy has a beneficial effect on the psychiatric manifestations of AIDS and HIV, depression responds to SSRI antidepressants used in tandem [1].

Suicide in dermatological patients

Suicide refers to a range of self-destructive behaviours ranging from non-lethal acts which have been called suicidal gestures, attempted suicide, parasuicide and, more recently, self-injury. A lethal action in which a patient dies is defined as a completed suicide. The rates of completed suicide in the UK are 8–10 in 100 000 people. It is therefore one of the 10 most common causes of death in the UK [1]. Psychiatric disorders are the main risk factors but numerous studies have also identified physical illness as an important contributory factor [1,2]. Chronic illness is a risk factor in suicidal ideation and completed suicide and, not surprisingly, disfiguring chronic dermatoses have been shown to put patients at risk.

In a study of 217 patients with psoriasis, 10% of patients reported a death wish and 6% reported active suicidal ideation at the time of the study [3]. In another group, 2.5% of outpatients and 7.2% of in-patients with psoriasis expressed suicidal ideas. The severity of the psoriasis was reflected in the frequency of suicidal ideation and also measurable clinical depression [4]. Facial acne was also associated with significant risk (5.6%) of suicidal ideation, which is also higher than the levels reported in general medical patients [1]. Suicide ideation was found in seven of 11 patients with Darier's disease related to the dis-

figurement, the intractability, social exclusion and smell of the dermatosis [5].

Some dermatological patients become so disturbed that they do commit suicide successfully [6–8]. A group of 16 patients has been described [6]—seven males and nine females—who successfully committed suicide after presenting with dermatological problems to two dermatologists working in the same skin department. The majority of these patients had either body-image disorders (dysmorphophobia; BDD) or acne. It is important to recognize that patients with dermatological non-disease, and particularly females with facial complaints, may be extremely depressed and at risk of suicide [9]. Even more strikingly, BDD in children and adolescents carries a much larger risk; 67% experienced suicidal ideation and 21% had attempted suicide [10]. Acne scarring can have just as profound an effect, or even a more profound effect, on body image, self-esteem and confidence as inflammatory acne. The positive therapeutic role of isotretinoin was emphasized [1,11].

There is a definite risk of suicide in patients with active HIV disease [12], and rates of suicide for people with AIDS were 66 times higher than in the general population in New York City. Men with AIDS aged 20–59 years were 36 times more likely to commit suicide than their counterparts without such a diagnosis. Half of the people in this particular sample had expressed suicidal intents and one-quarter killed themselves by jumping from the windows of medical units in general hospitals. Assisted suicide has occurred in up to 23% of patients with AIDS [13].

Treatment of psychocutaneous disorders [1]

General management

'Disease' is a perception of ill health rather than a physical entity. The same degree of physical damage will be translated into different 'diseases' by different patients. In many patients, psoriasis does not itch; in a few it is very itchy. The condition is the same; the perception and interpretation differ so that it is necessary first to understand the language in which the disease is expressed. Once translated, the key is provided for an understanding of a patient's particular concern, and for a valid channel of therapeutic communication.

When a rapid cure is possible, there is no great problem in management. However, where a disease is of unknown origin and unpredictable duration, it is likely to assume undue proportions in the patient's thoughts. In diseases of the skin, as in other spheres of life, the unknown is feared. The spots of acne are magnified in any mirror. The patient and the dermatologist see two different images. It is the patient rather than the spots that must be treated.

Psychiatry is not an exact science. Some anxiety or depression will be felt by many of the patients seen by a dermatologist. This may be unrelated to their skin disease but often plays some part in it or occasionally is the reason for its presentation. When the anxiety is reasonable and openly expressed—fear of cancer, ignorance of prognosis, anxiety about scarring and so on—it is sufficient to reassure the patient with a clear explanation, in easily understood terms. When anxiety is obviously present but at first denied, its nature must be elicited by careful questioning. Those whose conflicts are fully repressed, but whose skin lesions, often factitious in type, leave no doubt about the cause, present the most difficult problems.

All patients with skin disease respond to a receptive and sympathetic approach. Visible illness has a particularly disturbing emotional effect; itching intensifies this. The physician must have patience, sympathy and insight into human behaviour, and must inspire the patient to talk freely. Advice should be given sparingly and without expecting it always to be taken. The dermatologist must know when a psychological situation is out of control and must recognize organic mental disease and endogenous depression as such, and seek psychiatric help.

The therapeutic effect of the physician's personality is often underrated. The stronger this is, the less necessary are drugs. Even the act of touching a patient with skin disease relieves the anxiety of those who have marked feelings of guilt and ostracism. When it is necessary to draw out the patient's emotional difficulties, the 'listening ear' is as important as the 'seeing eye'. Tones of voice, hesitancy, a temporary stammer or an unguarded or ambiguous remark may provide the key to an important

emotional difficulty. Initial explanations given by a patient are often 'cover stories' and are not intended to be believed.

The first aim in management must be to determine whether any significant emotional situation is present, the second is whether the reaction is one of anxiety, depression or hysteria, and, thirdly, how environmental stresses can be reduced or the patient's frustration, guilt or aggression can be eased or rechannelled. Hidden fears can often be remedied once they are expressed; anxiety about a child, spouse or parent may lie behind apparent rudeness. Fatigue alone may provide a 'stressful situation' and the adjustment of household burdens, insistence on holidays or proper periods of rest, and the provision of 'emotional bunkers' when the situation cannot be avoided, are matters of common sense and experience of what is feasible. Feelings of guilt, 'dirtiness' and inadequacy, frequently components of a depressive state, are more difficult to dispel and may require expert help. Obsessional behaviour and phobias are also usually beyond the reach of superficial psychotherapy.

The English language is perhaps deficient in words that are not themselves emotive but can be used to describe emotional disturbances. To ask if a patient has 'any worries' is to invite a denial, which is often misleading. It may be more fruitful to ask about tiredness or depression. The manner of the reply matters more than the phrasing.

When a fuller assessment of the social and domestic situation is required, the services of a trained medical social worker are called for to extract information about family relationships and stresses and to indicate where these can be helped or eased.

The help of relatives must also often be enlisted, although their concern is not always disinterested if they are themselves part of the emotional situation. The parents of children with hair pulling or adolescents with artefacts must be approached tactfully. It is not they who have raised the cry for help, but they are often the cause of it. They may feel their honour impugned and their pride at stake. Employers, schoolteachers and rehabilitation officers can give further information or material help in particular situations. To some patients, a priest's aid is invaluable.

Three further general points have to be made. The patient may present with a dermatosis that represents only one facet of a complex psychocutaneous situation. It serves its function in expressing an emotional disturbance. If 'cured' too quickly, without attention being paid to the underlying emotional problem, the patient may develop other less accessible ills. Secondly, psychiatrists themselves are of different persuasions. Their views on aetiology and their approach to treatment differ considerably. It is well for the dermatologist to be aware of this lest the patient loses confidence by being given different explanations and advice. Finally, there is a small but important group of patients who do not want to get better [2]. They are skilled at deceiving their doctors, their spouses and their friends. They suffer from 'too good' husbands and 'too kind' doctors. Many have an histrionic personality. Once recognized, certain principles of management should be followed, even then the prognosis is not good. The patient has too much to lose by recovering.

Psychotropic drugs

The use of psychotropic drugs in dermatology has become much more refined as the diagnostic criteria for the psychodermatoses has clarified. In addition, the awareness and detection of psychological accompaniments to organic skin disease, particularly depression, has presented a greater need for the dermatologist to become familiar with the use of psychotropic drugs.

The most useful are the antidepressants, both SSRIs and tricyclics. These vary in their specific activity, which can be an advantage as a sedative action may be beneficial in some circumstances, or an anticompulsion effect may be helpful. The indications for antidepressants and suggested regimens are provided in Table 61.2.

There are excellent descriptions of the use of antidepressants in dermatology [1–4]. In general, the patient should be started on a low dosage, which has the benefit of helping compliance, and then to increase the dosage over the next month to the therapeutic range. SSRIs are usually well tolerated. The effects should be evident in 4–6 weeks. If the response is slow or side effects are too intolerable, then another SSRI or tricyclic should be substituted. This should be achieved by gradually tailing the dosage of the original and building the dosage of the new drug [5–7]. SSRIs should be continued for at least 6–12 months. They should be gradually withdrawn over 2–3 months to prevent the serotonin withdrawal syndrome [6]. Sudden withdrawal can precipitate dizziness, anxiety, agitation, insomnia, flu-like symptoms, abdominal cramps and mood swings.

There has been a healthy reaction in recent years against the overuse of benzodiazepine drugs in the management of patients with psychoneurotic disorders. However, short-term therapy with anxiolytics or sedatives may be as helpful to anxious, itching patients as analgesics are to those in pain. Sedative SSRIs and tricyclics are very effective for anxiety and if additional sedation is needed hydroxyzine can be added. Sleep deprivation is common, and the restoration of a normal pattern is an adequate reason for giving hypnotics.

Table 61.2 Antidepressant drugs: usage and dosage.

Drug class	Activity	Dose (min–max)	Particular side effect
Sertraline SSRI	Depression, obsession, compulsion, BDD, panic, anxiety	50–200 mg mane	Caution hepatic/renal disease
Fluvoxamine SSRI	Depression, BDD	100–300 mg mane	Weight loss, rash, drowsiness
Citalopram SSRI	Depression	10–40 mg mane	Dry mouth
Venlafaxine SSRI, norepinephrine (noradrenaline) RI	Depression, pain syndromes	12.5–100 mg mane	Hypertension
Amitriptyline tricyclic	Depression, anxiety, pruritus, dynias	10–100 mg hs	Dry mouth, visual blurring, sedation
Clomipramine tricyclic	Depression, phobias, compulsive behaviour	25–150 mg/day	As above
Doxepin tricyclic	Depression, pruritus, anxiety	25–100 mg hs	Sedative

hs, at bedtime; mane, in the morning.
BDD, body dysmorphic disorder; RI, reuptake inhibitors; SSRIs, serotonin reuptake inhibitors.

Most dermatologists will not need to prescribe antipsychotic drugs. The primary indications for antipsychotic drugs are schizophrenia, acute mania and other psychotic states including paranoid disorders. In dermatological use, the indications for use are cutaneous delusions, dysaesthesias, pain syndromes and the compulsive self-picking disorders [2]. Drugs include pimozide, sulpiride, olanzapine and risperidone. The major disadvantages are extrapyramidal symptoms, although at low dosage there are minimal side effects.

Hypnosis [1]

Hypnosis has always had its adherents and detractors but until recently there has been little attempt at scientific evaluation. Thus, there have been claims that hypnosis could induce inflammatory change and blisters in skin [2], and more than 30 years ago it was shown that immediate type 1 reactions, and even a Mantoux reaction, could be modified by hypnotic suggestion. The diminution in the Mantoux response was shown to be caused by a reduction in oedema rather than in the cellular response [3]. Hypnotic suggestion has been used to treat various types of ichthyosis [4–7]. It was claimed that the depth of the trance-like state could be important in determining the response to therapy, at least as far as patients with ichthyosis are concerned, and that the best results were obtained in deep-trance rather than light-trance subjects [5].

There are also many case reports detailing the response of warts to hypnosis [8–11], the most striking case being that where only half of each subject's body was treated. Disappearance of the warts on the treated side was observed while other warts on the control side remained unchanged [12].

Adults with extensive atopic dermatitis, resistant to conventional treatment, were treated with hypnotherapy with statistically significant benefit, measured both subjectively and objectively [13]. More encouragingly, the benefit was maintained at follow-up for up to 2 years. Moreover, 20 children with severe resistant atopic dermatitis were also treated by hypnosis and all but one showed immediate improvement, which was maintained subsequently. In 12 of the 20 children whose families replied to a questionnaire up to 18 months after treatment, 10 of them maintained improvement in mood. Long-term studies showed that a smaller proportion of patients with atopic dermatitis could be maintained without second-line therapy with regular hypnosis [14].

It may be that improvement with hypnosis can be achieved more by anxiety reduction and stress management than direct suggestion. Psychodermatoses such as acne excoriée, neurodermatitis and trichotillomania may all respond to hypnosis [15]. Relaxation techniques, which approximate to light hypnotic states, led to some improvement in patients with chronic urticaria, although the number of their weals did not lessen [16].

Miscellaneous therapies

Biofeedback techniques

In recent years interest has grown in biofeedback techniques, during which patients are given visual or auditory information about the level of a particular autonomic function and then learn, through mechanisms that are not yet clear, to exercise some voluntary control over it. Biofeedback has been used for dyshidrotic eczema [1] and for hyperhidrosis [2].

Behaviour therapy

Behaviour therapy has sometimes been useful for patients who scratch repeatedly. In one study [3], parents were trained to withdraw their attentions when their child scratched; in another [4] a patient was required to monitor his own scratching and, to gain his therapist's attention, intervals without scratching were required. These therapeutic methods require regular reinforcement until autonomy has been obtained. These interactions assume that there will eventually be recognition of the patient's problem and the acceptance that there is a somatic component to the illness. The therapy can be used to reinforce positive adaptive illness responses, to extinguish maladaptive habits like excoriations, or to foster self-control over intrusive ruminative thinking (e.g. BDD) [5]. Habit reversal therapy helped a group of patients with atopic eczema [6,7].

Group therapy

Group therapy has been tried in psoriasis [8] and eczema [9]. Small groups of psoriatics met to discuss their problems with a trained fellow patient and a physician; illness behaviour, anxiety and feelings of depression all decreased. Help along similar lines can come from self-help groups [10]. A 6-week cognitive–behavioural therapy programme as an adjunct to pharmaceutical treatments produced significant improvement in severity of psoriasis as compared to pharmaceutical treatment alone [11].

Psychiatric problems caused by dermatological treatment

It is well known that systemic glucocorticoid therapy can induce either depression or hypomania in 5% of cases. Steroid-induced psychosis is more likely with larger dosage, in females and those with systemic lupus erythematosus (SLE) or a history of affective disorder [1,2]. It is less well known that antimalarials such as chloroquine and mefloquine [3] can induce psychosis, as can dapsone [4]. Aciclovir-induced psychosis has also been described in patients with impaired renal function [5]. There is also a report of a man who applied 70% diethyltoluamide, the most common insect repellant, immediately before a sauna, and developed an acute manic psychosis after 2 weeks [6].

Skin disease in patients with learning disability

Mental deficiency is not a disease in its own right but a condition resulting from a variety of causes, some inborn and others acquired. As a rough guide, some 3% of the population have learning difficulties, with an IQ of below 70, but the terms 'idiot', 'imbecile' and 'moron' are now obsolete in the professional sense. The class of subjects with higher grade learning disabilities shades into that of the less intelligent members of the ordinary population [1].

The number of syndromes in which cutaneous lesions and mental deficiency may be associated is large, and many of them have been delineated only during the last few years. Although many of these genetic or developmental conditions are rare, when put together they constitute a formidable part of present day paediatrics [2]. In addition, there are a number of other skin abnormalities that seem to affect those with learning disabilities in particular.

However, the available statistics must be interpreted with caution as they relate to patients in special institutions to which admission is largely determined by social factors. The proportion of patients with disabilities of the lowest grade, and of those of any grade with associated severe physical difficulties, is likely to be higher in such institutions than in the population of those with learning difficulties as a whole. In addition, institutional life itself may influence the prevalence of skin disease by allowing the rapid spread of infections, and other conditions may be favoured by unsuspected nutritional deficiencies.

The skin abnormalities of people with learning disabilities fall into three broad groups as outlined below.

Cutaneous lesions specifically associated with syndromes of genetic or developmental origin

Many of the numerous associations of this type are dealt with in detail elsewhere. Sometimes, the nature of the defect is understood at a biochemical level (Table 61.3) and sometimes chromosomal abnormalities have been demonstrated (Table 61.4) but, in most cases, the mechanism of both the cutaneous changes and mental impairment remains obscure (Table 61.5). The severity of the mental defect and of the cutaneous involvement may run more or less in parallel as in epiloia, but in most of these conditions there is no such relationship and the prevalence and severity of the mental impairment are highly variable.

Table 61.3 Some metabolic disorders that may be associated with mental defect and skin changes.

Anginosuccinic amino aciduria	Trichorrhexis nodosa
Cretinism	Coarse, dry skin and hair
Gangliosidosis (type 1) [3]	Extensive mongolian spots
Hartnup's disease	Photosensitivity
Homocystinuria	Fine hair, livedo reticularis
Hunter's syndrome [4]	Ivory white papules
Lesch–Nyhan syndrome	Self-mutilation
Lipoid proteinosis	Skin nodules and plaques
Phenylketonuria	Eczema, long eyelashes
Menkes' syndrome	Hair defects

Non-specific cutaneous lesions showing an increased prevalence in patients with learning disability

Moniliform hamartoma (see Chapter 15). Beaded strands of papules, mainly on the forehead and temples, develop at puberty in some patients, more often in black people than in white people.

Atypical keratosis pilaris. A symmetrical eruption of erythematous follicular papules extending from the base of the neck to the lumbar region is seen in young adults in institutions for those with learning difficulties [13]. This might represent *Pityrosporum* folliculitis.

Abnormal hair patterns [14]. The frequency of abnormal patterns of hair growth has been emphasized and is confirmed by our experience. Fusion of the eyebrows and a low frontal hairline are often seen; the latter is characteristic of those with true microcephaly but occurs in those with other learning difficulties. Hypertrichosis of the trunk or limbs is not unusual. The significance of the abnormal patterns is unknown and further surveys are required.

Atopic dermatitis. Only one patient with atopic dermatitis was found among over 200 children with learning

Table 61.4 Some conditions in which chromosomal abnormalities may be associated with mental defect and skin changes.

Down's syndrome	Ichthyosis
Familial X/Y translocation [5]	Facial hypertrichosis
Partial trisomy 2P	Scalp defect, haemangiomas
Patau's syndrome (trisomy 13)	Depigmented spots, café-au-lait patches
Ring chromosome 14 [6]	Nail hypoplasia, lymphoedema
Trisomy 18	Pre-auricular skin tags, scalp defects, flame naevi
Wolf–Hirschhorn syndrome (4P deletion)	Acne
XYY syndrome (see Chapter 12)	

Albinism	Monilethrix
Alopecia/retardation syndromes [7]	Moynahan's syndrome
Anhidrotic ectodermal dysplasia	Naevus sebaceous syndrome
Apert's syndrome	Netherton's disease
Ataxia–telangiectasia	Neurofibromatosis
Basal cell naevus syndrome	Onchotrichodysplasia with neutropenia [8]
Cockayne's syndrome	Papillon–Léage syndrome
Coffin–Siris syndrome [9]	Poikiloderma congenitale
De Sanctis–Cacchione syndrome	Richner–Hanhart syndrome [10]
Dystrophia myotonica	Rubinstein–Taybi syndrome [11]
Fanconi's anaemia	Russell–Silver dwarfism
Focal dermal hypoplasia	Sjögren–Larsson syndrome [12]
Hallermann–Streiff syndrome	Spina bifida
IBIDS syndrome [1]	Sturge–Weber syndrome
Incontinentia pigmenti	Treacher Collins' syndrome
Leprechaunism	Werner's syndrome
Marfan's syndrome	Wyburn–Mason syndrome

Table 61.5 Some other conditions in which mental defect may be associated with skin abnormalities.

IBIDS syndrome, ichthyosis, brittle hair, impaired intelligence, decreased fertility and short stature.

difficulties examined (A.J. Rook, unpublished data, 1953). Others have noticed a low prevalence of eczema [14], but atopic dermatitis is frequent in patients with Down's syndrome and phenylketonuria.

Traumatic keratoses and hypertrichosis [15]. Those with severe disabilities develop the habit of biting or chewing the forearm, hand, fingers or lips when excited or angry. Repeated biting at the same site induces thickening, hyperpigmentation and hypertrichosis. More rarely, there may be atrophic scarring, particularly on the hands. Keratoses in unusual sites may result from the repeated adoption of the same posture.

Prader–Willi syndrome is a genetic disorder that affects multiple systems and results in a cluster of behaviours including hyperphagia, emotional lability and compulsive destructive skin picking [16].

Traumatic alopecia. This is the result of a hair pulling tic. The patch selected for plucking is usually in the frontoparietal region, but may be anywhere on the scalp and even in the pubic region (A.J. Rook, unpublished data, 1953). Multiple self-mutilations including traumatic alopecia are seen in children with familial sensory neuropathy.

Crusted scabies. The crusted form of scabies [17] (see Chapter 33) is particularly frequent in those with severe learning disabilities.

Bacterial infections. Pyogenic infections accounted for 34% of patients referred from an institution for a dermatologist's opinion. The high incidence suggests low resistance to pyogenic organisms but the part played by the unhygienic habits of the patients is difficult to evaluate. Folliculitis of the thighs occurred in children and adolescents of both sexes, predominantly in males. Chronic suppurative hidradenitis was seen exclusively in adolescent boys. Erythrasma has a high prevalence [18].

Mycoses. Trichophyton infections are often common and refractory in those with learning difficulties. It is possible that enzyme induction by other drugs administered reduces the efficacy of griseofulvin.

Intertrigo and perleche. Genitocrural intertrigo is common in incontinent patients, especially those who are bedridden. Perleche, frequently complicated by fissuring and secondary infection, is seen in a large proportion of patients who dribble constantly.

Primary irritant dermatitis. The failure to take reasonable care in the use of disinfectants and cleansing agents is responsible for a relatively high incidence of primary irritant dermatitis in those patients who are encouraged to carry out simple domestic duties. Allergic contact dermatitis is said to be uncommon [14], perhaps because exposure to potential sensitizing agents is limited.

Drug reactions. The higher incidence of epilepsy in those with learning difficulties accounts for the relative frequency of reactions to drugs.

Non-specific cutaneous lesions, the prevalence and cause of which are not proved to differ significantly from those of the general population

There is no reliable evidence that the other common dermatoses are either more or less frequent in those with learning difficulties than in normal individuals [17]. Doubt has been cast upon the widely accepted association between epilepsy and acne [19].

Chapter 62

Disorders of Nails

D.A.R. de Berker, R. Baran & R.P.R. Dawber

Introduction

The epithelial part of the nail apparatus develops *in utero* from the primitive epidermis. In generalized integumentary diseases, such as psoriasis, the nail apparatus, hair follicle and epidermis may all be structurally and functionally affected, presumably because of their common tissue of origin.

The main function of the nail apparatus is to produce a strong, relatively inflexible, keratinous nail plate over the dorsal surface of the end of each digit. The nail plate acts as a protective covering for the fingertip. By exerting counter-pressure over the volar skin and pulp, the flat nail plate allows precision and delicacy when picking up small objects and in many other subtle finger functions [1–3]. Fingernails typically cover approximately one-fifth of the dorsal surface, whereas on the great toe the nail may cover up to 50% of the dorsum of the digit.

Anatomy and biology of the nail unit

Structure

Gross anatomy [1–5]

The component parts of the nail apparatus are shown diagrammatically in Fig. 62.1. The rectangular nail plate is the largest structure, resting on and firmly attached to the nail bed; it is less adherent proximally, apart from the posterolateral corners. Approximately one-quarter of the nail is covered by the proximal nail fold, and a narrow margin of the sides of the nail plate is often occluded by the lateral nail folds. Underlying the proximal part of the nail is the white lunula (half-moon lunule); this area represents the most distal region of the matrix [6]. It is most prominent on the thumb and great toe and may be partly or completely concealed by the proximal nail fold in other digits. The reason for the white colour is not known [7–9]. The natural shape of the free margin of the nail is the same as the contour of the distal border of the lunula. The nail plate distal to the lunula usually appears pink, due to its translucency, which allows the redness of the vascular nail bed to be seen through it. The proximal nail fold has two epithelial surfaces, dorsal and ventral; at the junction of the two, the cuticle projects distally onto the nail surface. The lateral nail folds are in continuity with the skin on the sides of the digit laterally, and medially they are joined by the nail bed. Some authorities term the lateral

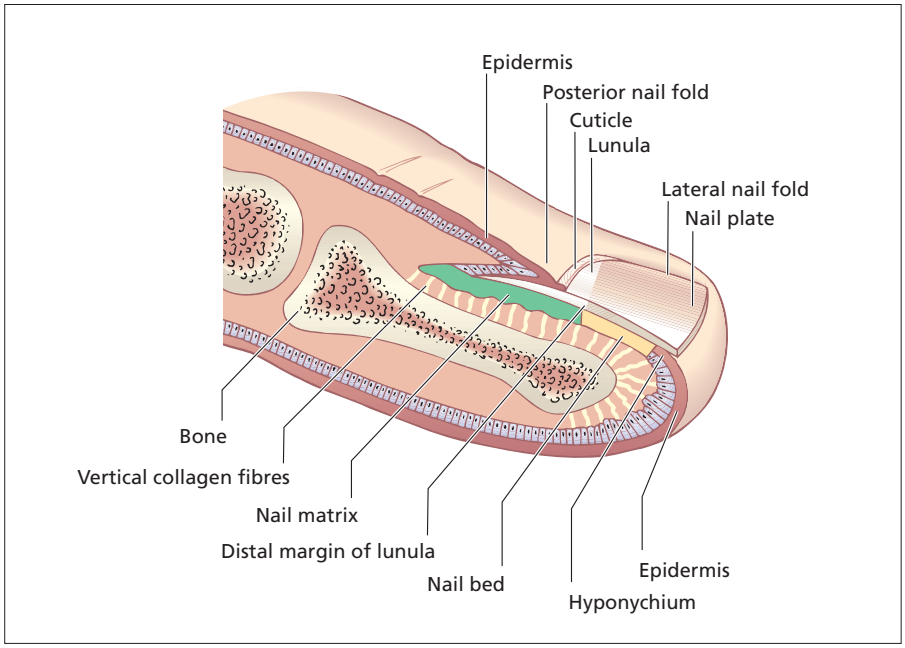

Fig. 62.1 Longitudinal section of a digit showing the dorsal nail apparatus.

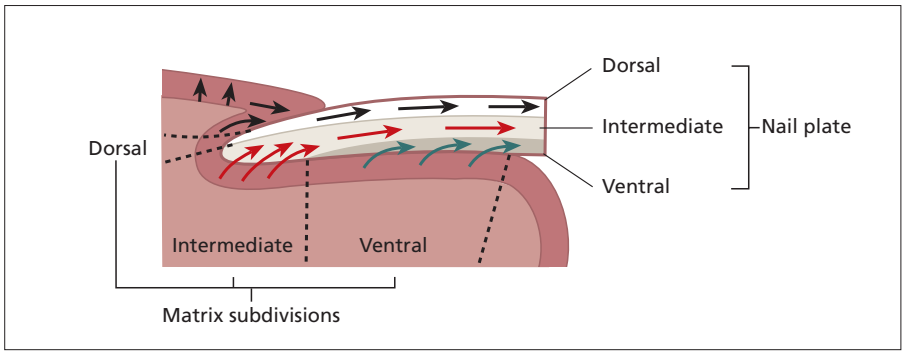

Fig. 62.2 Direction of differentiation and cell movement within the nail apparatus.

nail fold and adjacent tissue lateral to the nail fold the nail wall.

The definition of nail matrix is controversial [10]. There is common acceptance that there is a localized region beneath proximal nail which produces the major part of the normal nail plate. For those who consider this the sole source of nail it is termed simply the matrix, or germinal matrix. However, there is some evidence that other epithelial parts of the nail unit also contribute to the nail plate, and these are then also attributed matrix status. According to the histological criteria of Lewis and Montgomery [4] (Fig. 62.2), matrix can be subdivided into dorsal (ventral aspect of the proximal nail fold), intermediate (germinal matrix or matrix) and ventral (nail bed) sections. The nail bed is also termed the sterile matrix and its role in the production of nail is unclear. Although it appears that the nail plate may thicken by up to 30% as it passes from the distal margin of the lunula to the end of the nail bed [2], this is not associated with an increase in cell numbers and may represent compaction of the nail from distal tip trauma rather than nail bed or nail plate production [11]. The situation may change in disease, where the nail bed changes its histological appearance to gain a granular layer [12] and may contribute a false nail of cornified epithelium to the undersurface of the nail [5].

At the point of separation of the nail plate from the nail bed, the proximal part of the hyponychium may be modified as the *solehorn* [13]. This is a central thickened structure with a dermal core. It is usually found on the toes of elderly people, where there are often associated vascular abnormalities. Beyond the solehorn region, the hyponychium terminates at the distal nail groove; the tip of the digit beyond this ridge assumes the structure of the epidermis elsewhere.

When the attached nail plate is viewed from above, two distinct areas may be visible: the proximal lunula and the larger pink zone. On close examination, two further distal zones can often be identified: the distal yellowish-white margin and immediately proximal to this the onychodermal band [14]. Terry describes this as a barely perceptible,

narrow, transverse band 0.5–1.5 mm wide and more prominent in acrocyanosis. The exact anatomical basis for the onychodermal band is not known, but it appears to have a blood supply different from the main body of the nail bed; if the tip of the finger is pressed firmly, the band and an area just proximal to it blanch, and if the pressure is repeated several times the band reddens. Many changes in colour have been described in the onychodermal band in health and disease [13]. Histologically, it is defined as the most distal attachment of cornified epithelium to the undersurface of the nail. As such, it is structurally significant for the adherence of nail plate to the nail bed. Once breached, as in conditions such as psoriasis, separation of the nail bed from the nail plate can be progressive.

Microscopic anatomy [15]

Nail folds

The proximal nail folds are similar in structure to the adjacent skin but are normally devoid of dermatoglyphic markings and pilosebaceous glands. There is a normal granular layer. From the distal area of the proximal nail folds the cuticle adheres to the upper surface of the nail plate; it is composed of modified stratum corneum and serves to protect the structures at the base of the nail, particularly the germinal matrix, from environmental insults such as irritants, allergens and bacterial and fungal pathogens.

Nail matrix (intermediate matrix)

Nail matrix produces the nail plate in the absence of disease (Fig. 62.2). The basal compartment of the matrix is broader than the same region in normal epithelium or in other parts of the nail unit, such as the nail bed [10]. There is no granular layer, and cells differentiate with the expression of trichocyte 'hard' keratin as they become incorporated into the nail plate, alongside normal epithelial keratins [16,17]. During this process, they may retain their nuclei until more distal in the nail plate. These retained nuclei are called *pertinax bodies*. Apart from this, the detailed cytological changes seen in the matrix epithelium under the electron microscope are essentially the same as in the epidermis [18,19].

The nail matrix contains melanocytes in the lowest three cell layers and these donate pigment to the keratinocytes. The presence of 6.5 melanocytes per millimetre of matrix basement membrane can be used as a guide to a normal matrix melanocyte population [20]. The appearance of melanocytes separate from the basement membrane distinguishes them from those found in the nail folds, which are primarily basal [21]. Matrix melanocytes are further distinguished from those elsewhere by their failure to produce melanin in normal circumstances in white people. This can change, with melanotic streaks presenting in local inflammatory, naevoid or neoplastic disease. In non-white people, brown streaks are common and are almost universal in Afro-Caribbeans by the age of 60 years.

Langerhans' cells are detectable in the matrix by CD1a staining, and the matrix appears to contain basement membrane components indistinguishable from normal skin [22].

Nail bed

Nail bed consists of epidermis with underlying connective tissue closely apposed to the periosteum of the distal phalanx. There is no subcutaneous fat in the nail bed, although scattered dermal fat cells may be visible microscopically.

The nail bed epidermis is usually no more than two or three cells thick, although there may be tongues of epithelium that extend obliquely down. The transitional zone from living keratinocyte to dead ventral nail plate cell is abrupt, occurring in the space of one horizontal cell layer; in this regard it closely resembles the Henle layer of the internal root sheath of the epidermis [23]. Nail bed cells do not have any independent movement, and it is yet to be clearly demonstrated whether they are incorporated into an overlying nail plate as it grows distally [24]. The process of nail bed keratinization has been likened to that seen in rat-tail epidermis, possibly being affected by pressure changes. The loss of the overlying nail results in the development of a granular layer, which is otherwise present only in disease states [12,25,26].

The nail bed dermal collagen is mainly orientated vertically, being directly attached to the phalangeal periosteum and the epidermal basal lamina. Within the connective tissue network lie blood vessels, lymphatics, a fine network of elastic fibres and scattered fat cells; at the distal margin, eccrine sweat glands have been seen [1].

Nail plate

The nail plate comprises three horizontal layers: a thin dorsal lamina, the thicker intermediate lamina and a ventral layer from the nail bed [4]. This is not always apparent with normal light microscopy using routine stains, where the nail demonstrates a transition between flattened cells dorsally and thicker cells on the ventral aspect. Electron microscopy shows squamous cells with tortuous interlocking plasma membranes [18,19]. At high magnification, the contents of each cell show a uniform fine granularity similar to the hair cuticle [23].

The nail plate contains significant amounts of phospholipid, mainly in the dorsal and intermediate layers, which contribute to its flexibility. The detectable free fats and long-chain fatty acids may be of extrinsic origin. For further details of these and other histochemical changes in

the components of the nail apparatus, the reader is referred to more detailed texts [8,27].

The nail plate is rich in calcium, found as the phosphate in hydroxyapatite crystals; it is bound to phospholipids intracellularly [28]. The relevance of other metals (copper, manganese, zinc, iron and others), which are present in smaller amounts, is not known [25]. Calcium is present in a concentration of 0.1% by weight, 10 times greater than its concentration in hair. It is possible that calcium is not an intrinsic part of the nail but is incorporated from extrinsic sources. Calcium does not significantly contribute to the hardness of the nail [6].

Nail keratin

Nail keratin analysis shows essentially the same fractions as in hair:

1 fibrillar, low-sulphur protein;
2 globular, high-sulphur matrix protein;
3 high glycine–tyrosine-rich matrix protein.

Amino acid analysis shows higher cysteine, glutamic acid and serine and less tyrosine in nail compared with hair and wool [17,29].

An alternative classification of keratins defines them as 'soft' epithelial keratins or 'hard' trichocyte keratins. The latter are characteristic of hair and nail differentiation, where their high sulphur content is probably responsible for their rugged physical qualities. This is matched by the resistance of trichocyte keratins to dissolution in strong solvent.

Trichocyte and epithelial keratins are intermediate filaments representing the major cytoskeletal protein of epithelial cells. They share the normal classification into type I or type II based on gene hybridization, which reflects segregation on two-dimensional electrophoresis into acidic and basic proteins. Each acidic keratin is expressed in a tissue with a corresponding basic keratin to form specific heterodimers, which are assembled into higher-order protofibrils and protofilaments.

Keratin distribution in the nail and associated epithelium has been studied in adult [16,30], infant [17] and embryonic [31,32] digits. Immunohistochemistry of the epithelial structures of normal nail demonstrates that the suprabasal keratin pair K1/K10 is found on both aspects of the proximal nail fold and to a lesser degree in the matrix. However, it is absent from the nail bed. This is reversed when there is nail bed disease, such as onychomycosis or psoriasis, where a granular layer develops and K1/K10 becomes expressed at corresponding sites [23]. The nail bed contains keratin synthesized in normal basal layer epithelium, K5/K14, which is also found in nail matrix. An antibody marking the epitope characteristically associated with keratin expressed in the basal layer is found throughout the thickness of the nail bed, but only basally in the matrix [26].

Recent examination of the nail bed using monospecific monoclonal antibodies to the keratin pair K6/K16 demonstrates these proteins in the nail bed but not the germinal matrix [16]. This is paradoxical given our understanding that K6/K16 is characteristic of psoriasis and wound healing, where proliferation is a prominent feature. It has been shown that the nail bed has very low rates of proliferation [10,33], and it may be that K6/K16 more precisely illustrates a loss of differentiation, often associated with proliferation in skin but representing the resting state of nail bed epithelium.

The location of K6/K16 is reflected in the localization of the features of pachyonychia congenita. In this group of autosomal dominant disorders, there is thickening of the nail plate attributed to disease of the nail bed. In some forms of pachyonychia congenita, there is a missense mutation of the initiation peptide of K16 [34].

Trichocyte keratins can also be detected immunohistochemically within the epithelial structures of the nail unit. A monospecific antibody to Ha-1 has been created and characterized on nail, hair and skin. In the nail, it demonstrates a well-demarcated suprabasal region corresponding to the matrix [16]. Proximally, it does not extend onto the ventral aspect of the proximal nail fold, sometimes described as the dorsal matrix. Distally, the keratin expression is limited to a margin taken as corresponding to the lunula. Ha-1 is only one of at least 10 trichocyte keratins, but quantitatively it probably represents a large fraction of nail keratin. According to its distribution it appears to define a matrix consistent with the classic description of the germinal matrix.

Improved understanding of the distribution of keratins in the nail bed and matrix has accompanied further understanding of the molecular basis of pachyonychia congenita, where the various nail manifestations correlate with mutations within the keratin genes and corresponding phenotypes [35].

Development and comparative anatomy [1–3]

The nail apparatus develops and matures from the primitive epidermis between the ninth and 20th weeks of intrauterine growth. At 20 weeks, the matrix cells show postnatal-type cell division, differentiation and keratinization, and the nail plate begins to form and move distally [4,5]; the nail bed loses its granular layer at this stage [6]. By 36 weeks, the complete nail plate reaches the tip of the digit and is surrounded by prominent lateral nail folds and a well-formed cuticle.

The structure of claws and hooves and their evolutionary relationship to humans has been well reviewed [2,3,7]. In higher primates, nails have evolved with the acquisition of manual dexterity; other mammals do not possess such flattened claws from which nails have evolved. Claws and talons are harder than human nails, probably because of their high content of calcium phosphate as crystalline hydroxyapatite within keratinized cells compared with human nails [8]. The hard 'soft plate' under hooves is produced from an area equivalent to the subungual part of the claw. In some animals, cloven hooves have only developed on the 'digits' that touch the ground; in horses, the single large hoof is produced from the third digit. The keratin biochemistry of the human nail has many similarities to that of the anteater or pangolin [6,9].

Blood supply [1]

There is a rich arterial blood supply to the nail bed and matrix derived from paired digital arteries, a large palmar and small dorsal digital artery on either side. The palmar arteries are supplied from the large superficial and deep palmar arcades [2]. The main supply passes into the pulp space of the distal phalanx before reaching the dorsum of the digit (Fig. 62.3). Distally, the arteries are extremely tortuous and coiled, which allows them to be distorted without kinking to occlude supply. An accessory supply arises further back on the digit and does not enter the pulp space [3]. There are two main arterial arches (proximal and distal) supplying the nail bed and matrix, formed from anastomoses of the branches of the digital arteries. In the event of damage to the main supply in the pulp space, such as may occur with infection or scleroderma, there may be sufficient blood from the accessory vessels to permit normal growth of the nail.

There is a capillary loop system to the whole of the nail fold but the loops to the roof and matrix are flatter than those below the exposed nail [4]. The loops run longitudinally in the axis of splinter haemorrhages. Those in the nail bed are longest [5]. There are many arteriovenous

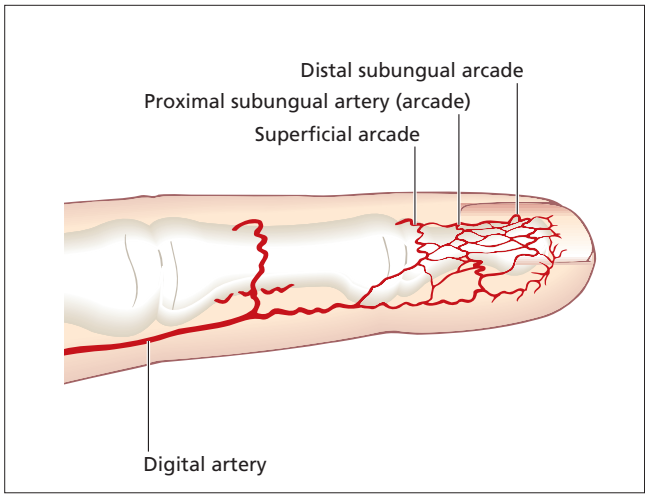

Fig. 62.3 Arterial supply of the distal finger.

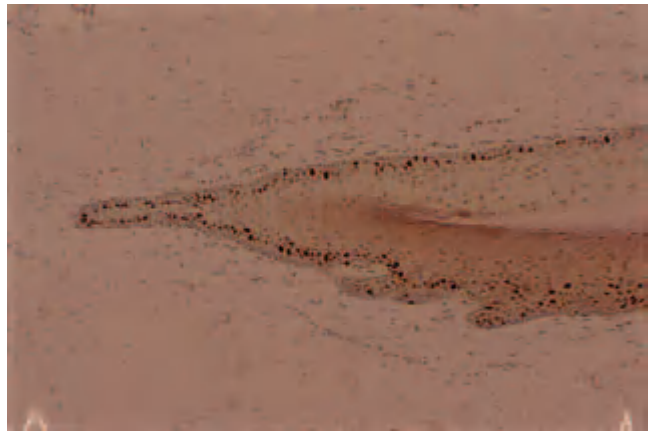

Fig. 62.4 Proliferating epithelial cells of the matrix and ventral aspect of the proximal nail fold, staining with the antibody MIB-1.

anastomoses beneath the nail—glomus bodies—which are concerned with heat regulation. Glomus bodies are important in maintaining acral circulation under cold conditions: arterioles constrict with cold but glomus bodies dilate [6]. These occupy the subdermal tissues and increase in number in a gradient towards the distal nail bed [7].

Nail growth and morphology

Clinicians used to observing the slow rate of growth of diseased or damaged nails are apt to view the nail apparatus as inert, although it is biochemically and kinetically active throughout life. In this respect, it differs from the hair follicle, which undergoes periods of quiescence as part of the follicular cycle.

Cell kinetics

The kinetic activity of the matrix has been examined using many techniques. These include immunohistochemistry, autoradiography and direct measurement of matrix product (i.e. nail plate) by ultrasound [1], micrometer or histology.

There is a broad basal compartment of proliferating cells in the matrix, which can be detected immunohistochemically with antibodies to proliferating cell nuclear antigen and Ki-67 (Fig. 62.4); both antigens are associated with proliferating cells [2]. The matrix is also the site of maximal inclusion of tritiated thymidine if injected into the peritoneum of squirrel monkeys and followed subsequently by autoradiography [3]. Although there was some inclusion of thymidine into the nail bed, Zaias and Alvarez interpreted the findings as indicating that the nail bed had no role in creation of the nail plate. Norton [4] drew a similar conclusion from work with live human subjects where labelled thymidine and glycine were injected locally to act as markers of proliferating and metabolically active keratinocytes, and both primarily labelled the matrix.

However, the earlier work of Lewis [5] suggested on histological grounds that the nail plate is a trilaminar structure originating from three separate matrix zones: the dorsal matrix (ventral aspect of proximal nail fold), intermediate matrix (germinal matrix) and ventral matrix (nail bed). In support of this, Johnson *et al*. [6,7] demonstrated that 21% of the nail thickness is gained as it passes over the nail bed, implying that the nail bed is generating this fraction of the nail plate. De Berker *et al*. [2] noted that the increase in nail thickness did not coincide with corresponding increases of nail plate cells. This challenges the interpretation that nail thickens over the nail bed through the contribution from underlying structures. An alternative explanation may be appropriate, such as compaction arising through repetitive distal trauma. Others have also debated this issue [8], and although the nail bed may have a significant contribution to make in disease [9], the evidence for its contribution at other times is conflicting.

Table 62.1 Physiological and environmental factors affecting the rate of nail growth.

Faster	Slower
Daytime	Night
Pregnancy [25]	First day of life [14]
Right-hand nails	Left-hand nails [28,29]
Youth, increasing age	Old age [18,23,30]
Fingers	Toes [31]
Summer [18]	Winter or cold environment [32,33]
Middle, ring and index fingers	Thumb and little finger [28,31,34,35]
Male gender	Female gender [27,35]
Minor trauma/nail biting [26,27]	

Table 62.2 Pathological factors affecting the rate of nail growth.

Faster	Slower
Psoriasis [36]	Finger immobilization [41]
Normal nails [23]	
Pitting	
Onycholysis [37]	
Pityriasis rubra pilaris [21,38]	Fever [42]
	Beau's lines [43]
Etretinate, rarely [39]	Methotrexate [24], azathioprine [24], etretinate [39]
Idiopathic onycholysis of women [37]	Denervation [44]
Bullous ichthyosiform erythroderma [13]	Poor nutrition
	Kwashiorkor [45]
Hyperthyroidism [28]	Hypothyroidism [28]
Levodopa [40]	Yellow nail syndrome [13]
Arteriovenous shunts [28]	Relapsing polychondritis [46]

Nail morphology

Why the nail grows flat, rather than as a heaped-up keratinous mass, has generated much thought and discussion [10–14]. Several factors probably combine to produce a relatively flat nail plate: the orientation of the matrix rete pegs and papillae; the direction of cell differentiation [15]; and moulding of the direction of nail growth between the proximal nail fold and distal phalanx [16]. Containment laterally within the lateral nail folds assists this orientation, and the adherent nature of the nail bed is likely to be important. In diseases such as psoriasis, the nail bed can lose its adherent properties, exhibiting onycholysis. In addition, there may be subungual hyperkeratosis. These combined factors make psoriasis the most common pathology in which up-growing nails are seen. Onychogryphosis is characterized by upward growth of thickened nail. In this condition, the nail matrix may become bucket-shaped and the effect of the overlying proximal nail fold is lost.

Linear nail growth [17–19]

Over the last century, many studies have been carried out on the linear growth of the nail plate in health and disease; these have been reviewed [20,21] and are listed in Tables 62.1 and 62.2 [22]. Most of these studies have been performed by observing the distal movement of a reference mark etched on the nail plate over a fixed period of time; this may well correlate with matrix germinative cell kinetics but there is no direct proof that it does. However, studies on nail growth in psoriasis, and its inhibition by cytostatic drugs [23,24], suggest that cell kinetics and linear growth rate do have a direct correlation.

Fingernails grow approximately 1 cm every 3 months and toenails at one-third of this rate.

Nails in childhood and old age

Childhood [1]

In early childhood, the nail plate is relatively thin and may show temporary koilonychia. This is particularly prominent on the great toes. Under the age of 5 years, nails are also prone to terminal onychoschizia (lamellar splitting). This can be most prominent on the sucked thumb, but is also seen on the toes. Sucking may also lead to paronychia, which can be a troublesome condition in childhood, with pain and nail dystrophy. Ingrowing can also cause pain and may present in different forms. At birth, there is often a degree of distal ingrowing, particularly in the great toe, as the nail has not surmounted the tip of the digit in its development [2]. In a more gross form, this may present as congenital hypertrophic lip of the hallux, where soft-tissue overgrowth may resemble fibrous tumours of the digit before spontaneously disappearing [3]. Painful distal embedding can lead to infection, but as long as the toenail is properly orientated with respect to the underlying phalanx, the condition usually subsides. In one series of seven children, two needed surgery due to painful persistence of the problem [4]. The changes associated with congenital malalignment of the great toe may also subside within 5–10 years in about 50% of children. In this condition, there is deviation of the tip of the great toe nail laterally, rotating on the distal phalanx. The nail is yellow, triangular, thickened and has transverse ridges [5].

Fungal infection is relatively uncommon in children, with a prevalence of 0.44% in one study [6].

Beau's lines can be seen in up to 92% of normal infants between 8 and 9 weeks of age [7]. One child demonstrated a transverse depression through the whole nail thickness on all 20 digits [8]. Normal surface markings of the nail can differ in children from those seen in adults. A herringbone pattern is common and gradually diminishes with time [9], which may reflect a gradual change in the pattern of matrix maturation.

Old age

Many of the changes seen in old age may occur in younger age groups in association with impaired arterial blood supply. Elastic tissue changes diffusely affecting the nail bed epidermis are often seen histologically [10]; these changes may be due to the effects of UV radiation, although it has been stated that the nail plate is an efficient filter of UVB radiation [11]. The whole subungual area in old age may show thickening of blood vessel walls with vascular elastic tissue fragmentation. Pertinax bodies are often seen in the nail plate. Nail growth is inversely proportional to age [12]; related to this slower growth, corneocytes are larger in old age [13].

The nail plate becomes paler, dull and opaque with advancing years, and white nails similar to those seen in cirrhosis, uraemia and hypoalbuminaemia may be seen in normal subjects. Longitudinal ridging is present to some degree in most people after 50 years of age and this may give a 'sausage links' or beaded appearance.

For details of the common traumatic abnormalities and

changes due to inadequate pedicure or neglect, detailed texts should be consulted [1,12].

Nail signs and systemic disease

It is important for clinicians to understand and accurately describe nail findings if they are to communicate accurately with their colleagues and avoid the vagueness that often surrounds nail pathology. Signs fall into categories of shape, surface and colour.

Abnormalities of shape

Clubbing

In clubbing there is increased transverse and longitudinal nail curvature with hypertrophy of the soft-tissue components of the digit pulp. Hyperplasia of the fibrovascular tissue at the base of the nail allows the nail to be 'rocked' and in causes associated with cardiopulmonary disease there may be local cyanosis.

There are three forms of geometric assessment that can be performed. *Lovibond's angle* is found at the junction between the nail plate and the proximal nail fold, and is normally less than 160°. This is altered to over 180° in clubbing (Fig. 62.5). *Curth's angle* at the distal interphalangeal joint is normally about 180°. This is diminished to less than 160° in clubbing (Fig. 62.6). *Schamroth's window* is seen when the dorsal aspects of two fingers from opposite hands are apposed, revealing a window of light, bordered laterally by the Lovibond angles. As this angle is obliterated in clubbing, the window closes [1]. Assessment of clubbing at the bedside shows poor agreement between examiners [2] in milder cases and there are problems in firm morphometric analysis that do not lend themselves to routine clinical solutions [3].

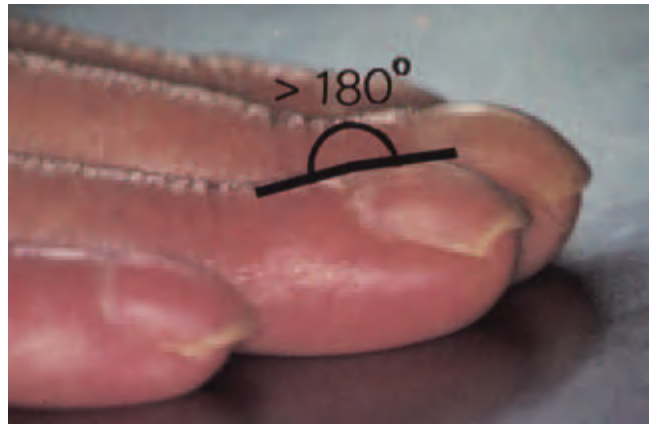

Fig. 62.5 Clubbing: Lovibond's profile sign. The angle is normally less than 160° but exceeds 180° in clubbing.

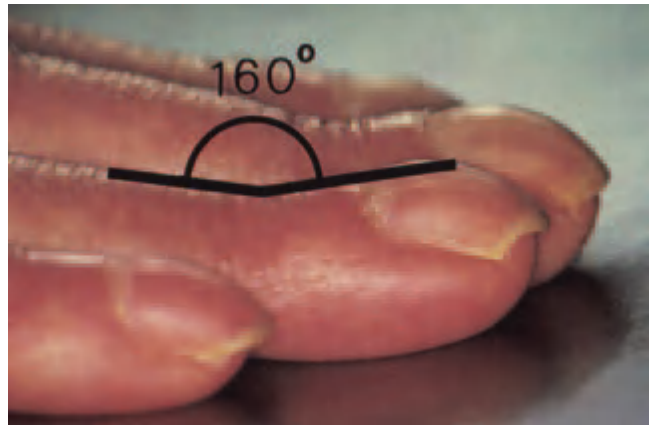

Fig. 62.6 Clubbing: Curth's modified profile sign.

Clubbing appears to be related more to increased blood flow through the vasodilated plexus of nail unit vasculature than to vessel hyperplasia. Altered vagal tone and microvascular infarcts have been implicated [4,5].

Pathological associations of clubbing include inflammatory bowel disease, carcinoma of the bronchus and cirrhosis. In forms associated with bronchiectasis or neoplasm, prominent inflammatory joint signs may also be seen, resulting in hypertrophic pulmonary osteoarthropathy. It has also been reported as a common finding in hemiplegic limbs [6] and can be a presenting feature of a subungual tumour when in a single digit [7]. In some cases of bronchiectasis, a variant of clubbing, *shell nail syndrome*, can be seen. This is distinguished from clubbing by the presence of atrophy of underlying bone and nail bed [8] and may have more in common with yellow nail syndrome than with clubbing.

Koilonychia

In koilonychia (Greek: *koilos*, hollow; *onyx*, nail), there is reverse curvature in the transverse and longitudinal axes giving a concave dorsal aspect to the nail [1]. Fingers and toes may be affected, with signs most prominent in the thumb or great toe. The nail may be thickened, thinned, softened or unchanged in quality. Koilonychia is common in infancy as a benign feature of the great toenail, although in some infants its persistence may be associated with a deficiency of cysteine-rich keratin [2] in trichothiodystrophy. The most common systemic association is with iron deficiency [3] and haemochromatosis, although the majority of adults with koilonychia demonstrate a familial pattern which may be autosomal dominant [4]. In dermatoses such as psoriasis and dermatophyte infection, nail bed hyperkeratosis may push the nail up distally to produce a spoon-shaped nail. In mechanics, softening of the nail with oil may be a factor [5], and in hairdressers, permanent wave solutions may be causal [6].

Pincer nail

SYN. INVOLUTED OR TRUMPET NAIL

Pincer nail describes a dystrophy where nail growth is pitched towards the midline, combined with increased transverse curvature. Although the changes in matrix geometry may only be slight, their effect is amplified by longitudinal growth of the nail such that the free edge may take on the shape of the apex of a cone in extreme cases. Pain may arise due to embedding of the pincer nail in the lateral nail folds and nail bed, which becomes most pronounced distally. Thumbs and great toes are the most commonly affected digits, with a gradient of involvement to more lateral digits. It occurs in several patterns [1–3]. It is seen as an isolated familial abnormality that usually becomes manifest in adulthood. It is also seen in association with psoriasis. Isolated digits may be affected as a result of trauma, degenerative joint changes or a subungual tumour that is displacing the nail upwards in the midline. Rarely, single associations with unusual presentations are reported [4–6].

Assessment should include imaging. Treatment is usually by surgery to relieve the pain. In toes it is usually best to perform a lateral ablation of the most embedded margin. This will sometimes lead to a shift of the nail such that the other side no longer embeds. If both sides require ablation, the dimensions of the toenail may mean that it is better to ablate the entire matrix rather than to leave a central zone of nail. The alternative of corrective surgery in toes has only a modest chance of success and ablation may ultimately be required as a definitive procedure. When treating the thumbs or fingers, the chance of success with corrective surgery is higher and the cosmetic and functional handicap of ablation may not be acceptable. Again, a lateral ablation may be adequate, but more complex procedures entail altering the alignment of the matrix [2,7,8] and addressing any midline hypertrophy of the distal phalanx. Some surgeons advocate a combination of reconstruction and ablation [9]. Nail braces rarely produce long-term benefit.

Macronychia and micronychia

Macronychia and micronychia are conditions where a nail is considered too large or too small in comparison with

Fig. 62.7 Racket nail associated with clubbing.

other nails on nearby digits. The nail disorder is usually associated with an abnormal digit, arising from underlying bony abnormalities such as local gigantism causing macronychia or megadactyly [1]. This is also the basis of racket thumb (Fig. 62.7), the most common form of benign, dominantly inherited macronychia. Plexiform neurofibromas may cause nail changes, and duplication of the terminal phalanges may cause bifid or small nails [2].

Anonychia

Anonychia is absence of all or part of one or several nails [1]. The term implies a permanent state, which can be congenital and associated with underlying bony changes [2]. If there is residual nail matrix, there may be some vestigial nail or hyperkeratosis. Temporary anonychia may arise from onychomadesis (nail loss) associated with transient local or systemic upset. If local, the appearance of the nail unit may reflect the precipitating cause.

Abnormalities of nail attachment

Nail shedding

Nails can be lost through different mechanisms.
1 Complete loss of the nail plate due to proximal nail separation extending distally [1] is called onychomadesis and is a progression of profound Beau's lines. This may reflect local or systemic disease and in the latter may result in temporary loss of all nails.
2 Local dermatoses such as the bullous disorders and paronychia may cause nail loss. Generalized dermatoses may be manifest, for example toxic epidermal necrolysis (TEN) and severe/rapid onset of pustular psoriasis. Scarring of the nail unit is seen in lichen planus and following TEN, which may both provoke nail loss.
3 Trauma is a common cause of recurrent loss and may reflect the nature of the activity, such as football, or some underlying abnormality of footwear [2] or pedal mechanics. It is often associated with subungual haemorrhage [3]. In the long term, athletes often develop thickened dystrophic nails matching a history of recurrent shedding.
4 Temporary loss has also been described due to retinoids [4], and large doses of cloxacillin and cephaloridine during the treatment of two anephric patients [5].
5 Onychoptosis defluvium or alopecia unguium describes atraumatic, familial, non-inflammatory nail loss [6]. It may be periodic and associated with dental amelogenesis imperfecta.
6 Nail shedding can be part of an inherited structural defect, most obviously in epidermolysis bullosa [7], although at times the diagnosis may be occult [8].

Onycholysis

Onycholysis is the distal and/or lateral separation of the nail from the nail bed [1,2]. Psoriatic onycholysis can be considered the reference point for other forms of onycholysis where it is typically distal, with variable lateral involvement. Areas of separation appear white or yellow due to air beneath the nail and sequestered debris, shed squames and glycoprotein exudate. Isolated islands of onycholysis present as 'oily spots' or 'salmon patches' in the nail bed. At the border of onycholysis, the nail bed is usually reddish-brown, reflecting the underlying psoriatic inflammatory changes. All the common causes are associated with diminished adherence of nail to nail bed

Fig. 62.8 Onycholysis: idiopathic type.

Fig. 62.9 Photo-onycholysis with a uniform pattern of discoloured onycholysis in the midline.

as a primary (idiopathic) or secondary event and include trauma, fungal infection, eczema and photo-onycholysis [3].

Idiopathic onycholysis

This is a painless separation of the nail from its bed, which occurs without apparent cause. Overzealous manicure, frequent wetting and cosmetic 'solvents' may be the cause but may not be admitted by the patient. There may, however, be a minor traumatic element, as the condition occurs rather more often in persons who keep their nails abnormally long. Maceration with water may also be a factor [3]. It must be distinguished from other causes of onycholysis (see below). The affected nails grow very quickly [4].

The condition usually starts at the tip of one or more nails and extends to involve the distal third of the nail bed (Fig. 62.8). Persistent manicure is attempted to remove the debris which accumulates within the onycholytic space, and this can result in a crescentic margin of onycholysis matching the onychocorneal band and appearing similar in all involved digits. Pain occurs only if there is further extension as a result of trauma or if active infection supervenes. More often there is microbial colonization of a mixed nature, including *Candida albicans* and several bacteria, of which *Pseudomonas pyocyanea* is the most common. If the condition persists for several months, the nail bed becomes dark and irregularly thickened.

The condition is mostly seen in women and many cases return to normal after a few months. The longer it lasts, the less likely is the nail to become reattached, due to keratinization of the exposed nail bed.

Treatment [5]. The patient should be advised to cut away as much as possible of the loosened nail and to apply a topical steroid preparation containing antibiotics and nystatin (e.g. Tri-Adcortyl cream) to the nail bed two or three times a day, or to use miconazole/hydrocortisone cream twice a day [1]. Reattachment is slow, and the loosened nail should be recut several times if necessary. The object of treatment is to prevent infection becoming established beneath the loosened nail, because this leads to thickening of the nail bed and prevents reattachment. Some authorities still recommend 4% thymol in chloroform (not available in the USA) as a means of preventing infection and further maceration of the nail bed [6]; however, 2% thymol is often as strong as the patient can tolerate and is usually effective. Where antimicrobial therapy is needed for *Pseudomonas*, gentamicin eye drops can be useful. Drying under the onycholytic nails with a hair dryer has been advocated in order to desiccate the environment in which *Pseudomonas* would otherwise grow.

Secondary onycholysis

There are many other causes of onycholysis, which is one of the commonest nail signs [5,7–9]. Psoriasis, fungal infections and dermatitis are common causes; congenital ectodermal defect is a rare one. Onycholysis occurs in general medical conditions, including impaired peripheral circulation, hypothyroidism [10], hyperthyroidism [11], hyperhidrosis, yellow nail syndrome and shell nail syndrome. Minor trauma is a common cause, and many occupational cases are due to trauma [6,12]. Immersion of the hands in soap and water may be considered traumatic, as also may the use of certain nail cosmetics. It has also been described after the application of 5% 5-fluorouracil to the fingertips [13]. There is a condition of hereditary partial onycholysis associated with hard nails [14]. Photo-onycholysis (Fig. 62.9) may occur during treatment with psoralens, demethylchlortetracycline and doxycycline [15,16], and rarely other antibiotics. This is sometimes associated with cutaneous photosensitivity (see Chapter 24). Drugs such as retinoids [17] and cancer chemotherapy [18] can also be implicated.

Pterygium [1]

The term 'pterygium' describes the winged appearance achieved when a central fibrotic band divides a nail proximally in two. However, the fibrotic tissue may not always grossly alter the nail and can extend from the lateral nail fold as well as the more typical proximal nail fold. A large pterygium may destroy the whole nail.

An inflammatory destructive process precedes pterygium formation. There is fusion between the nail fold and underlying nail bed. The fibrotic band then obstructs normal nail growth. Superficial abnormal vessels may be seen and there are no skin markings. It most typically develops in trauma or lichen planus and its variants, including idiopathic atrophy of the nail [2] and graft-versus-host disease [3]. It can also occur in leprosy, where it may represent scarring secondary to neuropathic damage and secondary purulent infection [4].

4 Patki AH, Mehta JM. Pterygium unguis in a patient with recurrent type 2 lepra reaction. *Cutis* 1989; **44**: 311–2.

Ventral pterygium [1]

Ventral pterygium or pterygium inversum unguis [2] occurs on the distal undersurface of the nail, with forward extension of the nail bed epithelium dislocating the hyponychium and obscuring the distal groove. Causes include trauma, systemic sclerosis [2,3], Raynaud's phenomenon, lupus erythematosus, familial [4] and infective [5]. The overlying nail may be normal, but adjacent soft tissues can be painful.

Subungual hyperkeratosis

Subungual hyperkeratosis entails hyperkeratosis of the nail bed and hyponychium and may occur in a range of conditions, including those where the primary diagnosis is not clear. Nail plate changes are variable, but thickening is common. Dry, white or yellow hyperkeratosis may crumble away from the overhanging nail. Hyperkeratosis may extend onto the digit pulp. Features of onychomycosis and wart virus infection (mainly toes) or psoriasis, pityriasis rubra pilaris and eczema (mainly fingers) may be found elsewhere to determine the aetiology.

The nail bed is an epithelium of low proliferative turnover. Any disease process that affects it is likely to result in an excess of squamous debris. The overlying nail prevents simple loss. The initial outcome is compaction of debris into layers of subungual hyperkeratosis. The only route of loss is by emerging distally with the growing nail.

Focal subungual keratoses are seen with Darier's disease, and keratotic debris beneath the nail in Norwegian (crusted) scabies may contain mites and eggs.

Nail thickening

Isolated thickening of the nail is associated with yellow discoloration as the nail bed vasculature is obscured. Common causes include psoriasis, eczema, trauma and onychomycosis, some of which may be associated with subungual hyperkeratosis. The shape of the nail may alter depending on the underlying cause, such as in yellow nail syndrome, where there is increased curvature in the longitudinal and transverse axes.

In the elderly and yellow nail syndrome, retarded longitudinal growth of the toenail is compensated for by

increased thickness [1]. Yellow nail may also develop where the nail bed produces abnormal nail [2]. Onychogryphosis describes thickened nails, usually the great toenail, which commonly grow upwards in a spiral. It is attributed to chronic distorting trauma and can be treated surgically or by conservative methods. These include trimming with an electric drill, chemical destruction with 40% urea paste, phenolization of the matrix to achieve total ablation (phenol time reduced to 2 min) or carbon dioxide laser.

Changes in nail surface

Longitudinal grooves

Longitudinal grooves may run all or part of the length of the nail in the longitudinal axis, and need to be distinguished from ridges which are proud of the nail surface [1]. Grooves may be full or partial thickness.

The median canaliform dystrophy of Heller [2] is the most distinctive form [3]. The nail is split, usually in the midline, with a fir-tree-like appearance of ridges angled backwards. The thumbs are most commonly affected and the involvement may be symmetrical. The cuticle may be normal, as distinct from the cuticle in habit tic deformity (washboard nails). After a period of months or years the nails often return to normal, but relapse may occur [4] and a ridge may replace the original defect. Some patients give a definite history of trauma [1], or the disorder can be attributed to oral retinoids [5]. Familial cases have been recorded. Sutton [6] described involvement of a toenail in which a flabby filament of fleshy tissue was present in the canal. Treatment is unnecessary, although the patient should be advised to apply an emollient cream to the nail fold.

Physiological furrows and ridges are accentuated in lichen planus, rheumatoid arthritis, peripheral vascular disease, old age and Darier's disease. *Onychorrhexis* may occur where there are superficial grooves in the nail that lead to a distal split.

Tumours (warts, myxoid cysts) pressing on the matrix, or a proximal nail fold pterygium, may produce a longitudinal groove.

Transverse grooves and Beau's lines [1]

Transverse grooves may be full or partial thickness through the nail. When they are endogenous they have an arcuate margin matching the lunula. If exogenous, such as those due to manicure, the margin may match the proximal nail fold and the grooves may be multiple as in washboard nails associated with a habit tic [2,3]. When multiple, it may be difficult to distinguish a habit tic from psoriasis. Transverse grooves may occur on isolated diseased digits (trauma, inflammation or neurological events) or may be generalized, reflecting a systemic event such as coronary thrombosis, measles, mumps or pneumonia. If endogenous, they are usually referred to as *Beau's lines* [4,5]. They arise through temporary interference with nail formation and become visible on the nail surface (Fig. 62.10) some weeks after the precipitant. The distance of the groove from the nail fold is related to the time since the onset of growth disturbance. The depth and width of the groove may be related to the severity and duration of disturbance, respectively. In many cases, grooves are seen on all 20 nails but are most prominent on the thumb and great toenail, and are deeper in the midline of the nail. Full-thickness grooves can be associated with distal extension

Fig. 62.10 Beau's lines present as transverse grooves in the nail matching the proximal margin of the nail matrix and lunula.

of the plane of separation of the nail plate. This can lead to nail loss, termed *onychomadesis*.

Pitting

Pitting presents as punctate erosions in the nail surface. Individual pits may be shallow or deep, with a regular or irregular outline. The individual pits of psoriasis are said to be less regular in form and in overall pattern than those of alopecia areata, but this is not always the case. When numerous, they appear randomly distributed upon the nail surface or have a geometric pattern. The latter may cause rippling or create a grid of pits. Extensive pitting combined with other surface irregularities results in the appearance of *trachyonychia*. An isolated large pit may produce a localized full-thickness defect in the nail plate termed *elkonyxis*, which is found in Reiter's disease, psoriasis and following trauma.

Histologically, pits represent foci of parakeratosis, reflecting isolated nail malformation [1].

REFERENCE

1 Zaias N. Psoriasis of the nail. A clinicopathologic study. *Arch Dermatol* 1969; **99**: 567–79.

Trachyonychia

Trachyonychia presents as a rough surface affecting all of the nail plate and up to 20 nails (20-nail dystrophy) [1]. The original French term was 'sand-blasted nails', which evokes the main clinical feature of a grey roughened surface (Fig. 62.11). It is mainly associated with alopecia areata [2], psoriasis and lichen planus, although the most common presentation is as an isolated nail abnormality. In the isolated form, histology shows spongiosis and a lymphocytic infiltrate [3] of the nail matrix. It may present as a self-limiting condition in childhood or as a more chronic problem in adulthood. There is some response to potent topical, locally injected and systemic steroids, but this may be temporary. Topical 5-fluorouracil has also been used to good effect [4], although it is important to be wary of associated onycholysis where the diagnosis is psoriasis, as onycholysis can be exacerbated by 5-fluorouracil. Childhood forms normally resolve spontaneously.

Onychoschizia

Onychoschizia is also known as lamellar dystrophy and is characterized by transverse splitting into layers at or near the free edge (Fig. 62.12) in fingers and toes, especially in infants [1]. This can result in discoloration because of sequestration of debris between the layers.

Fig. 62.12 Onychoschizia (lamellar splitting).

Variants include splitting at the lateral margins alone and multiple crenellated splits at the free edge. It is seldom associated with any systemic disorder, although it has been reported with polycythaemia [2], human immunodeficiency virus (HIV) infection [3] and glucagonoma [4].

Scanning electron microscopy illustrates the tendency of the lamellar structure of nail to separate after repeated immersion in water [5], although case–control studies show that occupation is not a major determinant of the condition [6]. However, efforts at retaining hydration (gloves, emollient and base coat with nail varnish) may help reverse clinical changes. Biotin has been used as systemic therapy, but the evidence for its efficacy is weak [7].

Brittle nails

Brittle nails [1–3] are often associated with onychoschizia and frequent immersion of the hands in water, especially if alkaline. Treatment is the same as for onychoschizia. Other common causes are iron deficiency anaemia and impaired peripheral circulation. A rare cause is disturbance of arginine metabolism, when it is also associated with diffuse alopecia [4].

Beading and ridging

Beading and ridging have been described as occurring more often than normal in patients with rheumatoid arthritis [1]. More recently, increased beading has been examined using optical profilometry in patients taking itraconazole for onychomycosis [2]. Itraconazole is known to increase the rate of nail growth, and it was proposed that beading may be a feature of this increase. As beading is more commonly a feature of old age, when nail growth rate slows down, one would not expect beading to correspond directly to faster linear nail growth. Both beading and ridging are common signs in normal ageing patients and at present their significance remains unclear.

Changes in colour [1–7]

Alteration in nail colour may occur because of changes affecting the dorsal nail surface, the substance of the nail plate, the undersurface of the nail or the nail bed.

Exogenous pigment

Exogenous pigment on the upper surface is easy to demonstrate by scraping the nail. If the proximal margin of the pigment is an arc matching the proximal nail fold, this is a further clue confirming an exogenous source. Often, the cuticle is less absorbent than nail and there will be a narrow proximal margin of unstained nail. This margin will broaden as the period since exposure lengthens. Hence the 'quitters' nail, which demonstrates the cessation of smoking and nicotine-free fingers for 2 months.

Exogenous pigment on the undersurface of the nail is less easy to demonstrate and may mean that part or all of the nail needs to be avulsed in order to scrape the undersurface and examine it separate from the nail bed. The green pigment of *Pseudomonas* infection [6] in association with onycholysis is a typical situation where partial avulsion is the best way to demonstrate the site of pigmentation, although it may not always be the best treatment.

Nail plate changes

The substance of the nail plate can be changed by the addition of pigment or the alteration of the normal cellular and intercellular organization such that there is loss of normal lucency. Pigment is typically added in the form of melanin produced by matrix melanocytes during nail formation. This produces a brown longitudinal streak the entire length of the nail. In white people this is abnormal and requires thorough assessment and, in some instances, biopsy. In darker-skinned people it is a common variant. The incorporation of heavy metals and some drugs into the nail via the matrix can also produce altered nail plate colour, such as the grey colour associated with silver. The disruption of normal nail plate formation by disease, chemotherapy, poisons or trauma can result in waves of

parakeratotic nail cells or small splits between cells within the nail. Both make the nail less lucent and produce the white marks of true *leukonychia*. Transmission electron microscopy suggests that there is a change in collagen fibre organization, which might provide an intracellular basis for altered diffractive properties. This disruption can be achieved at nail formation or subsequently in the case of fungal nail infection, where discoloration may start distolaterally rather than via the matrix.

Nail bed changes

In addition to generalized vascular changes in the nail bed, there can be localized changes, as seen with nail bed tumours. In the instance of a glomus tumour, this may be the sole method of localization and arises because of the differential blood supply in the tumour and surrounding nail bed. Subungual hyperkeratosis or the incorporation of drugs (antimalarials, phenothiazines) may also change the apparent colour of the nail. Splinter haemorrhages, representing ruptured nail bed vessels, deposit haemoglobin on the undersurface of the nail, which grows out. Cyanosis makes the nail bed blue and carbon monoxide poisoning makes it bright red.

True leukonychia

White discoloration of the nail attributable to matrix dysfunction occurs in a variety of patterns [1,2]. There is the rare, inherited form called total leukonychia, in which all nails are milky porcelain white [3]. In subtotal leukonychia, the proximal two-thirds are white, becoming pink distally. This is attributed to a delay in keratin maturation, and the nail may still appear white at the distal overhang (Fig. 62.13).

Transverse leukonychia (Mees' line) reflects a systemic disorder, such as chemotherapy or poisoning [4], or systemic infection [5] affecting matrix function. The 1–2-mm-wide transverse band is in the arcuate form of the lunula and is analogous to a Beau's line, with which it is occasionally found. Punctate leukonychia comprises white spots of 1–3 mm diameter attributed to minor matrix trauma (e.g. manicure) and is also seen in alopecia areata.

Fig. 62.13 True leukonychia with white nail in the distal free edge.

The pattern and number of spots may change as the nail grows. With longitudinal leukonychia, there is a parakeratotic focus in the matrix, sometimes attributable to Darier's disease or a small tumour.

Apparent leukonychia

In apparent leukonychia, changes in the nail bed are responsible for the white appearance [1,2]. Nail bed pallor may be a non-specific sign of anaemia, oedema or vascular impairment. It may occur in particular patterns which have become associated with certain conditions.

Terry's nail

This is white proximally and normal distally and is attributed to cirrhosis, congestive cardiac failure and adult-onset diabetes mellitus [3]. Nail bed biopsy reveals only mild changes of increased vascularity. This is similar to *half-and-half nails*, where there is a proximal white zone and distal (20–60%) brownish sharp demarcation, the histology of which suggests an increase of vessel wall thickness and melanin deposition. It is seen in 9–50% of patients with chronic renal failure and after chemotherapy. It is unclear whether the variant *Neapolitan nails*, where there are bands of white, brown and red, is a version of half-and-half or Terry's nails, or a feature of old age.

Muehrcke's paired white bands

These bands are parallel to the lunula in the nail bed, with pink between two white lines. They are commonly associated with hypoalbuminaemia, the correction of which by albumin infusion can reverse the sign. They have also recently been reported following placement of a left ventricular assist device in a patient with congestive heart failure [4].

Colour changes due to drugs [1]

There are a number of colour changes due to drugs. Yellowing of the nail is a rare occurrence in prolonged tetracycline therapy, which can also produce a pattern of dark distal photo-onycholysis associated with photosensitivity [2]. The whole nail is affected and returns to normal when the drug is discontinued. A similar effect, but of a bluish colour, is seen with mepacrine [3], the nails fluorescing yellow–green or white when viewed under Wood's light. Normal nails show slight fluorescence of violet–blue colour.

Chloroquine may produce blue-black pigmentation of the nail bed [4]. Other antimalarials may produce longitudinal or vertical bands of pigmentation on the nail bed or in the nail [5,6]. A fixed drug eruption of the nail bed can be dark blue [7]. Argyria may discolour the nails slate blue [8], and inorganic arsenic may produce longitudinal bands of pigment or transverse white stripes (*Mees' stripes*) across the nail.

Hyperpigmentation due to increased melanin in the nail and nail bed has been noted in children after 6 weeks of treatment with doxorubicin (adriamycin) [9,10]. Other similar cytotoxic drugs may cause a variety of patterns of increased pigmentation [1]. However, in acquired immune deficiency syndrome (AIDS), longitudinal melanonychia may be seen in untreated cases [11,12] as well as in those receiving zidovudine [9,13].

Yellow nail syndrome

The nails in yellow nail syndrome are yellow due to thickening, sometimes with a tinge of green possibly due to secondary infection. The lunula is obscured and there is increased transverse and longitudinal curvature and loss of cuticle (Fig. 62.14). Occasionally, there is chronic paronychia with onycholysis and transverse ridging [1]. The condition usually presents in adults, but may occur as early as the age of 8 years [2]. Some of the clinical features may overlap with lichen planus [3,4], although the latter does not have the other systemic features normally seen in this syndrome. The features are usually accompanied by lymphoedema [5] at one or more sites and respiratory or nasal sinus disease. The nails grow at a greatly reduced rate: 0.1–0.25 mm/week for fingernails compared with the lowest normal rate of 0.5 mm/week. All 20 nails may be involved, although often a few are spared. Histologically, in the nail bed and matrix, dense fibrous tissue is found replacing subungual stroma, with numerous ectatic endothelium-lined vessels [6]. A foreign-body reaction has been noted [7]. It has been suggested that obstruction of lymphatics by this dense stroma leads to the abnormal lymphatic function found in the affected digits in some [8] but not all [9] cases.

Fig. 62.14 Yellow nail syndrome.

The oedema most frequently affects the legs, and may not be seen for some months after the nail change has been noted. Less often it affects the face or hands and occasionally it is universal. Recurrent pleural effusions have been noted in a few cases [10,11]. Chronic bronchitis and bronchiectasis may also occur [12]. The oedema has been shown to be due to abnormalities of the lymphatics, either atresia or, in some cases, varicosity [11]. As other cases seem to have normal lymphatics, it is possible that a functional rather than an anatomical defect may be present [13], or perhaps only the smallest lymph vessels are defective. Although the nail changes may draw attention to the underlying lymphatic abnormality, they are found only in a minority of patients with congenital abnormality of the lymphatics. The condition may be associated with an increased incidence of malignant neoplasms [11,14,15]. Other associations include D-penicillamine therapy [5] and nephrotic syndrome [16]. In hypothyroidism and AIDS [17] there may be yellow nails, but it is debatable whether these represent yellow nail syndrome or simply the discoloration of nail associated with retarded growth [18].

Although the nail changes, once established, are usually permanent, complete reversion to normal may occur at times. Attempted treatments include oral [19] and topical [20] vitamin E, oral zinc [21] and treatment of chronic infection at other sites [22]. There is debate as to whether itraconazole is of value as treatment. The drug has been demonstrated to increase the rate of longitudinal growth, but an open trial in eight patients demonstrated that half gained no benefit with respect to nail changes [23]. It is reported that results are better when itraconazole or fluconazole are combined with oral vitamin E [24].

Red lunulae

Erythema of all or part of the lunula may affect all digits, but most prominently the thumb. Erythema is less intense in the distal lunula, where it can merge with the nail bed or be demarcated by a pale line, and can be obliterated by pressure on the nail plate. The appearance can fade over a few days. A single report of histological features failed to reveal vascular or epidermal changes [1]. Dotted red lunulae have been reported in psoriasis and alopecia areata, but otherwise the list of associations is so broad that it is unconvincing [2].

The exception to this is a red lunula seen in a single digit. In this setting, it often indicates a local disturbance of vascular flow, which is most likely to be a benign tumour. Glomus tumours and subungual myxoid cysts are the most common [3] and the colour may vary between blue and red.

Longitudinal erythronychia (Fig. 62.15)

A longitudinal red streak in the nail can have several causes. All will have a corresponding band of thinned nail plate as part of the defect. The effect of this is a strip where the nail bed is less compressed by the overlying nail so that blood pools and is more apparent. Equally, the colour is more easily seen because the nail is thinner in this line. Splinter haemorrhages may lie longitudinally within the erythronychia.

(a) (b)

Fig. 62.15 (a) Longitudinal erythronychia. (b) The longitudinal ridge in the nail bed corresponds to the groove on the undersurface of the nail plate.

A strip of thinned nail arises because of focal reduction of matrix function. This can be due to direct matrix disease, such as an epidermal pathology, or as a result of pressure on the matrix with secondary loss of function. This second category contains the full range of dermal tumours as well as tumours of bone and cartilage that arise from the distal phalanx.

Matrix epidermal disease covers a spectrum of pathologies. One group of pathologies has histological features of acantholytic dyskeratosis and/or multinucleate giant cells [1]. The original model for this clinical presentation and histology is Darier's disease, where the thin longitudinal red streak may terminate at the free edge with a split and small subungual keratosis [2]. Acantholytic dyskeratotic naevus and warty subungual dyskeratoma [3] may both represent localized forms of Darier's disease. Acrokeratosis verruciformis of Hopf has a greater focus on nail fold disease, but also demonstrates longitudinal erythronychia and both clinical and pathological overlap with Darier's disease.

Baran has coined the term 'onychopapilloma' to describe the isolated benign warty distal nail bed lesions found in association with longitudinal erythronychia where the diagnosis lies outside those described above [4]. The papilloma is a secondary element, given that it is found distally in the nail bed while the cause lies proximally within the matrix. However, there is a category of this disease where the matrix disease remains unclear and the distal papilloma represents the identifiable entity. At other times, despite a similar clinical presentation with erythronychia and splinter haemorrhages, the matrix pathology may reveal a specific alternative diagnosis such as Bowen's disease [4] or basal cell carcinoma [5]. This means that an isolated longitudinal erythronychia needs careful assessment, and biopsy may be warranted if there is evolution.

Not all causes of longitudinal erythronychia conform to these rules. This is particularly the case where there are multiple red streaks associated with a dermatosis and additional nail changes. It can be a feature of lichenoid diseases of the nail unit, discoid lupus erythematosus, psoriasis, Langerhans' cell histiocytosis and a number of other diseases where there is patchy nail atrophy.

Splinter haemorrhages

Splinter haemorrhages represent longitudinal haemorrhages in the nail bed conforming to the pattern of subungual vessels [1–4]. They are most frequently seen in the distal nail bed and on the fingers of the dominant hand, reflecting trauma as the cause. In dermatological practice, they are often found in association with psoriasis, dermatitis and fungal infection of the nails. As they occur under so many conditions, their importance as a sign of disease is often exaggerated. Focal pathology may also represent a cause, as in longitudinal erythronychia and onychomatricoma (see pp. 62.19 and 62.35).

Large numbers of proximal haemorrhages with no obvious traumatic origin may indicate a systemic cause [5], such as bacterial endocarditis or antiphospholipid syndrome [6]. Unilateral splinter haemorrhages may arise after arterial catheterization on the involved side. Examination under oil with a dermatoscope may reveal greater detail.

Developmental abnormalities of the nails [1,2]

Anonychia

Absence of the nails from birth is a rare congenital anomaly. It may occur as an isolated sign or be accompanied by other defects of the digits and other structures. Littman and Levin [3] described a girl with seven nails missing, and reported that her brother was similarly affected; it was suggested that this was a recessive trait. The mode of inheritance of most of these disorders has not yet been established with certainty. The condition described as anonychia with ectrodactylia [4] has been investigated more fully, however, and has been shown to be inherited as a dominant trait without sex linkage. In this condition, there is usually complete absence of the nails on the index and middle fingers, and when there is any nail on the thumb it is often present on the proximal lateral corners of the nail fold. On the ring fingers, the radial half of the nail is often absent, and the nail bed is also missing. In a minority of affected individuals there are striking and bizarre defects of the digits, sometimes restricted to one hand or foot. The defects usually take the form of absence of one or more digits. Two sisters in a sibship of five, whose parents were first cousins, are recorded as having rudimentary nails associated with congenital deafness. The parents showed neither abnormality [5]. Bart *et al*. [6] described a family with congenital absence of areas of skin, blistering of skin and mucous membranes, and absence or deformity of the nails, inherited as an autosomal dominant trait. It is now classified as a subtype of dominantly inherited dystrophic epidermolysis bullosa, with the responsible gene mapped to chromosome 3p [7]. Verbov [8] described a case with bizarre flexural pigmentation and anonychia, thought to be an autosomal dominant condition.

Nail–patella syndrome

This uncommon condition is of special interest because it involves abnormalities of ectodermal and mesodermal structure. It is inherited as an autosomal dominant trait. The disorder is caused by mutations in the LIM-homeodomain transcription factor β1 protein (LMX1B). This protein plays an important role in dorsoventral limb patterning during embryogenesis [1]. Gradients of expression of the protein determine the dominance of dorsal or ventral axon growth with concomitant trophic effects on mesoderm and ectoderm [2]. The gene maps to chromosome 9q34.1, with affected families showing a wide range of deletions and mutations [3]. In a typical case, the nails are grossly defective, being only one-third or half the normal size and never reaching the free edge of the finger [4]. In other cases, the thumbnails alone may be defective or only the ulnar half of each may be missing [5]. In every case, the thumbnails are most affected [6] and the remaining nails, if involved, are progressively less damaged from index to little finger. The lunulae may be triangular, with a distal peak (Fig. 62.16) in the midline [7]. Even when the

Fig. 62.16 Nail–patella syndrome with triangular lunula.

nail is completely missing, the nail bed is present. In addition to the nail changes, the patellae are smaller than normal and may be rudimentary, so that the knees are unstable. There are also bony spines arising from the posterior aspect of the iliac bones, visible on X-ray examination.

Other recorded features include hyperextension of the joints, skin laxity, hyperhidrosis [8] and renal abnormalities [9,10], and open angle glaucoma. LMX1B is known to influence transcription of genes affecting collagen IV in the glomerular basement membrane [11].

In 1965 there were 255 patients with this syndrome known to be living in the UK, and the prevalence is estimated at 1 per 22 million. The mutation rate is estimated at 1 per 1.9 million alleles per generation [12].

The condition must be distinguished from congenital ectodermal defects and pachyonychia congenita.

Congenital onychodysplasia of the index fingers [1,2]

SYN. ISO KIKUCHI SYNDROME

In this condition, the nail of the index finger is absent, small or represented by two nails of unequal size. There may be a family history suggestive of autosomal dominant inheritance, although there is frequently no clear genetic pattern, and involvement of other digits has been reported [1,3,4]. Underlying changes in the distal phalanx can usually be demonstrated by lateral radiography, where bifurcation of the distal phalanx is the norm [4]. Syndactyly is an associated hand anomaly in some cases [2].

Variants include a similar form of onychodysplasia affecting other digits, including toes [5].

Pachyonychia congenita (Fig. 62.17)

Pachyonychia congenita (PC) is a rare genodermatosis in which hypertrophy of the nails occurs, in some cases associated with nail bed and hyponychial hyperkeratosis [1,2]. Although Feinstein provides an excellent overview of the features, the disease divides best into two variants when the phenotype is interpreted in the light of the genotype. Autosomal dominant inheritance is the rule, although Haber and Rose [3] described cases transmitted in an autosomal recessive form.

The two variants of PC arise through mutations affecting the genes encoding keratins 6a and 16 in PC-1 [4,5] and 6b and 17 in PC-2 [6,7].

PC-1 (Jadassohn–Lewandosky type). The nails are normal at birth but within months they become discoloured and progressively thicken, more so on the hands than feet.

Fig. 62.17 Pachyonychia congenita.

Typical associated findings include palmar and plantar hyperkeratosis and warty skin lesions at various sites: knees, elbows, buttocks, legs, ankles and popliteal region. Acral bullae may be crippling and hyperhidrosis may be severe. Mouth and corneal dyskeratosis are less common findings.

PC-2 (Jackson–Lawler type). In this type, with less severe nail thickening and keratoses than type 1, many associations have been described: teeth may be present at birth; multiple epidermal cysts; sebocystomatosis; dry, lustreless and kinky scalp hair; eyebrows that stand straight out; and hamartomas.

The thickened nails can be treated surgically in some instances [8,9]. This is most likely to be warranted in PC-1. The localization of the four implicated keratins to the nail bed underlines that this is the main site of pathology [10]. Affected nails viewed end-on can appear almost normal, but with a dense wedge of subungual keratin, representing the focus of nail bed disease.

A range of associated features have been reported, including amyloidosis in one pedigree [11] and a case where PC coincided with tuberous sclerosis [12].

Infections of the nail and nail folds

Fungal nail infections

See Chapter 31.

Paronychia

Bacterial paronychia

Acute paronychia is a common complaint and is usually due to staphylococcal infection. It may result from local injuries, splits, splinters or nail biting, or there may be no preceding injury. It also occurs frequently as a complication of chronic paronychia, when other organisms may be involved, including streptococci, *Pseudomonas pyocyanea*, coliform organisms and *Proteus vulgaris*.

The condition presents as a painful swelling of the nail fold. If superficial it may point close to the nail and can easily be drained by incision with a size 11 scalpel, without anaesthesia [1]. Deeper lesions are best treated by antibiotics initially, but if they do not improve within 2 days, incision under local anaesthesia is required, particularly in childhood. A broad-spectrum antibiotic is preferred because it is unlikely that the organisms can be identified in advance. Some authorities recommend removing the proximal one-third of the nail plate without initial incisional drainage. This gives more rapid relief and more sustained drainage. There may be a place for treatment with topical steroid at the same time as antibiotic therapy [2].

Chronic paronychia

This is one of the most common specific nail complaints met within dermatological practice. It ranks in importance

Fig. 62.18 Chronic paronychia with nail plate discoloration due to *Pseudomonas pyocyanea*.

with fungal infection and psoriasis as a cause of nail disease, but presents more commonly and is often misdiagnosed and mistreated. It is an inflammatory dermatosis of the nail folds, with secondary effects on the nail matrix, nail growth and soft-tissue attachments. It may be associated with infection on the background of the dermatosis. The dermatosis may be directly due to an irritant associated with wet work or caustic materials. Alternatively, it may be on the background of atopy or psoriasis, where minor provocation can result in active disease.

Wet cold hands are predisposed to chronic paronychia [1,2]. Wet foods are a combined source of factors, where the food may be an irritant [3]. It is predominantly a disease of domestic workers, bar staff, canteen workers and fishmongers [4]. The majority of cases are in patients between 30 and 60 years of age [1], although chronic paronychia is also seen in children, especially as a result of finger- or thumb-sucking [5].

Any finger may be involved, most often the index and middle fingers of the right hand and the middle finger of the left [4]. These fingers may be more subject to minor trauma than the remainder. The condition begins as a slight swelling at the base of one or more nails (Fig. 62.18), which is tender but much less so than in acute paronychia. The cuticle is soon lost and pus may form below the nail fold. Inflammation adjacent to the matrix disturbs nail growth, resulting in irregular transverse ridges and other surface irregularities, which may be combined with discoloration (Fig. 62.18). There is some evidence that the darkening is due to the pigment from *Pseudomonas* infection of the nail [6]. In long-standing cases, the size of the nail may be reduced, and this reduction is exaggerated by bolstering of the fold all around the nail. Most of the nail deformity is due to the inflammation interfering with the formation of the nail, but a true *Candida* infection of the nail plate is occasionally seen.

There is a complex relationship with *Candida*, usually *Candida albicans* [7], which may be identified by swabs or scraping. Stone and Mullins [8] showed that chronic paronychia can be produced by non-viable *C. albicans* introduced into a relatively sterile nail fold. Much of the chronic inflammation seen in this disorder probably arises from an irritant reaction to material sequestered beneath the proximal nail fold. The loss of the cuticle means that detergent and other solvents may gain access to this tight space and act like a prolonged irritant patch test. This chronic non-infective inflammatory component is why topical steroids are useful in addition to antimicrobials as part of the treatment [9]. Acute exacerbations occur from time to time and are due to secondary bacterial infection. Various organisms may be found, including *Staphylococcus aureus* or *albus*, *Proteus vulgaris*, *Escherichia coli* and *Pseudomonas pyocyanea*. Barlow *et al*. [9] consider that *S. aureus* plays a more active part in initiating the process by penetrating the keratin at the base of the nail and opening up the nail fold. The role of *S. aureus* as a superantigen may also be relevant. Ingested allergens may also play a part [10].

Pemphigus [11] and squamous cell carcinoma [12] can present as chronic paronychia. The latter usually involves a single digit, and underlines the need for biopsy in isolated periungual conditions where the diagnosis is unclear. Cancer chemotherapy, antiretroviral medication and retinoids can provoke acute paronychia with features of pyogenic granuloma which may become chronic.

Treatment. Treatment is a combination of avoidance of precipitants, hand care and medication. Perhaps the most important part of the treatment, but the one most difficult to achieve, is to keep the hands dry. For all wet work the patients should be advised to wear cotton gloves under rubber gloves and avoid manicure of the proximal nail folds. Covering the affected fingers with porous surgical tape may afford some protection, but normal occlusion aggravates the problem. General hand care with emollient and protection during rough work is useful. If this stage of the therapy is not adequately pursued, the condition is likely to fail to settle whatever medical treatment is provided.

Topical therapy requires a combination of steroid [13] and antimicrobial. A potent steroid may be used for short periods when there is adequate antimicrobial cover. Injected triamcinolone (2.5 mg/mL) is useful in some

instances. Topical imidazoles are usually sufficient to treat *Candida* and may provide a modest therapy against some bacteria. More potent topical antibacterials may be needed. Barlow *et al*. [9] suggest using gentamicin ointment during the day and nystatin ointment at night. When features are marked, oral antibiotics appropriate for *S. aureus* should be used. Because of the 'mixed' aetiology of the inflammation, many clinicians use antiseptic or antibiotic/anticandida/steroid creams in the chronic phase.

Incision is not indicated unless the condition enters an acute tender purulent phase, where removal of the proximal third of the nail may help. Attempting to clean out the nail fold with a sharpened orange stick is not recommended. If there is obvious candidal infection elsewhere, or *Candida* onychomycosis, this must also be treated. Surgical removal of the proximal nail fold and adjacent part of the lateral nail folds may cure recalcitrant cases [14].

Pseudomonas infection

This is almost always a complication of onycholysis or chronic paronychia and is usually restricted to one or two nails (see Fig. 62.18). The nail plate has a characteristic bluish-black or green colour [1–3] and smells infected. This colour is due to accumulation of debris beneath the nail and the pigment pyocyanin adhering to the undersurface of the nail plate. Pigment may remain after the organism has been removed. In some cases, the nail plate appears to be invaded by the bacillus [2]. Subjects with nail extensions and nail wraps are susceptible to *Pseudomonas* colonization beneath the extensions. This has been documented as a risk factor for passing infection to patients in the medical setting [4]. Treatment [5] is as described for onycholysis or paronychia, whichever appears to be the prominent predisposing state. In addition, it is possible to treat with gentamicin or sulfacetamide (sulphacetamide) eye drops to eradicate the colonization where onycholysis is resistant to therapy.

Herpetic paronychia [1,2]

SYN. HERPETIC WHITLOW

This uncommon condition is due to primary inoculation of the herpes simplex virus and presents as single or grouped blisters close to the nail; it may give a honeycomb appearance. Clear at first, the blisters soon become purulent and may break and be replaced by crusts. It is usually very painful and takes about 3 weeks to resolve, with pain settling in half that time. Lymphangitis sometimes occurs and may precede vesiculation. Diagnosis may be established by recovering the virus from a recent blister and by cytological examination of the blister floor. Contact cases may occur.

Treatment probably does little to shorten the course of the disorder, but cleaning with 1/6000 potassium permanganate followed by application of a bland cream is recommended. Relapse may occur as with other primary herpetic infections. The value of thymidine analogues, such as 5% topical idoxuridine and oral or topical aciclovir, remains unproven at this site; if the lesion is seen within 2 days of onset, topical aciclovir may inhibit progression.

Numbness of the finger has been reported following infection [1] and persistent lymphoedema may occur. Persistent cases may have an atypical presentation in patients with HIV infection [3].

HIV infection

The most common nail changes in individuals with HIV infection are clubbing, transverse lines, onychoschizia, leukonychia and longitudinal melanonychia [1]. In addition, there is a lower threshold for infection with dermatophytes, yeasts and herpesvirus [1]. The patterns of infection may alter, such that proximal subungual white fungal infection is said to be a pointer to immunodeficiency and particularly HIV [2]. The nail folds may be red in the absence of infection [3] or be provoked into an appearance of pyogenic granuloma by retroviral therapy [4]. The nail can also manifest various patterns of melanonychia, which is usually ascribed to zidovudine therapy [5] but has also been attributed to hydroxycarbamide (hydroxyurea) [6].

Dermatoses affecting the nails

Psoriasis

Psoriasis is probably the most common disorder affecting fingernails, with consequent dystrophy. Between 1.5 and 3% of the population have psoriasis, and up to 50% of psoriatics have nail involvement [1]. Over a lifetime, this may cumulatively increase to 80–90% [2]. In children, nail involvement ranges from 7% [3] to 39% [4], and pitting has been observed in the first week of life in the offspring of a mother severely affected with psoriasis [5]. Psoriatic nail changes are prominent in the childhood nail disease of parakeratosis pustulosa. Approximately one-third of these children will develop the manifest diagnosis of psoriasis in time, a smaller fraction will have variants of eczema and half of the total will get better [6]. De Jong *et al*. [7] reported that 93% of those with nail psoriasis considered it a significant cosmetic handicap, 58% found that it interfered with their job and 52% described pain as a symptom.

Clinical features. In order of reducing frequency, nail signs of psoriasis include pits, onycholysis, subungual hyperkeratosis, nail plate discoloration, uneven nail surface, splinter haemorrhages, acute and chronic paronychia, and transverse midline depressions in the thumbnails.

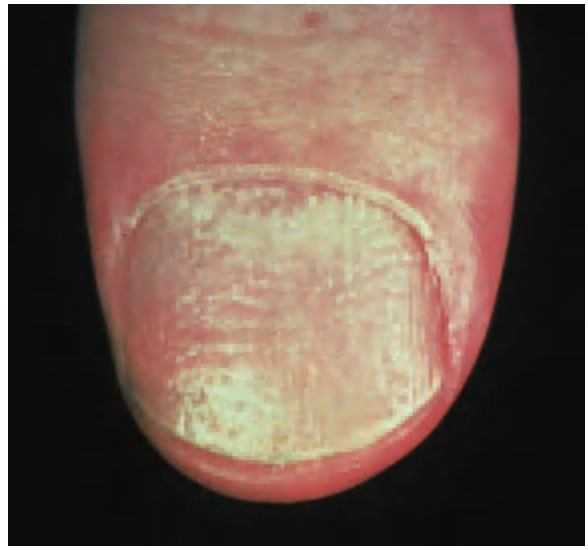

Fig. 62.19 Psoriasis: diffuse pitting.

Pits. Pits more commonly affect fingers than toes (Fig. 62.19). They represent punctate surface depressions arising from proximal matrix disease (Table 62.3). Zaias [1,8] has demonstrated small columns of pathological parakeratotic nail falling off the upper surface of the nail plate to produce a pit. Some authorities advocate nail plate histology as a means of diagnosing nail psoriasis [9]. This can be useful for exclusion of fungal infection, although the specificity of nail plate changes in psoriasis is yet to be established. The origin of pits means that they can be influenced by disease in the proximal nail fold and it is thought that injection of triamcinolone into the nail fold alone can suppress this clinical feature. The pattern of pitting may be disorganized or occur in transverse/longitudinal rows as seen in alopecia areata [2]. Pits may be shallow or large [8], to the point of leaving a punched-out hole in the nail plate (elkonyxis).

Onycholysis. Focal nail bed parakeratosis produces an 'oily spot' or 'salmon patch'. Extension of this area to the free edge gives onycholysis, which typically has a reddish-brown margin. Alternatively, onycholysis may commence at the distal edge (Fig. 62.20), representing disruption of the onychocorneal band [10]. Once this band of firm attachment has been breached, the condition is often progressive. Minor manicure, wet work and leverage from long nails exacerbates the condition.

Discoloration. Discoloration in psoriasis is multifactorial. The major factors are nail thickening and subungual hyperkeratosis. Both of these contribute to a yellow

Table 62.3 Relationship between clinical features and site of disease activity in psoriasis of the nail. (From Zaias [1].)

Clinical feature	Area of disease	Duration of disease
Changes in nail plate	*Matrix*	
Pits	Proximal matrix	Episodic: short
Transverse furrows	Proximal matrix; distal extension depends on depth of furrow	1–2 weeks
Crumbling nail plate	Entire matrix	Prolonged
Leukonychia with rough surface	Proximal matrix; leukonychia may involve distal matrix	Variable
Changes in nail bed and hyponychium	*Nail bed*	
Splinter haemorrhages	Nail bed dermal ridge haemorrhage	Short
Oily spot/onycholysis	Nail bed psoriasis	Prolonged
False nail following onychomadesis	Nail bed psoriasis	Prolonged
Subungual hyperkeratosis	Nail bed psoriasis	Prolonged
Yellow/green discoloration of nail bed	Secondary infection by yeasts or *Pseudomonas*	Prolonged

Fig. 62.20 Psoriasis: onycholysis.

appearance particularly common in the toes. It is possible that at this site repeated trauma elicits the isomorphic reaction, with local exacerbation of psoriasis. The coincidence of onychomycosis and psoriasis is also seen in the toenails [11] and can add to the pathological appearance. *Candida* spp. and *Pseudomonas* infection can result in green discoloration. While non-dermatophytes and bacteria are common, dermatophytes are rare [1].

Subungual hyperkeratosis. Subungual hyperkeratosis represents nail bed disease (Fig. 62.21). Substantial nail plate thickening may result from subungual hyperkeratosis, which is most marked distally and extends proximally. The fingertip may become very tender where there is gross subungual hyperkeratosis, as the nail plate attachment is greatly reduced and the nail can easily be caught and tug on the matrix attachment. Subungual hyperkeratosis is a prominent feature when pityriasis rubra pilaris affects the nail and is often seen with splinter haemorrhages [12,13].

Fig. 62.21 Psoriasis: subungual hyperkeratosis.

Nail plate abnormalities. Splits, atrophy and fragility may be seen. The nail may also thicken, independent of subungual hyperkeratosis. Transverse midline depressions resembling the nail changes seen in 'washboard nails' [14] are also seen. Normally, they are attributed to the habit tic of disrupting the cuticle (Fig. 62.22) and although this may play a part in psoriasis, it appears that there is a lower threshold for the development of this midline feature in the presence of psoriasis.

Splinter haemorrhages. Splinter haemorrhages are seen in the nail bed of 42% of fingernails and 6% of toenails [15]. This may be due to the increased capillary prominence and fragility in nail bed dermis in psoriasis and the

Fig. 62.22 Multiple transverse grooves of the thumbnails.

presence of dystrophy. Where transverse overcurvature occurs for reasons other than psoriasis, splinter haemorrhages are also common, suggesting that mechanical factors may contribute to splinter haemorrhage formation.

Subacute and chronic paronychia. Periungual involvement may be dramatic and inflammatory, giving rise to gross disruption of nail matrix. Loss of the nail may follow, with scaling of the nail bed or a deep transverse furrow.

Chronic psoriatic paronychia causes loss of the cuticle. The nail plate can become thin [16], although this may be offset by matrix disease, which can result in thickened nail. The nail fold may be scaly, in the form of psoriasis seen elsewhere.

Acropustulosis. This form of psoriasis involves destructive pustulation of the nail unit. It may present as part of pustular psoriasis, palmoplantar pustulosis [17], acrodermatitis continua of Hallopeau [18] or parakeratosis pustulosa (typically in young girls) on isolated digits. The nail plate may be lifted off by sterile pustules in the nail bed and matrix. There is associated erythema and discomfort of the end of the digit. There may be long-term nail loss, except in parakeratosis pustulosa, which usually resolves spontaneously. Parakeratosis pustulosa may affect only part of one digit. There is pitting and ridging combined with fine scaling erythema of the periunguium and only very rarely pustules. It is usually interpreted as a form of psoriasis [6], although it shares histological features with eczema [19], and some consider it a variant of eczema [20].

Acrodermatitis continua of Hallopeau can be very aggressive and result in resorptive osteolysis [21] or loss of toes and distal parts of fingers [22]. In a study of 20 patients with the condition, seven were male and 13 female, with a mean age of 46 years, and all had involvement of only one digit, with no features of psoriasis elsewhere [23].

Differential diagnosis. When the diagnosis of psoriatic nail dystrophy is in doubt, the main differential diagnoses are onychomycosis and lichen planus. In onychomycosis, the features usually present in the toes, whereas the fingernails are more commonly affected in psoriasis. Equally, there are often changes on the nail surface alone in psoriasis, whereas in onychomycosis features are usually within or beneath the nail plate. If there is fingernail involvement in onychomycosis, it is usually of only one or a minority of digits, in contrast with psoriasis where there are usually several digits affected.

Some forms of fingernail lichen planus and psoriasis are very difficult to distinguish. Both may result in roughened nails (trachyonychia) with subungual hyperkeratosis. If pits are prominent the diagnosis of psoriasis can be made, but if they are subtle and difficult to distinguish from other surface changes, they may be part of lichen planus. The nails in Reiter's disease and pityriasis rubra pilaris can also be difficult to distinguish from psoriasis [24,25], where distal subungual hyperkeratosis and splinter haemorrhages are common [8]. Aggressive forms of atypical nail psoriasis presenting in later life may represent acrokeratosis paraneoplastica. The patient is usually male, with subungual hyperkeratosis and scaling of the periunguium, ears and nose associated with malignancies of the upper gastrointestinal or respiratory tract [26–28].

Arthritis of the distal interphalangeal joint suggests a psoriatic cause of any associated dystrophy [29], with the exception of changes due to a myxoid pseudocyst associated with adjacent osteoarthritis. Baker *et al*. [30] found that there was no strict relationship between which joints are arthritic and which nails are dystrophic, although Jones *et al*. [31] noted that in a group of 100 psoriatics with arthritis, where there was nail involvement there was a significantly greater chance of joint disease in the adjacent distal interphalangeal joint. There was also a significant correlation between PASI (Psoriasis Area and Severity Index) score and scoring of nail disease, and nail disease increased with the duration of psoriasis. A variant of nail psoriasis presents with pain and soft-tissue swelling of the distal digit associated with psoriatic nail changes, and underlying bone erosion and periosteal reaction. This can be in the absence of joint involvement and has been termed 'psoriatic onycho-pachydermo-periostitis' [32].

Histopathology. Histopathology varies according to the clinical focus of the disease [1,33]. The matrix and nail bed develop a granular layer. Conversely, the hyponychium, where a granular layer is normally present, no longer has one [1]. Where there is subungual hyperkeratosis, there are mounds of parakeratotic keratinocytes beneath the nail plate. Neutrophils may be found throughout these mounds and Munro microabscesses may form. Similar features are seen in acrodermatitis continua of Hallopeau [23]. Amorphous material interpreted as glycoprotein

may accumulate within the keratotic mass [1]. Acanthosis and elongation of the rete ridges is present, with increased dilatation and tortuosity of the capillaries of the dermal papillae. Where the nail is lost, the nail bed may form a false nail of compacted hyperkeratosis [34]. The matrix can become quiescent, which can be demonstrated immunohistochemically by the absence of synthesis of the hard keratin Ha-1, which is normally a major constituent of nail [35].

The nail plate may show faults, clinically manifest as transverse splits and pits, which are lined with parakeratotic cells. These probably originate from the most proximal part of the matrix, or the ventral aspect of the proximal nail fold [1].

Treatment [36]. General hand care is important to avoid provocation of the isomorphic (Koebner) response, whereby minor trauma may elicit psoriasis. These measures include avoiding manicure, keeping the nails short, wearing gloves for wet work and heavy or greasy manual work, avoiding direct exposure to solvents and encouraging emollient usage. Concealment with nail lacquer is a reasonable approach to milder forms of psoriasis, and surface irregularities can be smoothed by the use of nail gel. This is a polymer, applied by a beautician and hardened by exposure to a table-top UVA source. The gel can then be shaped and buffed. Gel or other forms of sculptured or adherent artificial nails have the potential for aggravating onycholysis and are not usually recommended if this is a prominent feature.

Active treatments are mainly directed at the more dystrophic forms of nail involvement and may sometimes help with onycholysis. Often the focus of therapy is the proximal nail fold, where active psoriasis is disturbing the underlying matrix and lack of cuticle is promoting chronic paronychia. Medical treatments include the following.

Local steroids. Clobetasol propionate ointment may be used without occlusion, rubbed into the nail fold. Duration of treatment is limited by local atrophy. It is useful for psoriatic paronychia where there are secondary nail plate changes. Onycholysis may benefit if the nail is clipped back to the point of nail plate attachment and the nail bed treated topically. *Candida* is a frequent colonizer of this space and warrants treatment at the same time. Triamcinolone acetonide may be used by injection into the nail fold or nail bed with regional or digital ring block. Using 0.1-mL injections of 10 mg/mL triamcinolone acetonide at matrix and nail bed sites, on no more than two or three occasions, de Berker and Lawrence [37] report a good response in subungual hyperkeratosis, nail plate thickening and ridging. However, onycholysis and pitting improved in only 50% of nails. Alternative regimens employ more dilute triamcinolone (2.5–5 mg/mL) and are routinely used more than two or three times per digit, infiltrating the proximal nail fold alone and making a ring block optional. Triamcinolone has also been used with the Port-O-Jet or Dermojet, with improvement of pitting as well as other features [38]. There is a single anecdotal report that use of these devices has been associated with implantation epidermoid cysts, and many reports that local infection is more likely with this form of steroid delivery than with injection [39].

Topical vitamin D analogues. Calcipotriol can be useful where there is subungual hyperkeratosis and nail thickening [40]. It has also been used in combination with topical steroid on an alternating basis (a.m./p.m.) [41] and it is now possible to use it as a combined steroid and calcipotriol ointment. Calcipotriol has the advantage of avoiding the risk of atrophy with long-term use, but it is not as beneficial in treating the nail fold inflammation and consequent changes in proximal matrix function, which manifest as ridging and pitting.

Maintenance treatment with calcipotriol may also be one of the most effective topical therapies for pustular nail psoriasis [42].

Photochemotherapy. Subjects may improve as part of their general psoralen and UVA (PUVA) therapy or may have local PUVA to the nail unit. This can be done with topical or systemic psoralen. Specific high-dose handsets of UVA lamps have been advocated. As part of whole-body PUVA, 18 of 26 patients showed a greater than 50% improvement in nail changes, although pitting was unresponsive [43]. With local therapy, four of five patients improved: onycholysis was more responsive than pitting, but one patient with severe pitting showed improvement [44].

Retinoids. The nail plate is made thin by acitretin and etretinate. This reduces subungual hyperkeratosis. Pitting or onycholysis may be exacerbated [45,46]. Pustulation may be improved. Topical tazarotene 0.1% can be helpful for the treatment of onycholysis and pitting when applied under occlusion [47].

Others. Systemic methotrexate and ciclosporin (cyclosporin) may both help the nail unit but would not usually be advocated as therapy for this area of disease alone. Acrodermatitis continua of Hallopeau and psoriatic onychopachydermo-periostitis [48] are exceptions, and may respond to methotrexate.

Topical ciclosporin has been reported as useful in a single case report [49]. 5-Fluorouracil 1% has been used topically in 20% urea [50] and also in propylene glycol [51]. Pitting and subungual hyperkeratosis were thought to respond well to the former. Both are contraindicated in onycholysis.

Superficial radiotherapy [52] and electron-beam therapy [53] have been shown to be only of temporary benefit and are not usually recommended.

Treatment of coincident fungal infection may provide clinical benefit, although it is seldom a dermatophyte and positive cultures may only represent colonization.

Darier's disease [1–5]

Nail involvement is common in Darier's disease; 96% of patients are reported to have acral changes, of which nail changes are the most common [2]. These include red and/or white longitudinal streaks in the nail, often terminating in a V-shaped nick (Fig. 62.23). The streak may represent a zone of fragile or thinned nail, which makes it prone to fragmentation at the tip with the consequent nick. In severe cases, the nails are almost lost by extension of the fragmentation process to involve the entire matrix. Subungual hyperkeratotic papules can be found in the hyponychium. Histologically, matrix and nail bed changes resemble the acantholysis seen in involved skin, with the addition of multinucleate giant cells and epithelial hyperplasia in the nail bed [5]. These histological features make it possible to diagnose Darier's disease when it is confined to the nail [1]. Excess ridging and a rough nail surface may also be found, as may total leukonychia. Occasionally, marked thickening of the nail plate occurs. It is probable

Fig. 62.23 Darier's disease: white and red longitudinal lines and distal notching.

that the nail is sometimes affected in the absence of disease elsewhere [1].

Hailey–Hailey disease has some histological similarities and may also present with longitudinal white streaks [2]. However, the disease does not have the same destructive effect and is not associated with hyperkeratoses or symptoms of the nail apparatus.

A case of squamous cell carcinoma developing in a nail bed with chronic changes of Darier's disease has been reported [6]. Pain or conspicuous uncharacteristic features in a nail apparatus affected by Darier's disease may therefore be indications for biopsy.

Eczema

Nail changes in eczema may be seen in the context of eczema elsewhere or as an isolated finding. Endogenous and exogenous factors may contribute. The nail changes may reflect this division, in that they may be in response to a systemic atopic disposition, with pitting in the absence of inflammation, or may demonstrate the effects of local eczema in the nail unit influencing nail formation.

The common allergens such as nickel, fragrance and medicaments rarely have particular bearing on nail abnormalities. However, rubber, chrome and irritant dermatitis are significant factors in hand dermatitis. These materials, and hand dermatitis in general, are associated with particular occupations. Selective exposure to such allergens or strong irritants is as important as chronic low-grade irritation from milder agents, such as water, seen in catering workers.

Cyanoacrylates used in prosthetic nails can provoke local and distant allergic reactions. Formaldehyde, occasionally used as a nail hardener, can provoke painful onycholysis if the patient becomes sensitized, or sometimes when acting solely as an irritant. Some allergens may cause nail dystrophy without associated inflammation.

A combination of atopy and an exogenous irritant or allergic contact reaction is common.

Clinical features. Nail matrix disturbance is reflected in thickening, pits, nail loss, transverse ridges and furrows in a pattern similar to psoriatic nail disease (Table 62.4).

Nail bed disease can produce subungual hyperkeratosis, splinter haemorrhages, onycholysis and pain. Allergens and irritants can be sequestered beneath the free edge of the nail to achieve high concentrations and prolonged exposure.

Nail changes may betray eczema elsewhere and the nails may be buffed smooth and shiny, indicating their use as a tool for rubbing.

Associated hand dermatitis may show vesicles, scaling, erythema, cracks and swollen fingers, although the

Table 62.4 Differential diagnosis between four common nail disorders: fungal infections, psoriasis, chronic paronychia and dermatitis.

	Fungal infections	Psoriasis	Chronic paronychia	Dermatitis
Colour	Often yellow or brown; part or whole of nail	May be normal or yellow or brown	Edge of nail often discoloured brown or black	May be normal
Onycholysis	Frequent	Frequent	Usually absent	Confined to tip or absent
Pitting	Infrequent	Often present and fine	Uncommon	Coarse pits frequent
Filaments or spores in potash preparations	Filaments, usually abundant	Absent	May be spores in edge of nail; filaments and spores in scrapings from nail fold	Absent
Cross-ridging	Absent	Uncommon	Frequent	Frequent
Other	Associated fungal infections elsewhere	Associated psoriasis elsewhere or family history of psoriasis	Predominantly women; wet work and cold hands cause predisposition	Recent history of dermatitis on hands

presence of vesicles will not always distinguish the condition from psoriasis, which should be sought at other sites. The distribution on the hand or foot may give some clues as to possible local causes, such as gloves, shoes, prosthetic nails or nail varnish. Hands and feet should always be examined together, as the presence of disease in both diminishes the likelihood of a contact dermatitis.

Defining the presence of atopy or patch testing can be useful even in the absence of active eczema as subungual hyperkeratosis and discomfort may be disproportionate to the cutaneous features [1].

Treatment. General hand care is important, with the avoidance of soap, irritants, wet work and any identified cause. Protective gloves should be used, with copious emollient application. Barrier creams are not usually adequate protection once features have developed. Potent topical steroids may be needed, sometimes with additional topical or systemic antimicrobial therapy. These should be rubbed in around the nail folds. In the young, steroids may precipitate premature closure of the phalangeal epiphyses if too potent or used for too long [2]. Osteomyelitis has also been reported in children using potent topical steroids in this area.

Hand or foot PUVA can help.

Lichen planus

Nails are involved in about 10% of cases of disseminated lichen planus [1]. In a study of 24 adults with nail lichen planus, nail changes were the sole manifestation of the disease in 75% [2,3], and the figure may be higher in children [4,5], in whom lichen planus of all types is rare. This suggests only a modest degree of overlap between the disease process in the nail unit and at other sites. Although the skin lesions may itch intensely, nail disease may be relatively asymptomatic except when nails are shed.

Clinical features. The disease can involve the proximal nail folds with bluish-red discoloration. Nail plate changes include thinning, onychorrhexis, brittleness, crumbling or fragmentation, and accentuation of surface longitudinal ridging. All these features are secondary to disease affecting the matrix, which can also produce transient or permanent longitudinal melanonychia [6] or leukonychia as a post-inflammatory phenomenon (Fig. 62.24). When inflammation is intense and widespread within the nail apparatus, nails may be shed. Single longitudinal depressions in the nail, with a distal notch or entire split, may arise from a pterygium. This is a fibrotic band of tissue fusing the proximal nail fold with the nail bed and matrix, following destructive local inflammation. Surviving proximal matrix is unable to push growing nail through the scar tissue, with a consequent split. Thickening, with features resembling yellow nail syndrome, is a less common pattern of presentation [7]. Where this occurs there is usually little difficulty in making the distinction in the fingernails as the prominent surface changes and/or atrophy of lichen planus are seen. However, these changes are less obvious in the toes, where yellow discoloration due to thickening can be marked [8].

Fig. 62.24 Lichen planus with longitudinal melanonychia.

Fig. 62.25 Anonychia following lichen planus.

Nail bed disease can produce subungual hyperkeratosis and onycholysis. Bullous lichen planus may affect the soles of the feet and in particular the toenails. Permanent anonychia may follow [9] (Fig. 62.25).

Twenty-nail dystrophy, with stippling of the nail plate (see Fig. 62.11) in up to 20 nails, is seen in a range of autoimmune diseases [10], alopecia areata [3], primary biliary cirrhosis and possibly in pemphigus [11]. In itself, it does not indicate the diagnosis of lichen planus, but is one of the recognized forms of the disease. It is one of the more common childhood patterns of presentation in which the nails feel rough and lose their lustre [12]. It has a reasonably good prognosis, in contrast with idiopathic atrophy of the nails, which may also occur in children. In this form, the surface change is less marked and the change in overall nail morphology greater, with thinning and shrivelling of the nail plate. Although nail biopsy is seldom undertaken in children, it may be warranted where the diagnosis of lichen planus needs to be explored. If destructive lichen planus is not treated in childhood, there will be lifelong loss of nails.

In the related disorder, lichen nitidus, numerous pits giving a fine rippling effect have been reported [13]. Longitudinal ridging, beads and thickening may occur and nails become brittle.

In keratosis lichenoides chronica, although the skin condition may resemble hyperkeratotic lichen planus, the nail changes may mimic psoriasis; 30% have nail involvement, with hyperkeratotic hypertrophy of periungual tissues.

Lichen planus nail changes are seen in graft-versus-host disease [14] and in the disseminated lichenoid papular dermatosis of AIDS. There can be an overlap between lichen planus and discoid lupus erythematosus, both in the skin and nails. Coexistence of skin and nail lichen sclerosus has been reported [15]. Lichen striatus may extend down a limb to the nails [16].

The differential diagnosis for the range of appearances of lichen planus in the nail unit includes Stevens–Johnson syndrome, infection, peripheral vascular disease, trauma and radiodermatitis.

Histology. In 20-nail dystrophy, there is a granular layer in the nail bed and matrix, with marked spongiosis [3]. The hypergranulosis is believed to reflect the disordered keratinization that causes both subungual hyperkeratosis and the poor nail plate formation. In other forms of nail lichen planus, in addition to hypergranulosis, there is occasionally saw-toothing of the rete pattern, and colloid bodies are rarely seen [2,17,18].

In 20-nail dystrophy it may be useful to perform a screen for organ-specific antibodies because of the association with alopecia areata and the related autoimmune diathesis [3].

Treatment. Potent topical steroids may help when rubbed into the nail folds in the active stage. Triamcinolone acetonide may be instilled into the proximal nail fold under local anaesthetic. In children, potent steroid therapy puts them at risk of premature closure of the phalangeal epiphyses. Oral steroids at up to 60 mg/day have been used to arrest severe scarring nail lichen planus [2]. Triamcinolone acetonide can be given intramuscularly at a dose of 0.5–1 mg/kg per month for 3–6 months [12]. Failure to deliver effective treatment in progressive disease may result in permanent nail loss or dystrophy. Ciclosporin can also be of benefit and azathioprine has been used to good effect in erosive disease [19]. Ulcerative lichen planus of the nail unit may benefit from grafting the nail bed.

Tumours under or adjacent to the nail

Tumours of the nail apparatus and adjacent structures are relatively common. Neoplasms of the nail area can be divided into benign, benign but aggressive lesions (e.g. keratoacanthoma, recurring digital fibrous tumours of childhood and some warts) and malignant tumours.

Clinical diagnosis is often difficult because of traumatic factors, infection, pigmentation, and because the translucent nail plate masks physical signs in the nail bed. Also, common tumours, easily recognized at other sites, may behave differently in the nail apparatus. An X-ray

Fig. 62.26 The entire periunguium is affected by wart, with secondary nail changes.

investigation should be carried out on all swellings in or around the nail apparatus, particularly those affecting a single digit, to exclude osteoma. Where changes are primarily in soft tissues, magnetic resonance imaging (MRI) may be preferable [1].

Benign tumours

Viral warts

This is the most common tumour involving the nail, usually found in one of the nail folds but also seen in the digit pulp and less commonly on the nail bed. In the lateral nail folds, there may be no nail plate changes, although proximal nail fold warts can result in longitudinal ridging and nail plate distortion (Fig. 62.26) and nail bed warts may cause onycholysis (Fig. 62.27). Erosion of underlying bone has also been reported.

The causal human papillomavirus is usually type 1, 2 or 4. Nail biting and certain occupations, such as butcher, may predispose to warts and complicate therapy. Warts are more common and difficult to eradicate in the immunosuppressed, particularly in organ-transplant recipients.

The most significant lesion from which warts need to be distinguished is squamous cell (epidermoid) carcinoma. However, this malignancy often destroys part of the matrix and nail bed and is usually painful; both features are uncommon in benign viral warts, unless aggressive cryosurgery has been used or there has been bacterial infection. Other disorders, such as syringometaplasia,

Fig. 62.27 Nail bed warts can cause onycholysis and nail plate disruption.

amyloid, subungual corn and verrucous epidermal naevus [2], may mimic viral warts.

Although most warts remit spontaneously, a wide range of therapies are available [3], including topical salicylic acid (paste, on plaster or in collodion), salicylic acid combined with abrasion [4], cryosurgery [4–7], bleomycin [8,9], cantharidin [10], imiquimod [11], curettage and carbon dioxide laser therapy [12,13], pulsed dye laser [14] and interferon [15]. Immunotherapy can be successful using sensitization to diphencyprone [16], or relying on naturally acquired immune sensitivity to pathogens such as mumps or *Candida* [17].

Fibrous tumours

There are several types of fibrous tumours of the nail apparatus, which can be differentiated on clinical and histological grounds [1,2]. Koenen tumours are associated with tuberous sclerosis and present at puberty as periungual fibromas. They are often multiple, large or small, elongated or nodular, and may produce a longitudinal groove in the nail plate due to matrix compression. Histologically, they show loose collagen with numerous small vessels distally, but with dense collagen and few vessels proximally.

Acquired periungual fibrokeratoma [3] is probably the same as acquired digital fibrokeratoma and garlic clove fibroma (Fig. 62.28). They are all benign asymptomatic fibromas with a hyperkeratotic tip and narrow base arising in the periunguium, especially at the proximal aspect of the matrix. They grow out along the nail resulting in a longitudinal groove. There are three histological variants:
1 thick, dense, closely packed collagen bundles;
2 similar to type 1, but with increased fibroblasts in the cutis;
3 oedematous and loose dermis.

Fibrous dermatofibroma is a true fibroma presenting as a smooth-edged tumour, commonly in the periungual tissues rather than within the nail unit. There is no collar of elevated skin as is often seen in acquired fibrokeratomas and it lacks the hyperkeratotic tip. It is hypocellular but with prominent collagen bundles, and rarely has a histiocytic dermal component. Occasionally, fibromas can be confused with other lesions, such as Bowen's disease, exostosis, keloid, dermatofibrosarcoma, eccrine poroma, neurofibroma and verruca. Multiple soft fibromas presenting on the dorsal aspect of digits in childhood may be infantile digital fibromatosis. These are benign and resolve with age [4,5]. Periungual fibromas may act as a diagnostic clue for tuberous sclerosis, although they normally occur in association with at least one other feature such as hypomelanotic macules that allows corroboration [6]. They are rarely seen before the age of 5 years, but are present in 23% of subjects with tuberous sclerosis at 14 years, rising to 88% over 30 [6]. Presentation with a single periungual fibroma should lead to a full history and examination to establish whether it is a feature of undiagnosed tuberous sclerosis. However, if nothing else is found, it is unlikely that the tumour has broader significance [7].

Treatment is by excision. In acquired periungual fibrokeratoma arising in the proximal matrix, great care is needed to remove the origin of the tumour without damaging the matrix: there is a fine balance between allowing recurrence and producing long-term nail dystrophy. Koenen tumours are particularly prone to relapse, probably because of their dermal origin.

Onychomatricoma

Onychomatricoma may be considered a form of fibroma of the proximal nail fold [1,2], closely associated with the matrix. Its location means that the main features are those of altered nail, which becomes thickened with increased longitudinal ridging (Fig. 62.29). There may be increased transverse and longitudinal curvature in larger tumours. Splinter haemorrhages within the zone of altered nail are common. When the onychomatricoma is small it may occupy only a narrow band of altered nail which is thickened and grey or yellow. As it enlarges, the band broadens

(a)

(b)

Fig. 62.29 (a) Subtle longitudinal thickening and opacity of the nail plate due to an onychomatricoma. (b) Onychomatricoma on MRI.

and thickens. When avulsed, the proximal aspect of the nail reveals multiple honeycomb channels corresponding to the digitations of the matrix, which has changed shape in response to the dermal matrix tumour. The tumour has normal immunohistochemical markers for a benign fibroma [2,3]. The matrix epithelium is normal in cytology and differentiation with respect to keratins [3]. Electron microscopy demonstrates decreased amounts of tonofilaments and desmosomes in basal epithelial cells [4]. It is the

Fig. 62.30 Subungual exostosis.

marked change in shape that leads to the altered nail and characteristic clinical presentation.

Less classic presentations of the tumour may have nail features of melanonychia and onychomycosis [5].

Treatment is by excision. The margins need to include a proximal element of the proximal nail fold and extend down to bone and into proximal nail bed to obtain the whole tumour. This typically sacrifices a significant fraction of the matrix and may mean that total matrix excision is the best option.

Subungual exostosis

A subungual exostosis is a benign bony outgrowth of the terminal phalanx. It is usually found on the great toe [1] or rarely a finger [2] in subjects between the ages of 10 and 35 years (Fig. 62.30). It is not clear whether trauma is causal or contributory. Where there are hereditary multiple exostoses, the problem is inherited in a dominant pattern and

attributable to mutations of the *EXT1* and *EXT2* genes on chromosomes 8q and 11p, respectively. These genes encode the proteins exostosin 1 and 2, which are part of a family of glycosyltransferases required for the synthesis of heparan sulphate chains. Heparan sulphate is integral to the expression of proteoglycans on the cell surface and in the extracellular matrix [3]. Mutations of *EXT1* and *EXT2* are also found in specimens of solitary exostoses [3]. This corresponds to the absence of heparan sulphate in the chondrocyte zones of exostosis growth plates [4], consistent with the proposal that such changes in chondrocyte biology are associated with abnormal cell signalling.

Pain as a presenting feature is common. It is usually associated with trauma, but is also caused by ingrowing of the nail plate as it is displaced by the tumour [5]. The nail plate is elevated laterally but rarely damaged by the tumour. Radiography reveals an outgrowth of trabeculated bone [6], which may seem modest in comparison with the clinical complaint because of the large radiolucent cartilaginous cap. The X-ray examination should include a lateral view, as typically a view from above will miss the pathology.

Distinction from a subungual osteochondroma may be possible histologically because fibrous cartilage caps the bony outgrowth in exostosis and hyaline cartilage in osteochondroma [7]. Whereas this rule is often stated, it is not clear whether an absolute distinction can be made between the two lesions.

Where multiple exostoses exist, autosomal dominant multiple exostosis syndrome must be considered. The tumours in this condition are 'near the knee and far from the elbow' and can be destructive to nail [8]. The importance of making the diagnosis lies in the remote possibility of transformation of individual tumours to chondrosarcoma —an estimated figure for malignant change is 0.5% [9]. Older patients may have a different variety of exostosis, which represents hyperostosis of the distal tuft. This can cause elevation of the nail and pincer deformity, whereby the distal and lateral borders of the nail curve downward and inward to act as a pincer upon the nail bed.

Treatment. Treatment of subungual exostosis is by partial nail avulsion or fish-mouth elevation of nail bed and plate and removal of the tumour using bone nibblers or a chisel [7]. A margin of normal bone should be removed at the base to prevent recurrence. There is a 10% relapse rate following surgery, and children are more prone to relapse than adults [5]. Permanent matrix damage may follow surgery if tumours undermine the matrix.

Other bone tumours

Enchondroma

An enchondroma is a cartilage tumour, which may present as a painful solitary tumour of the distal phalanx with clubbing, paronychia, nail thickening, discoloration, ridging and elevation of the nail, and pathological fractures [1]. In Ollier's disease, multiple digits are usually affected. In Maffuci's syndrome there are multiple subcutaneous angiomas and hard cartilaginous nodules of the epiphyseal line, which may distort the entire hand or foot [2].

X-ray shows lucent expansion of distal phalanges alone, with spotty calcification in simple enchondromas. In Maffuci's syndrome there is widespread lucency in many phalanges of all the digits. Treatment is by enucleation of the tumour and autologous cancellous bone grafting. All these tumours can be associated with chondrosarcoma, angiosarcoma being an additional risk in Maffuci's syndrome [3].

Osteoid osteoma [4–6]

Osteoid osteomas of the distal phalanx present with enlargement of the entire digit tip in a young adult, with thickening of nail, clubbing, increased local sweating and violaceous skin changes. A tender tumour may be palpated within the diffuse swelling, and the tumour may cause a nagging pain, characteristically relieved by non-steroidal anti-inflammatory drugs.

X-ray reveals a small area of rarefaction surrounded by sclerosis, although symptoms may precede this appearance and an isotope bone scan or MRI may show the focus earlier. Arteriography and thermography demonstrate the hypervascularity. Surgical treatment of this benign condition is by en bloc resection through a fish-mouth incision.

Implantation epidermoid cyst

Implantation epidermoid cyst may produce gradual enlargement of the tip of the digit, with the appearance of clubbing, or pincer nail. Pain may arise due to disturbance

of the underlying bone where there is erosion, with distortion of cortical bone seen on X-ray, or a cyst may be demarcated on MRI. There is sometimes a history of previous trauma or surgery. Surgery is generally curative [7,8].

Metastases

Metastatic tumours present as inflamed swellings at the tip of a digit, with relatively few symptoms. X-ray reveals an osteolytic lesion, and systemic examination and investigation may reveal the primary focus; 50% will be from carcinoma of the lung [9,10].

Vascular tumours

Glomus tumour

Glomus tumours are the most characteristic of vascular nail bed tumours. There is pain, which may be spontaneous or evoked by mild trauma or temperature change. Nail plate changes depend on the location of the tumour. Matrix tumours cause splitting and distortion of the nail plate. Nail bed lesions are most likely to appear as bluish or red foci, 1–5 mm in diameter, beneath the nail [1]. On X-ray, 36% show a depression in the underlying phalanx [1]; MRI can reveal the exact site of the tumour [2]. It is of particular value when there is pain after excision in order to help determine whether the pain is a complication of surgery or due to recurrent tumour [3]. High-resolution ultrasound has also been used with some success [4].

Histology is the definitive investigation and reveals vascular channels lined with endothelium and cuboidal glomus cells. These have dark nuclei and pale cytoplasm. Myelinated and non-myelinated nerves are found, which may account for the associated symptoms; neuromas must be considered in the differential diagnosis [5].

Treatment. Excision is the treatment of choice. Some surgeons advocate approaching the pathology by a fish-mouth incision, expecially when the tumour is in the nail bed [6]. However, this assumes a clear knowledge as to the location and nature of the tumour before surgery. Often it is necessary to remove the nail for preliminary assessment and this also facilitates matrix repair [5,7]. Where there is persistent pain after treatment, it may be due to the earlier surgery or further tumour. MRI can help in assessing this [2]. Residual scarring of the nail may remain, depending on the nature of the surgery and the extent of preoperative damage.

Pyogenic granuloma and periungual vascular lesions

Pyogenic granulomas are benign eruptive haemangiomas. They may involve the nail fold, with a prominent collar of epithelium, or be subungual and penetrate the nail plate (Fig. 62.31). In this location, they almost invariably arise from the matrix and produce a localized deformity of the nail plate, visible as the nail grows distally. Mild penetrating injury, friction [1] and immobilization of the limb in a cast [2] are physical causes. Medication can also be relevant. Retinoids [3], ciclosporin [4], cancer chemotherapy and antiretroviral treatment for HIV infection are all potential initiating factors. With these medications, the presentation is often of excessive granulation tissue on more than one digit as part of an ingrowing nail, rather than the classic isolated lesion puncturing the matrix and emerging from beneath the proximal nail fold. There may be features that blur the distinction between focal lesions and areas of hyperaemia with inflammation [5] and onycholysis [5–7]. Pain can be a significant feature [7] and docetaxel, used in breast and prostate cancer, has been implicated in such cases. Where antiretroviral medication is implicated, it is usually in association with nucleoside reverse transcriptase inhibitors [8,9].

Fig. 62.31 Pyogenic granuloma penetrating the nail plate.

A pyogenic granuloma bleeds easily and must be distinguished from an amelanotic malignant melanoma, histiocytoid haemangioma [10], granulation tissue reaction to ingrowing nail and cavernous angioma. Where the clinical evolution is slow, the differential diagnosis includes squamous cell carcinoma and a range of benign tumours [11]. The possibility of malignancy and other progressive tumours makes histological examination important. Bacteriology is also required and may help with the diagnosis of coccal nail fold angiomatosis, which may resemble a pyogenic granuloma arising from the matrix. This can relapse locally and on other digits [12].

Treatment. Once histology is available, if the lesion persists, destructive therapy such as carbon dioxide laser or suppressive therapy such as a potent topical steroid can be used. The latter is preferable and adequate for matrix lesions where infection has been adequately treated. Potassium permanganate soaks, or local or systemic antibiotics, may be needed if there is secondary infection with excessive oozing.

Arteriovenous abnormalities

Periungual and subungual arteriovenous tumours (cirsoid aneurysms) are firm, bluish, non-pulsatile nodules in a nail fold or penetrating the nail [1]. Treatment by excision reveals histology of thick-walled vascular channels with fibrous tissue boundaries and no internal elastic lamina. In the presence of a digital arteriovenous malformation, the digit and nail bed are purple, with gradual shrinkage and overcurvature of the nail plate [2]. Growth may be rapid in young people, in whom the digit may become bulbous and painful. X-ray may reveal aneurysmal destruction of the terminal phalanx, and more precise detail may be gained by MRI.

Myxoid cyst

SYN. MYXOID OR MUCOID PSEUDOCYST

This benign cystic swelling has many names and is often termed a pseudocyst because a cellular cyst wall can seldom be demonstrated. It is usually located between the crease of the distal interphalangeal joint on the dorsal surface and the proximal nail fold. Less commonly it is found between the proximal nail fold and the nail plate, beneath the nail matrix or in the digit pulp. Pressure on the matrix results in a longitudinal groove or gutter in the nail plate (Fig. 62.32), which may have transverse ridges within it, reflecting episodes of decreased matrix pressure when the cyst is decompressed through discharge of its contents. When the tumour occupies the space between the nail and proximal nail fold, it may protrude from beneath the nail fold with what appears to be a keratotic tip, mimicking a fibrokeratoma. When located beneath the matrix, the nail becomes misshapen, with increased transverse curvature, and the lunula appears red [1].

Fig. 62.32 Nail plate groove due to proximal myxoid cyst.

Myxoid cysts are more common in the fingers than the toes. They contain a clear gelatinous fluid that may discharge spontaneously or on minor trauma. This fluid may be the product of mucoid degeneration of connective tissue or be derived directly from the adjacent distal interphalangeal joint with which a communication is usually demonstrable by injection of methylene blue into the joint [2,3]. The condition of the joint is a major factor in the origin of the tumour, with osteoarthritic osteophytes damaging the joint capsule and provoking the flaw through which synovial fluid escapes. Infection of the ruptured pseudocyst may cause septic arthritis or local paronychia, although this is uncommon.

High-resolution ultrasound or MRI provides non-invasive visualization to confirm the diagnosis or to localize the pedicle in recurrent cases. However, it may be more practical to attempt transillumination with a pen torch. This will distinguish it from a giant cell tendon sheath tumour, which is usually found overlying the dorsal distal interphalangeal crease in women with osteoarthritis [4,5]. Giant cell tendon sheath tumours are often rubbery and fail to transilluminate. Alternatively, a myxoid cyst will easily puncture using a size 11 scalpel, with sterile technique, revealing the diagnostic gelatinous contents.

Histology usually reveals a pseudocyst cavity within a fibrous capsule containing a myxomatous stroma with scattered fibroblasts. Areas of myxomatous change may merge to form a multilobular pseudocyst. Some workers report a mesothelial lining to the pseudocyst, consistent with continuity with the synovial joint space. This is not always confirmed and may mean that there are different histological forms of myxoid pseudocysts.

Treatment. There are many conservative approaches to cure [6,7], none of which is definitive. These include incision and drainage (pricking with a sterile blade or needle) and which may be repeated by the patient [8], injected sclerosant [9] or steroid [10,11], cryosurgery [12,13], laser [14] and infrared photocoagulation [15].

Surgical therapy may entail removal of osteophytes involving the distal interphalangeal joint [16–19], excising the distal margin of the proximal nail fold if the tumour is located there [20], or tracing the communication between the joint and cyst with methylene blue and tying it off [3,21].

There is a high relapse rate after single treatments with less invasive therapies. More detailed surgical therapies are more effective [19,21].

Fig. 62.33 Bowen's disease with melanonychia.

Squamous cell carcinoma

SYN. EPIDERMOID CARCINOMA

Squamous cell carcinoma of the nail unit includes *in situ* (Bowen's disease) and invasive forms (Fig. 62.33). A single biopsy may fail to make a distinction between them. A tumour that appears *in situ* at one site may be invasive elsewhere [1]. Periungual features include hyperkeratotic warty changes, erosions and fissuring, macerated cuticle, periungual swelling, erythema and occasional secondary infection. Subungual changes include onycholysis with a friable or warty nail bed, longitudinal melanonychia, nail dystrophy, ingrowing or loss. Some cases may be as subtle as a single red longitudinal streak [2] (see p. 62.19). Nodular change with ulceration and bleeding is a late development. The condition may affect many digits [3]. Common misdiagnoses include onychomycosis, periungual warts, recurrent paronychia, pyogenic granuloma and subungual exostosis. As some of these conditions do not warrant biopsy and clinicians seldom think of squamous cell carcinoma at this site, the diagnosis is frequently delayed. Mean periods of 52 months [4], 9 years [5] and 5 years [6] have been reported. This slow progression may mean that the diagnosis is never made on older people, with the consequent impression that the disease is less common than is the case [7].

Predisposing factors include radiation exposure [3,8], human papillomaviruses 16, 18 and 34 [4,5,8–10], and possibly ectodermal dysplasias and chronic trauma. Features of chronic radiation damage to the periunguium may precede the onset of malignancy [11]. History and examination should include a note of genital wart infection or cervical dysplasia in the patient or partner [8]. Appropriate investigation includes X-ray and biopsy of a large and representative area. Failed diagnosis can be attributed to poor diagnostic biopsy technique. Prognosis is good and there are only five cases of metastatic disease in the literature [9], two of which were in patients with ectodermal dysplasia [12,13].

Treatment. Mohs' micrographic surgery is the treatment of choice for ill-defined lesions, as long as there is no evidence of bone involvement [1,6,14]. The technique allows the digit to be preserved in most instances. Horizontal sections in the context of the complex three-dimensional anatomy and histology of the nail unit require careful and experienced interpretation [15]. Alternative treatments include local excision, digit amputation and radiotherapy [16].

Epithelioma cuniculatum [1,2]

Epithelioma cuniculatum is a slow-growing, locally destructive, low-grade tumour, histologically related to squamous cell carcinoma [1,2]. It is typically found on

the sole of the foot, but may involve the periunguium, mucosal surfaces and other locations [3]. It is warty, with discharge of foul-smelling yellow material from nail bed sinuses. The overlying nail is disrupted by onycholysis or destruction at the matrix, and there may be paronychia. The underlying bone is usually affected and X-ray reveals destruction of the terminal phalanx in most cases. Biopsy confirms the diagnosis. A system of epithelium-lined channels within the tumour form fistulae extruding keratinous debris. Mitoses and dyskeratotic cells are rare and the benign appearance may lead to the misdiagnosis of pseudoepitheliomatous hyperplasia. Mohs' micrographic surgery is a useful treatment.

Keratoacanthoma

Subungual or periungual keratoacanthomas are typically painful, rapidly enlarging lesions that are usually solitary [1,2]. They are often referred to by the acronym SUKA. Keratoacanthoma is a misleading term as there is no indication that the tumour follows the same pattern of involution seen in keratoacanthomas elsewhere; also, there is no apparent relationship with sun exposure. Although trauma and wire wool have been implicated [3], in most cases there is no obvious precipitating factor. Erosion of bone is seen on X-ray, which is an essential preliminary investigation [4–7]. This feature is likely to represent a pressure effect of rapid subungual expansion, rather than bone invasion. The diagnosis is made partly on the history but largely from the histology, which closely resembles that of a keratoacanthoma seen elsewhere but showing little or no squamous dysplasia [4]. Subungual wart, squamous cell carcinoma and subungual exostosis are among the differential diagnoses. Clinically, subungual keratotic incontinentia pigmenti tumours fall between the appearance of fibroma and keratoacanthoma [8,9]. They resemble the latter in often being painful and causing underlying bone changes. They are commonly multiple and seen with the other features of incontinentia pigmenti, which is usually lethal in males. These tumours can be treated with oral retinoids [10], but may eventually require surgery.

Treatment. Treatment of subungual keratoacanthoma can be by Mohs' micrographic surgery or curettage. More aggressive treatments, including amputation of the digit, have been employed in the past, but are not warranted. Given the concern that the tumour may represent a form of squamous cell carcinoma, micrographic surgery may be the treatment of choice.

Melanocytic lesions

Benign melanocytic lesions usually present as longitudinal melanonychia (LM). This is also a common appearance of early malignant melanoma of the nail matrix [1]. An understanding of the causes of benign nail pigmentation is important in order to judge when biopsy is indicated to exclude melanoma.

Benign causes of LM

Laugier–Hunziker syndrome

Laugier–Hunziker syndrome gradually evolves with pale-brown LM on one or more digits [2,3]. There may be periungual involvement resembling Hutchinson's sign and the oral and genital mucosae may be affected with pigmented macules. The macules are amenable to laser treatment [4].

Subungual naevi

Subungual naevi may present in adulthood or early in life with LM or with naevoid melanosis of the nail plate [5] (Fig. 62.34). This has been described in European [6,7] and Japanese [8] adults and children.

Drug therapy

Drug therapy with minocycline, zidovudine [9] and antimalarials may produce brown streaks in the nail (see

Fig. 62.34 Benign longitudinal melanonychia due to a subungual naevus.

Fig. 62.35 Malignant melanoma arising in the nail matrix and invading the nail bed.

p. 62.18), as may dermatoses such as lichen planus [10] and onychomycosis [11], trauma [12] and non-melanocytic tumours such as squamous cell carcinoma *in situ* [13] (see Fig. 62.33). Subungual blood pigment may resemble melanin, but associated features in the history and appearance usually make it possible to distinguish the two.

Benign racial pigmentation

The most common cause of LM is racial variation; 77% of Afro-Caribbeans over 20 years of age have LM and this prevalence rises to almost 100% by the age of 50 years [14]. It is present in 10–20% of Japanese [15] and is more common in Mediterranean races than in northern Europeans. However, in this context, the percentage of malignant melanomas presenting in the nail unit is higher in Afro-Caribbeans (15–20%) [14] than in any other group (3% in white populations [16]). This contrasts with the low incidence of malignant melanoma at other skin sites in Afro-Caribbeans.

Malignant melanoma [17–20]

There are many features of LM that should suggest the possibility of malignant melanoma. These include the presence of brown-black periungual pigmentation (Hutchinson's sign) [21], especially when the pigmentation develops in a single digit in adult life and is evolving to become darker and broader and has blurred edges. Hutchinson's sign needs careful assessment and does not necessarily carry a bad prognosis [2,22]. Dermatoscopic examination through the nail may help with diagnosis [23,24]. The suspicion of melanoma is raised further if the individual has any other risk factors for melanoma, if the involved digit is a thumb, great toe or index finger, and if the nail has become dystrophic.

Despite the importance of LM as a warning sign, 25% of subungual melanomas present as amelanotic tumours. This exceeds the percentage of melanomas presenting as an amelanotic tumour elsewhere. It is difficult to determine whether these tumours were always amelanotic [25] or whether loss of pigment is due to development of the disease process (Fig. 62.35). This form of melanoma usually has associated nail plate damage and easily bleeds. With this appearance, the differential diagnosis includes pyogenic granuloma, chronic paronychia and vascular tumour.

The assessment of pigmented streaks in children is complex. The earlier dictum that they were all benign and could be left has some ramifications. Indeed they are almost all benign [7], although very rare cases of melanoma are reported [26]. This alone may make diagnostic biopsy warranted in some or all. In addition, it is documented that pigmented streaks arising in childhood can evolve into melanoma, even after an initial biopsy with benign histology (S. Goettmann-Bonvallot, personal communication). The implication of this is that repeated biopsies may be needed as a pigmented streak evolves, and lifelong monitoring is required for children with such signs. Faced with this, complete excision of the matrix origin can sometimes be the best option, even when there is permanent loss of all or part of the nail.

The significance of preceding trauma is unclear [25]. Such a history is present in a large number of cases. It is thought that primary malignant melanoma of the nail unit arises only from within the matrix and not from the nail bed. This is consistent with the absence of antigenically identifiable melanocytes in the nail bed [27,28] and can provide some reassurance when assessing pigmented lesions not arising from the matrix. However, such lesions may arise from the nail folds, or be secondary malignant melanomas.

Biopsy of LM

Given the gravity of the potential cause of melanonychia, there should be a low threshold for biopsy. The type of biopsy can be determined by a range of factors [12].

1 Periungual pigmentation present. This indicates high risk of malignancy. If there are no other factors to account for this pigmentation, the whole area of affected nail unit should be removed en bloc down to bone with a 1-mm margin of normal tissue. Cosmetic considerations are secondary.

2 Lateral third of nail plate involved. This indicates lateral longitudinal biopsy. The cosmetic outcome is reasonable and the assurance provided by complete removal of the affected area is usually worthwhile.

3 Mid portion of the nail plate involved. The cosmetic outcome of complete excision at this site is potentially bad. This is particularly so if the origin of melanocytes is proximal in the matrix. This may be determined by sampling the free edge of the nail plate and performing a Masson–Fontana stain. Pigment in the lower part of the nail reflects a distal matrix origin, compared with ventral nail pigment reflecting an origin in the proximal matrix. The latter carries a high risk of scarring following excision.

For lesions less than 3 mm wide. The potential for postoperative dystrophy in midline lesions warrants preliminary investigation of thin (< 3 mm) pigmented streaks with a matrix punch biopsy unless the clinical evidence of malignancy is overwhelming. This technique involves:

1 reflection of proximal nail fold to visualize the origin of the pigment;

2 a 3-mm punch biopsy through the nail down to bone at the pigment origin, but leaving the biopsy *in situ*;

3 proximal hemi-avulsion, which will leave the 3-mm biopsy of nail remaining;

4 examination of fully exposed matrix;

5 careful removal of 3-mm biopsy of matrix and nail with iris scissors;

6 after gentle undermining, partial approximation and suture of the wound with 7/0 monofilament may be attempted for proximal matrix wounds.

Removal of the nail plate before biopsy can mean one loses the site of pigment origin once the clue of melanonychia has gone. Removal of the 3-mm biopsy without hemi-avulsion of the surrounding nail is difficult and may result in damage to the specimen, which compromises histological interpretation. For these reasons, the method outlined above is preferred.

For lesions 3–6 mm wide. If the pigment arises from distal matrix, a transverse matrix biopsy can be performed. Proximal matrix pigment requires an en bloc removal and repair using a Schernberg and Amiel flap.

For lesions greater than 6 mm wide. Matrix punch or transverse biopsy is usually adequate as the preliminary investigation.

Treatment and prognosis

Nail unit melanoma has a record of delayed treatment and poor prognosis [29]. It affects light and dark skinned people, those of African origin representing 12% of patients in one North American series [30]. The most common pattern is of acral lentiginous melanoma [17], although one series reported the superficial spreading type as being marginally more common [31]. In the acral lentiginous form, there is lentiginous spread of pleomorphic, often dendritic, atypical melanocytes in the basal and suprabasal layers of the epidermis. Epidermal melanoma cells may be incorporated into the nail plate and seen on stained clippings of nail taken from the free edge. Dermal melanoma cells are pleomorphic, with spindle, epithelioid, polygonal, dendritic and bizarre shapes.

Hutchinson's sign is represented histologically by atypical melanocytes mainly in the basal layer, with a few higher in the epidermis. *In situ* subungual melanoma has junctional nests of melanoma cells. Nodular patterns of melanoma are rare.

Amputation of the digit is the routine treatment, although local excision is occasionally practised for small shallow lesions. Mohs' micrographic surgery is used in some centres, but is still at a relatively early stage of evaluation [32]. In one series of 14 patients, three had recurrence at the margins of treatment. Adjuvant isolated limb perfusion has failed to show benefit in stage 1 subungual melanoma [33], although use of a more aggressive regimen has possibly been associated with improved survival [34].

Recent British surveys suggest that the poor prognosis of subungual melanoma is related to the depth of invasion at diagnosis (4.7 mm). This reflects late diagnosis (3 months to 12 years) [31,35,36]. The mean 5-year survival was 41% compared with 61% for a control group of primary cutaneous malignant melanomas in the same study [35]. Other series have produced similar results, although recent Japanese evidence supports the idea that diagnosing subungual melanoma early, with a lower Breslow

thickness, improves prognosis, with an 87% 5-year survival rate [34].

Nail surgery [1,2]

Nail surgery is delicate and requires attention to detail. It is important that anyone performing a nail biopsy appreciates the principles outlined in the preliminary section of this chapter on anatomy and physiology and that they obtain tuition in detailed technique. Once in this position, the outcome of nail unit surgery is usually excellent and provides useful and definitive diagnostic material [3].

For many procedures, the routine skin surgery pack needs to be supplemented by specialized instruments. These include a Freer septum elevator for finger work and a larger elevator for the great toenail. English nail splitters are essential for performing partial avulsion. They have a flat undersurface, which can be introduced beneath the nail to act as an anvil and a sharp upper part that cuts down upon the nail to meet the other half of the instrument. For bone surgery, such as removal of exostoses, bone rongeurs and McKindoes are needed.

Indications

A nail biopsy may perform several functions. It can provide useful positive diagnostic information or help exclude a malignant condition, such as squamous cell carcinoma of the nail bed. Painful conditions may be relieved by the drainage of pus with proximal hemi-avulsion, or ablation of an ingrowing toenail. Focal pathology, such as a glomus tumour or the origin of melanonychia, can be completely excised and provide the diagnosis. If a positive diagnostic and therapeutic attitude is taken to the nail disorder, a good outcome can be expected.

Diagnostic nail biopsy may be undertaken as part of the investigation of nail dystrophy of unknown cause in the presence of more than one negative mycology sample.

Biopsy of the nail plate alone, or with associated nail bed and occasionally matrix biopsy, may be needed to confirm fungal infection in atypical cases, although biopsies are more commonly directed at distinguishing between

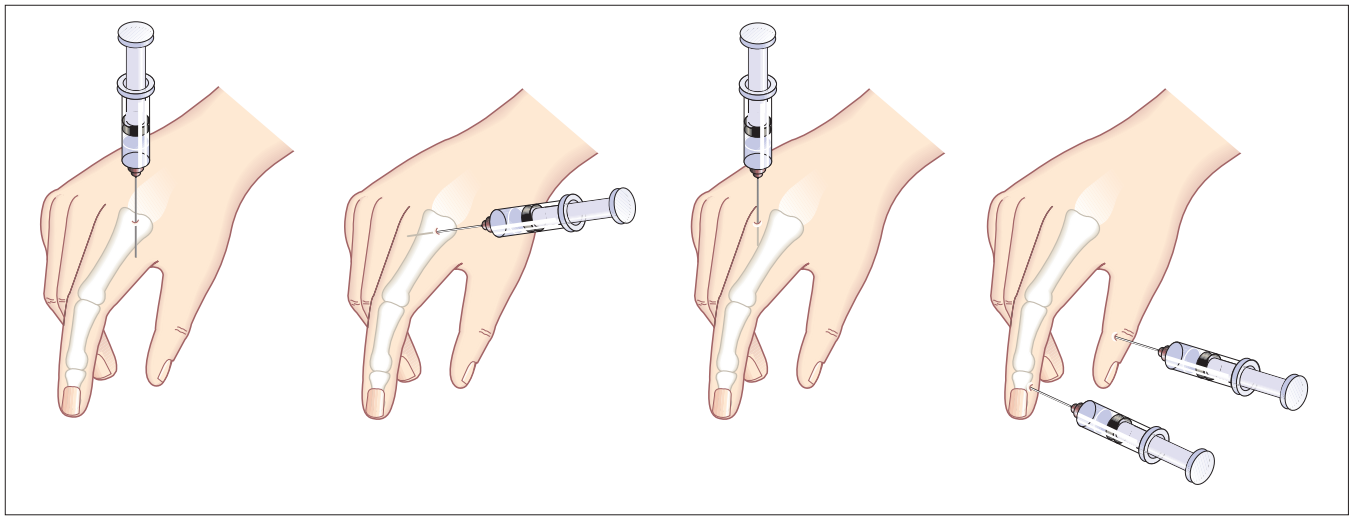

Fig. 62.36 Digital sites of injection for a ring block.

dermatoses affecting the nail, such as lichen planus, psoriasis or infiltrative disease. In instances of nail dystrophy of a single digit, it is appropriate to biopsy to exclude a neoplasm once necessary imaging has been performed.

Caution is needed in patients with relevant medical and circulatory problems. The latter are subject to poor reperfusion following the tourniquet and it may be necessary to abbreviate the procedure to ensure no inadvertent damage is done. The wound must be seen to bleed and the digit colour return before the dressing is applied in these cases, and this can take several minutes. This contrasts with the usual pace at which dressings are applied to prevent bleeding in a healthy digit. Diabetics may have ischaemia combined with immune impairment and frequently need attention to toenail problems. Paradoxically, they are cited as a group in whom cold steel surgery for nail problems is preferable to other techniques such as phenolic ablation or cryosurgery. This is because the course of healing in these wounds is predictable and often shorter than wounds produced by other therapies.

Preoperatively

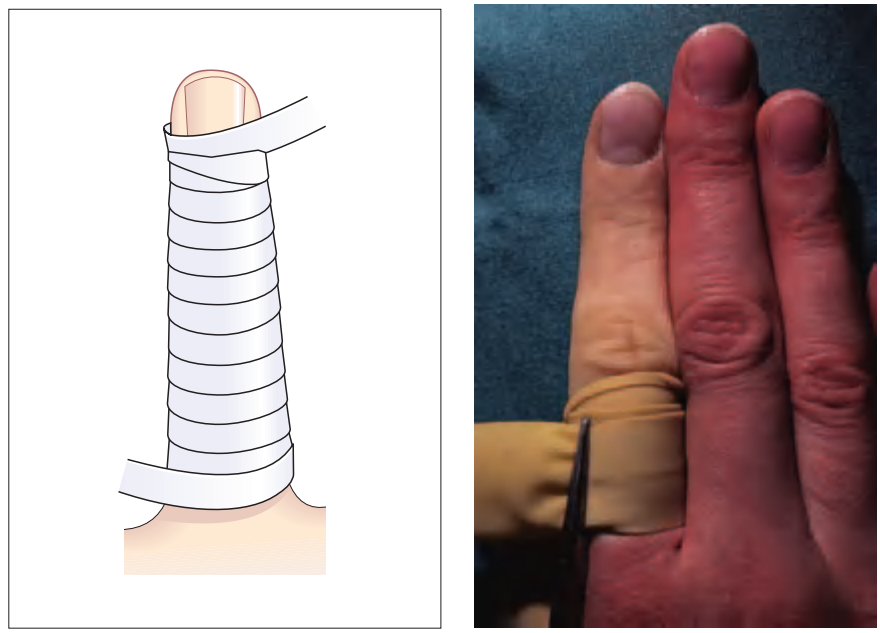
It is essential to prepare the patient for the procedure by a discussion on a day separate from surgery. In this discussion, the patient must appreciate the potential benefits and problems of the biopsy. It is useful to make it clear that it will be painful and that they will have a degree of disability postoperatively for which they must make provision at home and at work. The best surgical technique can be utterly confounded by a patient who goes back to a dirty workplace the next day. Much of the information concerning scarring, the need for elevation, dressings and analgesia needs to be repeated on the day of the procedure. The patient should have a means of transport home that does not involve them driving or standing for prolonged periods.

The affected digit should be soaked in warm antiseptic and scrubbed in a manner similar to that used by the surgeon prior to gloving. This will diminish the bacterial load beneath the free edge of the nail, which is a source of potential pathogens. Soaking for 10 min softens the nail and facilitates removal of parts of the nail plate, so avoiding complete avulsion. During this period, the local anaesthetic can take effect.

Anaesthetic (Fig. 62.36)

Lidocaine (lignocaine) 2% or equivalent can be used [4]. Bupivacaine can be used to provide prolonged analgesia. The use of epinephrine (adrenaline) in anaesthetic remains controversial. There are several publications illustrating how anaesthetic containing 1 in 200 000 epinephrine has been used safely [5]. The ischaemia and prolongation of anaesthesia is a potential advantage. If subjects with peripheral ischaemic or vasospastic disease are avoided, anaesthetic with 1 in 200 000 epinephrine appears safe. An alternative is to use ropivacaine. This local anaesthetic has physiological and pharmacological properties somewhere between bupivacaine and lidocaine. It has a moderately quick onset of action and can produce anaesthesia for over 12 h, combined with a modest short-term vasoconstrictive effect [6]. We use ropivacaine 7.5 mg/mL in the same way as lidocaine, with very good results. A 30-gauge needle causes less discomfort during injection than larger needles, and minimizes the risk of damage to digital nerves when inserting a ring block. Risk of nerve trauma may be reduced further by the use of nerve-block needles, which have less traumatic tips.

The most common form of anaesthesia is a ring block (digital nerve block), which is delivered by injection of



(a) (b)

Fig. 62.37 (a) A Penrose drain is applied from the tip and wound down the digit achieving exsanguination. (b) The drain is then unwound from the top, with the base maintained secure with artery forceps.

anaesthetic into the dorsolateral aspect of the digit at the base, with about 1–2 mL on each side of the phalanx. Greater than 5 mL may impair circulation, but this can be assessed visually during the procedure and is very variable according to the bulk of individual digits. Anaesthesia may take 10–20 min to become total. In the great toe, additional anaesthetic should be placed ventrally. After 10 min, efficacy of the block can be assessed at the digit tip with the same needle; if the anaesthesia is incomplete, it can be supplemented by a small local injection at the site of surgery. However, this can increase tissue turgor and render fine manipulation difficult.

Other ring block techniques can be employed, including a method that aims to infiltrate the anaesthetic via the flexor tendon as a transthecal block [7,8]. An alternative is the distal 'wing' block given 2–3 mm proximal to the junction of the proximal and lateral nail folds. The injection is first directed distally into the lateral nail fold. After partial withdrawal, it is redirected over the proximal nail fold. Sufficient is used to produce blanching in both nail folds. The procedure is repeated on the other side to achieve complete block. The digit is more sensitive distally than proximally and it is often more comfortable to provide the traditional proximal digital nerve block.

For invasive procedures on many digits concurrently, more proximal or regional blocks can be employed [9]. In children it can be worthwhile to use a topical anaesthetic as a preliminary measure before ring block. Evidence of its efficacy in adults is mixed [10,11].

Tourniquet

It is important that the area of applied pressure beneath the tourniquet is as broad as possible to avoid pressure damage to underlying structures. In particular, neuritis may be a long-term complication of a narrow, tight, prolonged tourniquet. This effect can be exacerbated by topping up anaesthetic near the tourniquet after it is in place. Ischaemia can be tolerated in a normal digit for 20 min and possibly longer, with no complications as long as there is no local trauma from the tourniquet.

The standard tourniquet for local anaesthetic is the Penrose drain (Fig. 62.37), which may be wound around the digit from the tip proximally. This exsanguinates the digit and provides a tourniquet effect that can be maintained with a pair of artery forceps. A sterile glove is an alternative. It is worn by the patient and the tip of the glove digit at the site of surgery is snipped off. It is then rolled back to the base of the digit, exsanguinating it, providing a tourniquet, and avoiding contamination from adjacent digits peroperatively. With general anaesthetic, an exsanguinating cuff can be used on the forearm or calf.

Specimen

The specimen must be delivered to the pathologist undistorted and with the maximum of clinical and operative information. It is useful to allow the specimen to adhere lightly to a piece of paper before immersion in fixative, or to enclose it in a small plastic mesh cassette. This should be matched with a detailed drawing on the histopathology request form. It is helpful to work regularly with the same pathologist for nail specimens, as processing requires specialized understanding of specimen preparation and histological interpretation.

Postoperatively

Dressings should be ready before removal of the tourniquet. They must be firm and moderately bulky. An acceptable dressing includes an antimicrobial ointment under a greasy tulle, padding and a small bandage. Calcium alginate dressings can also be useful if there is an area that needs to heal by secondary intention. Dressings should be held in place with oblique or longitudinal sticky tape to avoid a tourniquet effect if the digit swells. A sling or plastic overshoe should be provided.

The frequency of change of dressings is determined by the nature of the procedure and the patient. An antiseptic soak is normally needed to remove the dressing and clean the wound. Infection should be treated vigorously with systemic antibiotics combined with daily antiseptic soaks.

It is good practice to provide a moderately strong analgesic and to recommend taking it regularly in the first 48 h. It may prove unnecessary, but the distress of unrelieved pain in the few who suffer warrants caution. Some patients need night-time sedation.

In most cases, it is wise to arrange review within 2 days of surgery to change the dressing, assess the wound and answer any questions which have arisen.

Complications

Pain can sometimes be disproportionate to the wound [12]. When it is severe, the patient is at risk of reflex sympathetic dystrophy [13]. They should receive regular potent analgesics, including non-steroidal anti-inflammatory agents, amitriptyline and sometimes an anxiolytic such as diazepam.

Bleeding is very common and should be accommodated by firm, bulky dressings. Once blood has clotted in these dressings they can be rock-like and represent an infection risk—good reasons for an early dressing change.

Infection is a potential problem and can be devastating to the matrix. Prophylactic antibiotics are a reasonable precaution when the surgical site is likely to be heavily colonized due to skin changes or a dystrophic nail. Children or patients with poor hygiene may also warrant antibiotics.

Longer term, complications are mainly related to scarring dystrophy and loss of function. The former is always a potential risk of any surgery involving the matrix and should be discussed preoperatively as part of the risk assessment with the patient. Loss of function can be modest, with a tendency for the nail to catch, or more significant if associated with pain or marked paraesthesia. Mild paraesthesia is quite common in the short term and is sometimes seen with cold sensitivity. Complications involving the tendons of the distal interphalangeal joint are very rare and usually related to more proximal surgery.

Patterns of nail biopsy

Nail avulsion [1,2]

Nail avulsion can be performed in order to examine underlying tissues or to provide temporary relief in cases of soft-tissue trauma. In isolation, it is not a treatment for ingrowing toenails. The procedure requires a distal or ring block, and an elevator in addition to the routine instrument pack. For a partial avulsion, nail splitters are also needed.

To minimize the trauma of the procedure, soft-tissue nail attachments should be loosened at all sites prior to removal. This minimizes tearing damage to the nail folds. The cuticle may need disrupting with fine scissors or a blade, but all other detachments can be performed with a septum elevator. Once this is done, the nail is gripped with a pair of rugged artery forceps and removed by a mixed twisting and lifting action (Fig. 62.38).

With a lateral partial avulsion, the nail splitter is used to define the medial margin and only the attachments of the piece of nail to be removed need to be interrupted.

Proximal hemi-avulsion of the nail plate entails the following technique.

1 The origin of the nail and its proximal lateral aspects are undermined with a septum elevator.

2 In nails with a shallow lateral nail fold, a nail splitter may be inserted and the nail transversely bisected.

3 In nails with a deep lateral nail fold, a deep transverse score is placed with a scalpel across the nail halfway down.

4 The septum elevator is then fully inserted through the transverse score to loosen and elevate the proximal nail.

Nail bed biopsy [1–4]

Biopsy of the nail bed is usually performed to investigate a focal abnormality of nail bed or changes in the nail plate arising distally. Occasionally, it may be appropriate to biopsy through the nail plate where the histological relationship between nail bed and plate is under investigation. More commonly, the nail bed is visualized first, following complete or partial avulsion. A thin ellipse is taken down to bone in the long axis of the digit (Fig. 62.39). An alternative is to employ a double punch technique, where a 6-mm hole can be made in the nail plate with a biopsy punch over the area of nail bed to be examined. The nail bed may then be sampled using a smaller punch.

If there has been nail avulsion, it is possible to close the wound, which may require gentle undermining. In small biopsies this may be unnecessary, and the wound will heal well by secondary intention. When the nail is left *in situ* or if the double punch technique is used, closure is not possible. After a double punch, as long as there is complete haemostasis, the original disc of nail plate can be returned after soaking in antiseptic; it may reattach or at least provide a natural dressing during the early healing phase.

No scarring is anticipated from this biopsy if it is small and does not extend into the nail matrix.

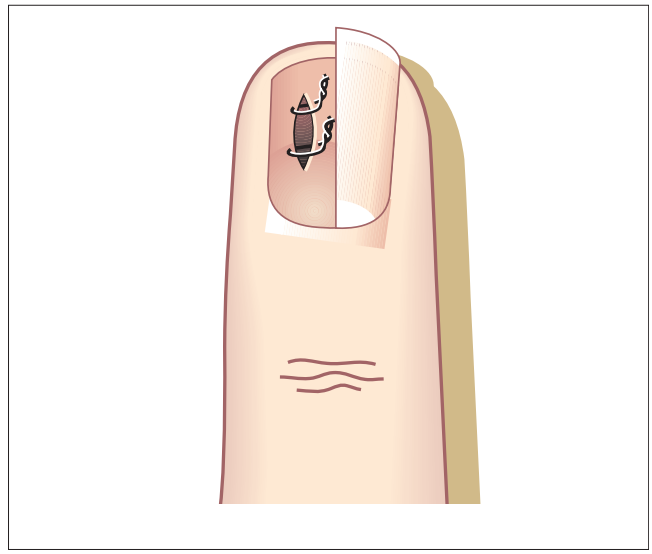

Fig. 62.39 After partial nail avulsion, the nail bed can be seen and biopsied along the longitudinal access.

Matrix biopsy

Lateral longitudinal nail biopsy [1,2]

Lateral longitudinal nail biopsy is the definitive method for sampling all the tissues of the nail unit. It is most commonly required when there is dystrophy affecting the whole nail or for the excision of a melanonychia. If focal

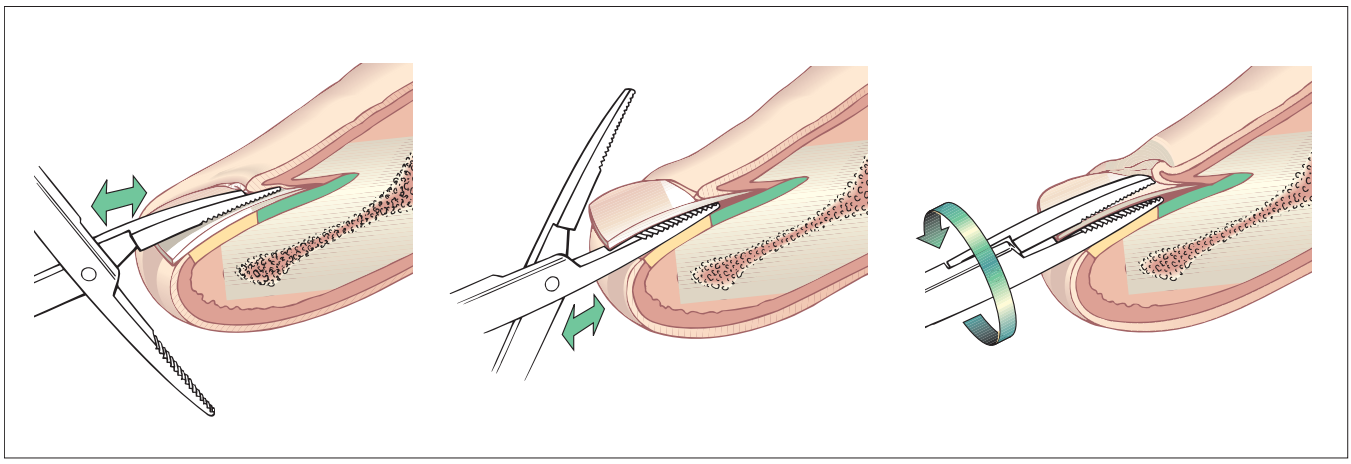

Fig. 62.38 The three stages of standard nail avulsion.

matrix pathology occurs laterally, longitudinal biopsy may be warranted to preserve the shape of the nail, which can otherwise be altered by local matrix surgery. Early literature suggested that longitudinal biopsies of less than 3 mm in width could be taken from the midline of the nail without scarring [3] but it is now accepted that this may produce long-term nail dystrophy.

The first incision starts in the lateral nail sulcus, between the nail and nail fold. The distal limit is just beneath the distal groove, in the tip of the digit. Proximally, the incision extends almost to the first of the transverse skin markings of the distal interphalangeal joint. The medial margin of the ellipse is formed by an incision through the nail plate, which has been softened by an antiseptic soak. Both incisions are down to bone and separated by 3 mm at the widest point. The specimen is released from its deep attachment from the distal point proximally. The nail can be lifted at the free edge with forceps, allowing the bottom of the specimen to be released with curved iris scissors. Particular care is needed at the proximal end to ensure that the matrix is fully sampled without damage.

A 3/0 or 4/0 monofilament suture is used for closure. One suture closes the wound through the proximal nail fold. One or two further sutures are needed through the nail plate and lateral nail fold. The suture is designed to elevate the lateral nail fold and enhance the embedding of the new nail edge in the nail fold (Fig. 62.40).

The nail will be permanently narrowed following this procedure and the contour of the lateral and proximal nail fold intersection is altered to provide a more acute angle. In spite of the specialized suture to elevate the lateral nail fold, the nail is seldom fully embedded in a new lateral sulcus. Where biopsies of greater than 3 mm width are taken, the nail may develop malalignment, with distal deviation towards the side of the biopsy [4].

Fig. 62.40 A large, lateral, longitudinal nail biopsy is closed with sutures designed to reconstruct the lateral nail fold.

Transverse matrix biopsy (Fig. 62.41)

A transverse matrix biopsy may be performed to investigate focal abnormality of a nail dystrophy arising from the matrix.

The proximal nail fold is reflected following an oblique incision at the junction with the lateral nail folds and gentle separation of the proximal nail fold from the dorsal aspect of the nail plate. The matrix is then visualized by performing a proximal hemi-avulsion. A thin ellipse is taken from the distal matrix with the distal margin of the excision matching the shape of the lunula.

The wound may be gently undermined, taking care with the extremely fragile matrix epithelium and undermining most on the distal nail bed margin. Loose sutures with resorbable 6/0 monofilament can be used.

Once healed, a blemish may remain in the margin of the lunula. The nail plate will show changes in thickness proportional to the extent of the biopsy.

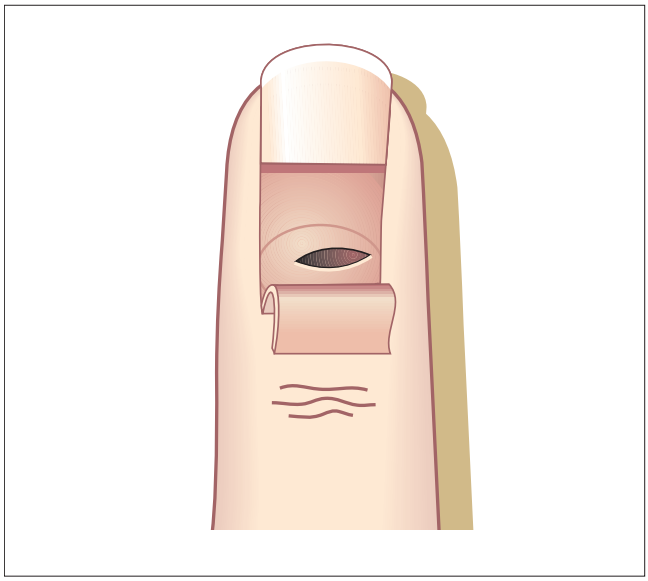

Fig. 62.41 Crescentic or narrow elliptical transverse matrix biopsy, which can be performed after removal of the proximal half of the nail plate alone.

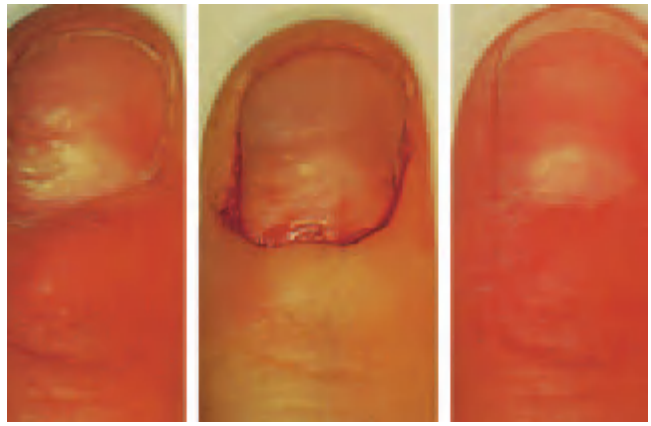

Fig. 62.42 Crescentic shave of the distal proximal nail fold and cuticle as treatment for chronic paronychia. Also provides histological specimen where biopsy relevant.

Nail fold biopsy [1–4]

Proximal nail fold biopsy

It may be necessary to biopsy the proximal nail fold to investigate a local dermatosis, connective tissue disease or focal tumour. The biopsy can be taken in different axes, but preservation of the symmetry and curvature of the proximal nail fold is a priority. If sutures are to be used, a distal wing block should be avoided, as the tissues will become turgid and difficult to manipulate.

Transverse nail fold biopsy

A transverse ellipse (for connective tissue disease), a 2-mm punch (far from the free edge) or a shave biopsy are simple nail fold procedures. The transverse ellipse and punch biopsies are down to the dorsal aspect of the nail plate. The matrix may require protection from cutting trauma and this can be achieved by inserting a septum elevator between the nail fold and the nail.

The transverse biopsy requires 4/0 monofilament suture. Wounds from other biopsy methods can be left to heal by secondary intention. Postoperatively, a thin line may remain in the nail fold after the transverse biopsy; otherwise, these techniques leave little or no scarring. There is no nail plate change.

Crescentic nail fold biopsy (Fig. 62.42)

A larger nail fold biopsy can be taken as a distal crescentic wedge. A crescentic incision is performed just proximal to the cuticle with the blade bevelled to direct trauma away from the proximal matrix if the nail is penetrated. Additional matrix protection may be provided by inserting a septum elevator beneath the proximal nail fold. The distal fraction of the proximal nail fold (including the cuticle) can be removed, although the width of the specimen should not exceed 4–5 mm in the midline. The contour is aimed at recreating a new edge to the entire nail fold. The wound heals by secondary intention and a new cuticle usually reforms, depending upon the original problem. The amount of exposed nail is permanently enlarged, but the nail surface is unchanged unless ridging or grooves produced by the original pathology are reversed.

This technique can be used for the excision of chronic paronychia resistant to routine therapy. It has also been recommended for the excision of digital mucous cysts occupying the most distal margin of the nail fold. At this site, it is argued that the lesions are solely degenerative and do not communicate with the joint space [3,4].

Focal nail fold biopsy

Focal pathology in the nail fold can be excised by a V-shaped incision into the nail fold. The excision is through the entire thickness of the nail fold, but should not penetrate underlying nail. Relaxing incisions are made at one or both of the lateral margins of the proximal nail fold (Fig. 62.43). The primary defect is closed with 4/0 monofilament and the relaxing incisions heal by secondary intention. Wounds in the midline of the nail fold can leave some scarring, but the nail plate is usually unaffected.

Nail plate biopsy [1,2]

It is sometimes useful to biopsy the nail plate, with or without a small piece of the hyponychium. This may help differentiate between onychomycosis and psoriasis. If hyponychium is included, a small bleb of anaesthetic will be needed or a distal wing block can be performed. A chunk of distal nail plate of at least 3 mm width is then removed with large nail clippers. Subungual debris should also be obtained and a scalpel may be needed if hyponychium is attached. Hyponychial wounds heal by secondary intention after cautery haemostasis and leave no scarring.

Lateral matrix phenolization [1,2]

Ingrowing nails, particularly toenails, are treated in many different ways [1–5]. However, phenolization is quick, relatively painless and has a high success rate [6]. Any area of matrix may be phenolized, including total ablation. The procedure yields no specimen other than the nail plate.

After anaesthetic, antiseptic soak and tourniquet, the margin of lateral ingrowing nail is avulsed using nail splitters to separate it from the rest of the nail plate. The nail folds are then protected with a layer of yellow soft paraffin and 85% aqueous phenol is applied on the end of an orange stick to the exposed matrix. This is done for 3 min (one stick per min), before douching with 70% alcohol to neutralize the chemical cautery. Although 3 min is common practice [1], in a series of 537 ingrowing nails, phenol was applied for 5–6 min and a 99% 1-year cure rate was achieved, with a mean healing period of 20 days [2].

As a result of this chemical burn, there is some ooze from the wound, which can occasionally last several weeks, but it is seldom infected and often pain-free. If the ooze is prominent, the toe should receive daily potassium permanganate or povidone–iodine soaks, after culture for specific microbes. The nail is permanently narrowed.

There is occasionally a small element of lateral nail regrowth, although further surgery is only indicated if there is repeated symptomatic ingrowing. Complete nail ablation can be achieved using the same technique applied to the entire matrix.

Other surgical modalities

Mohs' micrographic surgery

This technique applied to the nail unit exploits the principle of maximum conservation of healthy tissue while ensuring tissue clearance of tumour. It is particularly use-

ful in squamous cell carcinoma of the nail unit (see p. 62.41), where it should be offered as an alternative to digit amputation when there is no evidence of invasion of bone by tumour [1,2]. At this site, the conservation of normal tissue is of considerable functional significance. The place of Mohs' surgery in treatment of pigmented lesions of the nail apparatus remains to be fully explored. There is limited evidence of its use in nail melanoma [3].

Cryosurgery

Cryosurgery is widely used for the treatment of periungual warts. There is a small risk of damage to the tendons in the finger with aggressive freezing techniques. It is also used for myxoid cysts [4,5]. The cysts should be evacuated of their mucoid contents before a double 20-s freeze–thaw cycle. EMLA (eutectic mixture of local anaesthetics) or injected local anaesthetic may sometimes be needed. This regimen produces cure in approximately 25% of cases [5], although more aggressive freezing can produce better results [4].

Infrared photocoagulation

This has been used as a treatment for myxoid cysts of the proximal nail fold [6]. The contents are evacuated through a puncture wound before treatment.

Carbon dioxide laser

There is a range of indications for carbon dioxide laser [7–9], and its virtue may be in provision of a bloodless wound which allows a good view of the surgical procedure. This can only normally be provided in cold-steel surgery by an effective tourniquet.

The bulk of laser work on the nail unit is for subungual and periungual warts. This uses the defocused mode with a 1–2 mm spot at 5–10 W output and can be intermittent, in 0.05-s bursts, or continuous. Haemostasis may not be complete, and both anaesthetic and tourniquet are usually used with the laser.

It is also useful as a focused destructive instrument in the treatment of myxoid cysts [10] and ablation of abnormal nail in irreversible nail disorders. This includes partial destruction of the matrix of nails in ingrowing nails [11] and in pachyonychia congenita to reduce nail thickness.

Traumatic nail disorders

Nails may show signs of acute trauma, scars following acute trauma or chronic repetitive trauma.

Acute trauma

Acute trauma is classified with respect to severity, ranging from a small haematoma to digit amputation (Table 62.5).

Table 62.5 Classification of acute trauma. (From Van Beek *et al*. [1].)

Type	Effect	Therapy
I	Small haematoma associated with a small break in the nail bed	Fenestration of nail over the haematoma
II	Large haematoma with significant nail bed injury	Remove nail in order to identify site and nature of subungual damage
III	Large haematoma, nail plate displaced	X-ray may reveal fracture of terminal phalanx, usually in association with nail bed laceration which requires resorbable 6/0 suture
IV	Severe crush injury	Avulsion needed to reveal matrix, with multiple lacerations requiring careful reconstruction
V	Amputation of tip of digit, may include parts of matrix	If tip can be retrieved, it should be used as a graft. Otherwise nail bed from other sites may provide autologous grafts

Nail bed laceration

The nail bed may be lacerated by different forms of trauma, including incisions, crush and avulsion injuries. In simple injuries there is displacement of the nail plate, which may be found proximally avulsed but retaining distal attachment to the nail bed. In this form of trauma, and in many others, the nail plate can be used as a useful splint [1]. Initially, the nail bed damage should be assessed by avulsion, and then the nail can be replaced after any necessary nail bed repair has been performed; a small window for drainage of blood and exudate is made in the nail [2]. More complicated injuries may require flap or graft reconstructions and, in some instances, vascularized composite nail grafts are used with microvascular anastomoses. When the wounds arise from crush injury, fracture is relatively common. If the distal tuft has been fractured to leave fragments of bone dispersed in the soft tissues, it may prevent long-term morbidity if these are removed [3].

Delayed trauma

The most common kind of chronic deformity following an acute injury is a split nail or reduction in the length of the nail bed with consequent overcurvature of the tip of the nail.

Cure of a split-nail deformity is difficult, with only a modest chance of success [1]. Sometimes, there is an associated pterygium. Treatment entails excision of the nail bed and matrix scar and, in the case of a pterygium, a split-skin graft may be placed on the ventral aspect of the proximal nail fold to help prevent recurrence of the pterygium. It is important to keep the wounded aspects of nail bed or matrix separate from the overlying nail fold after surgery, and this is often best done by returning the nail plate after soaking it in antiseptic during the procedure.

If treatment is required for a shortened distal phalanx with nail bed changes, there are two choices [2]: the entire nail can be phenolized, or a V–Y advancement flap can be performed based on two neurovascular pedicles.

Haematoma [1,2]

Subungual bleeding is a common sign. It may present as a feature of acute trauma, with pain due to the recent event in combination with pain arising from the pressure exerted by the subungual accumulation of blood. A haematoma arising within the matrix will be incorporated into the nail plate [3]. The only treatment that can be offered is to relieve the pressure, and if seen soon after the injury this can be done by puncturing the nail, for instance with a hot pointed implement, cautery or a small drill. This procedure will relieve pain and may save the nail. The possibility of an underlying fracture must be considered for larger haematomas [1]. As a general rule, if more than 25% of the visible nail is affected, the nail plate should be removed. However, there is evidence to challenge this rule. A comparison between two groups of children having exploration and repair or trephination alone showed fewer complications in the latter group and considerably less investment in medical time [4]. With less extreme trauma, a haematoma may not develop immediately and may be painless. This is most common in the toes and may give rise to clinical uncertainty as to whether it represents early subungual melanoma. A history of traumatic sporting hobbies is useful, and signs of symmetrical nail trauma and inappropriate footwear all point towards trauma as the cause of the appearance. In this situation, making a small punch in the surface of the nail may reveal old blood as the source of pigment. Malignancies can bleed and so confirmation of blood does not refute the possibility of a tumour; however, as an isolated finding in the absence of other clues, this test should be sufficient to obviate the need for surgical exploration. An alternative is to score a transverse groove in the nail at the proximal margin of the pigment and observe over a few weeks as the discoloration grows out. If pigment continues to spread proximal to the groove, surgical exploration is needed.

Chronic repetitive trauma

Chronic repetitive trauma may take several forms. Some have been considered in other sections detailing transverse ridges produced by a habit tic (see Fig. 62.22, p. 62.28), the canaliform dystrophy of Heller (Fig. 62.44; see p. 62.55) and chronic paronychia (see Fig. 62.18, p. 62.24).

Fig. 62.44 Median canaliform dystrophy of Heller.

Fig. 62.45 Nail biting can be extensive, with damage to the nail folds and nail plate causing subungual haemorrhage.

Nail biting

The nail plate, periunguium and nail bed are all subject to nail biting and picking. Although fingers are most commonly involved, rarely toenails are also bitten [1]. This produces distinctive features, which are found in 60% of children, 45% of adolescents and 10% of adults [2]. The majority of moderate nail biters have no associated psychiatric disorder [3,4]. Focal abnormalities, such as viral warts, are often a complication, whether as a cause or as a result of the Koebner effect after biting. Severe damage may be associated with self-mutilating disorders such as Lesch–Nyhan syndrome.

The nails are typically short, with up to 50% of the nail bed exposed. The free edge may be even or ragged. Surface change may include splitting of the nail into layers or a sand-papered effect, and the nail may acquire a brown longitudinal streak [5]. The most aggressive nail biting (onychotillomania/onychophagia) can produce subungual haemorrhage, strips of nail loss, with residual spurs or loss of the entire nail (Fig. 62.45). Onychotillomania may be allied to parasitophobia when the patient picks off pieces claiming that they contain parasites [6]. A rough and irregular nail and nail fold may result. Many fingernails are involved. Oral pimozide may be beneficial [7].

Direct damage and secondary infection may make nail loss permanent or result in pterygium formation. The nail folds are sometimes bitten in addition to, or as a substitute for, the nail. This can lead to bleeding and chronic paronychia with acute infective exacerbations. This in turn may lead to nail plate damage or ridging and nail fold scarring. In cases associated with infection, osteomyelitis of the terminal phalanx can develop [8,9]. Subjects will sometimes deny nail biting and attribute the appearance to a disease that stops nail growth. Transverse grooves scored proximally in the nail plate will confirm that the nail is growing by moving distally with time. In aggressive nail biting, the groove may be eroded from the surface.

Trauma is sometimes inflicted by other nails, with pushing back of the proximal nail fold as part of a habit tic (see p. 62.28). This results in serial transverse ridges and depressions running up the midline of the nail, associated with loss of the cuticle. In more conscious forms of self-damage, sharp instruments are used to produce dermatitis artefacta of the nail unit, and the nail fold is commonly preserved [10].

Treatment. Treatment is often unsuccessful and cure relies largely on the motivation of the patient. Local antiseptics and antimicrobial ointments may help settle the infection secondary to nail unit damage. Those with the most bitter taste are often prescribed in the belief that this will discourage biting. This is seldom the case. Antidepressants [11] and behavioural therapy [12] have been used with some success in limited studies.

Hang nails

These are due to hard pieces of epidermis breaking away from the lateral nail folds. Although often due to nail biting, they may result from many other minor injuries. The splits may be painful when they penetrate to the underlying dermis. They should be removed with sharp pointed scissors.

Nutcracker nails

Under this heading, Cohen [1] described splitting and onycholysis caused by the habit of separating the two halves of cracked walnuts over a period of 10 years.

REFERENCE

Damage from nail manicure instruments

Metal instruments, such as a nail file or scissors, wooden or plastic orange sticks, or nail whitener pencils may create acute or chronic injuries in the nail area. Onycholysis may result from using the sharp point for cleaning under the nail plate. Nails, however, are best cleaned with a nail brush and soap, because overzealous manicure, pushing back the cuticles, may result in white streaks across several nails. Cleaning around the nail with contaminated instruments may lead to acute or chronic paronychia. According to Brauer and Baran [1], it is not advisable to cut or clip the nail plate, as this produces a shearing action that weakens the natural layered structure and promotes fracturing and splitting. An emery board is preferred for shaping the fingernail by filing from the sides of the nail towards the centre.

Fig. 62.46 Early onychogryphosis of the left great toenail.

Trauma from footwear

Onychogryphosis and nail hypertrophy [1–5]

Onychogryphosis is an acquired dystrophy usually affecting the great toenail, which is thickened, yellow and twisted. It is most commonly seen in the elderly [1,2,4], although trauma and biomechanical foot problems may precipitate similar changes in middle age or earlier.

At one time, onychogryphosis was known as ostlers' nail, owing to the fact that some cases could be traced to injury caused by a horse trampling on the foot of the ostler. Competitive sport is a more contemporary cause. The injury once sustained is aggravated by footwear and, as the nail becomes longer and thicker, the damage from the footwear becomes progressively more important. Nail hypertrophy implies thickening and increase in length, whereas onychogryphosis implies curvature also.

Some cases of nail hypertrophy are intrinsic, and this applies especially to toenails other than the nail of the great toe. The nail becomes thick and circular in cross-section instead of flat, and thus comes to resemble a claw. There are two possible explanations for this formation.

1 There is insufficient matrix under cover of the posterior fold to exert a flattening effect. The altered relationship between matrix and proximal nail fold in post-mortem specimens supports this.

2 The nail bed is contributing a greater quantity of keratin to the nail than usual. It is usually possible to exclude this on clinical grounds as there is often an element of onycholysis that separates the dystrophic nail from the nail bed.

Hypertrophy of fingernails is usually traumatic in origin and is often the result of a single injury.

In onychogryphosis, one or more nails become greatly thickened (Fig. 62.46) and, with neglect, increase in length, becoming curved like a ram's horn. The nails of the great toes are most often involved, but no toenail is exempt. It is possible that the nail plate distortion produced by chronic untreated onychomycosis may be partly responsible for

Fig. 62.47 (a–c) Onychogryphosis is often best treated with ablation of the nail matrix.

onychogryphosis at a later stage. In extreme cases, the free edge may press on or even re-enter the soft tissues of the foot.

Treatment of onychogryphosis and nail hypertrophy is either radical or palliative. Radical treatment consists of surgical removal of the nail and matrix and is recommended in those with good circulation (Fig. 62.47). Palliative treatment requires regular paring and trimming of the affected nails, usually by a chiropodist using nail clippers and a file or mechanical burr. The thickened nails are extremely hard and trimming is difficult. Not infrequently, the nail is invaded by granulation tissue from the nail bed, and incision of this during trimming will result in pain and haemorrhage.

Other causes of thickened nails are psoriasis, pityriasis rubra pilaris, Darier's disease, fungal infections, pachyonychia congenita, congenital ectodermal defects and congenital malalignment of the great toenails [6].

Ingrowing toenail [1–3]

SYN. ONYCHOCRYPTOSIS

The soft tissue at the side of the nail (lateral nail fold) is penetrated by the edge of the nail plate, resulting in pain, sepsis and, later, the formation of granulation tissue [4]. Penetration is often caused by spicules of nail at the edge of the nail plate, which have been separated from the main portion of the nail. The great toes are those most often affected. The main cause for the deformity is compression of the toe from the side due to ill-fitting footwear, and the main contributory cause is cutting the toenails in a half-circle instead of straight across. Anatomical features, such as an abnormally long great toe and prominent lateral nail folds, are important in some cases. In recent years, the condition may have been caused in a minority of cases by the successful therapy of fungal infections of the nails with griseofulvin: a nail that has been infected for a long time is reduced in size, and the nail bed shrinks around it; when the infection is even partly overcome the nail plate is increased in size, the nail bed is no longer large enough to accommodate the whole of the new nail, and the lateral nail fold may be penetrated on each side.

In infancy, ingrowing toenail most commonly occurs before shoes are worn, associated with crawling, 'pedalling' or wearing undersized 'jumpsuits' [5]; acute paronychia may be associated [6]. Rarely, it is congenital [7] and even familial [2]. In children, ingrowing is commonly distal rather than lateral. Management is conservative in most instances, with topical steroid and antiseptic preparations. Surgery is occasionally required [8].

The first symptoms are pain and redness, shortly followed by swelling and pus formation. Granulation tissue then forms and adds to the swelling and discharge. More severe infection may follow. There is seldom any difficulty with diagnosis. Excess nail fold granulation tissue can also be a feature of amelanotic melanoma and reactions to medications such as retinoids, ciclosporin, antiretroviral drugs and chemotherapy [9–15].

Treatment. Treatment may be difficult and prolonged. The first essential is to insist on the patient wearing shoes sufficiently wide and pliable to remove lateral pressure [16]. Any abnormality of foot/toe function should be corrected. The patient must also be instructed to cut the nail straight across instead of in a semicircle. The nail must be allowed to grow until its edges are clear of the end of the toe before it is cut; this prevents the further formation of marginal spicules. In the early stages, the infection may be overcome by the application of antiseptics and by inserting a pledget of cotton-wool under the edge of the nail. Taping the toe or applying plastic gutters between nail edge and nail fold are alternatives [17]. Twice-daily warm-water baths followed by careful drying and powdering are helpful. If the infection is more severe and there is local cellulitis, an appropriate systemic antibiotic should be administered. When granulation tissue forms this should be destroyed by cauterization with a silver nitrate stick. It is important that an amelanotic melanoma is not missed [18], and if there are atypical features a biopsy should be performed.

If conservative measures fail, operative intervention will be necessary. Removing the nail alone is likely to result in recurrence of ingrowing when the nail returns [19] and so should be combined with a curative procedure such as phenolization of the relevant part of the matrix [4,20]. Although surgical excision of matrix can provide an excellent result, it is more dependent than phenolization on the skill of the practitioner. In large studies, phenol treatment results in a greater cure rate and less morbidity [19]. Where there is diabetes or impaired peripheral circulation, surgery may require avoidance of prolonged or tight tourniquet application, and close follow-up. Phenolization can be undertaken safely in diabetics [21]. Carbon dioxide laser has been used, although it lacks the analgesic properties intrinsic to phenol [22].

The nail and cosmetics

Dermatologists need to know the therapeutic options open to a patient when drugs or surgery may not provide the ideal aesthetic or functional solution to a medical problem. Professional cosmetic advice may be the most appropriate step in some cases, such as individuals with permanent unsightly dystrophy. However, the dermatologist may gain most experience of nail cosmetic products through their adverse effects, as they occasionally cause injury to the nail and surrounding tissues and may cause reactions at distant sites. In this section, the basic ingredients of nail preparations are considered together with the pathological changes sometimes induced by them [1,2]. In assessing eczematous and other periungual reactions, it is important also to realize that nail tissues, particularly the subungual and paronychial areas, may be 'reservoirs' for small amounts of cosmetic preparations applied by hand to other parts of the skin, leading to 'ectopic dermatitis'; these may also, rarely, be responsible for dystrophy of the nail apparatus.

Nail coatings represent an attractive nail enhancement. They may harden upon evaporation (nail polish) or polymerize (sculptured nails, gels, preformed artificial nails).

Coatings that harden upon evaporation

Nail polish

The term 'nail lacquer' is sometimes used to include enamels, top coats and base coats, either as separate entities or combined in one product. Although chemically similar, they contain different ratios of the same constituents to lend different characteristics. The base coat is used to improve the adhesion or bonding of enamel to the nail. A top coat improves the depth and lustre of the enamel and increases its resistance to chipping and abrasion. Nail polishes consist of solids and solvent ingredients, the former representing about 30%, the latter 70% of the product. The ingredients can be divided into six principal groups.

1 Cellulose film formers (e.g. nitrocellulose): provide gloss, body and gel structure.

2 Resins (e.g. toluene sulphonamide formaldehyde resin): improve the gloss and adhesion of the film.

3 Plasticizers (e.g. dibutylphthalate): give the film pliability, minimize shrinkage, and soften and plasticize the cellulose.

4 Thixotropic suspending agents (e.g. bentonite) for non-settling and flow: keep pigments in suspension on shaking.

5 Solvents and diluents (e.g. toluene): keep nitrocellulose, resin and plasticizer in the liquid state and control the application and drying time.

6 Colour substances: these are either inorganic (iron oxides) or a variety of certified organic colours (D and C yellow A1 lakes).

Recently, there has been a move away from toluene and formaldehyde resin, and most recently avoidance of dibutylphthalate due to potential health risk.

'Pearls' or 'frosts' are produced by bismuth oxychloride and titanium dioxide coated with mica and guanine (obtained from fish scales). 'Clears' contain a small tint.

The base coat is formulated in a manner similar to standard lacquer, but it has a lower non-volatile content (less nitrocellulose) and lower viscosity, because a thinner film is desirable; it may also contain hydrolysed gelatine. In the top coat the nitrocellulose content is increased and the resin is reduced. A slight increase in plasticizer content improves elasticity of the film. There is no pigment. The top coat often has an added sunscreen.

Reactions such as an allergic contact dermatitis to nail polish frequently appear on any part of the body accessible to the nails, with paradoxically no signs in or around the nail apparatus [3]. The commonest areas involved are the eyelids, the lower half of the face, the sides of the neck and the upper chest. Generalized dermatitis may rarely occur. Sometimes the use of nail polish on stockings to stop 'runs' or on nickel-plated costume jewellery to prevent nickel dermatitis may induce nail-polish dermatitis on the legs or at the site of metal contact. Nail-polish dermatitis may occur in the user's partner or other close contacts. Although any ingredient may account for distant allergic contact dermatitis, toluene sulphonamide formaldehyde resin is the most common culprit. After the nail polish is removed, the dermatitis usually clears rapidly unless secondary infection or lichenification has occurred. Metal pellets present in some bottles to maintain a liquid state may cause nickel reactions and onycholysis.

Nail plate staining from the use of polish is most commonly yellow/orange in colour. It typically starts near the cuticle, extends to the nail tip and becomes progressively darker from base to tip. With time, the dyes penetrate the nail too deeply to be removed. Injury to the nail plate from nail lacquers is rare. However, 'granulation' of nail keratin, a superficial friability, can be observed in some instances where individuals leave nail lacquer on for many weeks or where there is poor formulation of the product. For patch testing, several nail lacquers should be used and tested 'as is'; they should be allowed to dry for 15 min because the solvents and diluents may cause false-positive reactions. The following substances should be included in the test battery.

Toluene sulphonamide formaldehyde resin (10% in petrolatum)

Nickel (5% in petrolatum); dimethylglyoxime spot test for nickel

Glyceryl phthalate resin (polymer resin) (10% in petrolatum)

Pearly material: guanine powder (pure)

Formaldehyde (1% aqueous)

Colophony (20% in petrolatum); drometrizole (Tinuvin P) (1–5% in petrolatum).

The resin contains no free formaldehyde. Formaldehyde is merely the chemical moiety on which the resin is formed. Usually, formaldehyde-sensitive individuals do not cross-react with this resin. However, it has been suggested that there is always a small amount of free formaldehyde present in many preparations. Various cosmetic companies now make varnishes that are formulated without the sensitizing resin and are toluene-free.

Nail polish removers. These are composed of various solvents such as acetone. Occasionally, nail polish removers cause trouble by excessive drying of the nail plate and may be responsible for some inflammation of nail folds.

Coatings that polymerize [4,5]

Sculptured nails

The basic kit of sculptured nails is sold as a set containing a template, a liquid monomer and a powdered polymer. Self-curing acrylic resins are created by polymerization of methyl methacrylate monomer and polymethyl methacrylate powder with an organic peroxide and an accelerator. They harden at room temperature. The compound has to be moulded on the natural nail. The acrylic compound is applied to the nail, which has been roughened on the surface. When hardened, the compound produces a prosthetic nail that is enlarged and elongated by repeated applications. The prosthesis can be filed and manicured to shape; as the plate grows out, further applications of acrylic can be made to maintain a regular contour.

Technicians who sculpt nails should be instructed to wash their hands before touching the face or eye area. Usually, the area involved is the chin, which technicians tend to rest in their hands. Additionally, they should be warned to avoid contact with the dust of freshly applied product and to avoid using the wet product.

Allergic reactions. Allergic reactions due to sculptured nails may occur 2–4 months, and even as long as 16 months, after the first application. The first indication is an itch in the nail bed. Paronychia, which is usually present in allergic reactions, is associated with excruciating pain in the nail area, and sometimes with paraesthesia. The nail bed is dry and thickened, and there is usually onycholysis. The natural nail plate becomes thinner, split and sometimes discoloured. It takes several months for the nails to return to normal. Permanent nail loss is exceptional, as is intractable prolonged paraesthesia [6].

Patch tests most commonly show reactions to the acrylic liquid monomer and not to the polymer; this is similar to denture allergy (see Chapter 20).

Improper application and maintenance. With continued wear, the edges of the sculptured nails become loose. These must be clipped and then rebuilt to prevent the development of an environment prone to bacterial and, beneath the nail plate, candidal infection. In fact, this is a result of improper application and maintenance. Failure to file the prosthetic nail every 2 weeks will result in the creation of a lever arm that predisposes to traumatic onycholysis or damage to the natural nail. Onycholysis is very common with nail extensions that are too long.

Irritant reactions. Irritant reactions to monomers are possible. These manifest as a thickening of the nail bed's keratin layer, which can sometimes cause the entire nail bed to thicken with or without onycholysis. Nonetheless, the overwhelming majority of cases result from physical trauma or abuse.

Damage to the natural nail is not unusual after 2–4 months of wear of a sculptured nail. If it becomes yellow or crumbly, this means that the product was applied and maintained incorrectly. The patient should find a better-qualified nail technician. The problem may well not be the acrylic nail materials but rather the thinning of the nail due to excessive filing with heavy abrasives.

Primer (methacrylic acid) is a strong irritant, which may produce third-degree burns. It is hazardous if the cuticles are flooded or spills are not washed out immediately. Primer can permeate the plate and soak into the nail bed if the nails are too thin. Soap or baking soda, used with water, are excellent neutralizers. If primer gets into the eye, it should be flushed with water for at least 15 min, and a Poisons Information Centre should be contacted.

Premixed acrylic gels

Gel system products are premixed and either acrylic-based (14% of the market) or cyanoacrylate-based (1% or less of the market). Their virtual lack of odour makes gels popular in full-service beauty salons. UV light-cured gels are the best known of the different gel technologies. These gels contain urethanes and (meth)acrylate compounds, a photoinitiator and cellulose, which necessitates antiyellowing agents and a UV light unit. The gel remains in a semi-liquid form until cured in a photobonding box. The proportion of resins to monomers determines the gel consistency. When the gel is exposed to light of an appropriate wavelength, polymerization occurs, resulting in hardening of the gel. UV gels never involve catalysts and often do not employ primers.

Gel enhancement products shrink by up to 20%, which may result in lifting and tip cracking. As an effect of excessive shrinkage, clients may comment that the enhancement feels tight on the nail bed. Other symptoms include throbbing or warmth below the nail plate. This may lead to tender, sore fingertips. Photobonded acrylate has been observed to cause nail reactions, sometimes with nail loss and paraesthesia. Hemmer *et al*. [7] have patch tested

'hypoallergenic' commercial products in patients wearing photobonded acrylic nails who had perionychial and subungual eczema. Triethyleneglycol dimethacrylate, hydroxyfunctional methacrylates, and (meth)-acrylated urethanes proved to be relevant allergens in photobonded nail preparations. Meth-acrylated epoxy resin sensitization was not observed. The omission of irritant methacrylic acid in UV-curable gels does not reduce the high sensitizing potential of new acrylates. Contrary to the manufacturers' declarations, all 'hypoallergenic' products continue to include acrylate functional monomers and therefore continue to cause allergic sensitization. Gels and acrylics, being chemically distinct entities, will not necessarily cross-react.

Unreacted UV gel in the dusts and filings may produce distant allergic reactions. Although sensitization to butylhydroxytoluene is possible, gels usually contain acrylated oligomers and monomers. Acrylates are far more likely to cause sensitization than methacrylates or stabilizers.

Finally, thick ornately painted gel false nails that may be difficult to remove present a real challenge to pulse oximetry. It appears to be the polish more than the sculpted nail that interferes with the readings [8,9].

Preformed plastic nails

Preformed plastic nails are packaged in several shapes and sizes to conform to the normal nail plate configuration. Such nails are trimmed to fit the fingertip and are fixed with cyanoacrylate adhesive supplied with the kit. The usefulness of these prosthetic nails is limited by the need for some normal nail to be present for attachment. Normal physical and chemical insults to the nails cause the preformed plastic nails to loosen. If the preformed nails remain in place for more than 3 or 4 days, they may cause onycholysis and nail-surface damage. Eczematous, painful paronychia due to cyanoacrylate nail preparations may be observed after about 3 months. Dystrophy and discoloration of the nails may become apparent and last for several months. In some cases, distant contact dermatitis of the face and eyelids occurs. On patch testing, the patients react far more often to the adhesive than to the prosthetic nails. Suggested test substances are *p*-tertiarybutylphenol resin (1% in petrolatum), tricresyl ethyl phthalate (5% in petrolatum), cyanoacrylates and other glues (5% in methylethylketone).

Nail-mending kits

These include paper strips of a basic film-forming product to create a 'splint' for the partially fractured nail plate. The split is first bonded with cyanoacrylate glue, then the nail is painted with fibred clear nail polish. A piece of wrap fabric is cut and shaped to fit over the nail surface. This is then embedded in polish of high solid content, and several coats are applied.

Nail wrapping

In nail wrapping, the free edge of the nail should be long enough to be splinted with paper, silk, linen, plastic film or fibreglass and fixed with cyanoacrylate glue. After drying, the edge is shaped, and the nail is coated with enamel.

Removal of nail coatings that polymerize. The most commonly used solvent for removal of nail products is acetone. Warming the solvent with great care can cut product removal time in half. However, most gels are difficult to remove because they are highly cross-linked and resistant to many solvents. Therefore, if gel enhancements have to be removed, slowly file (not drill) the enhancement with a medium-grit file, leaving a very thin layer of product. Soak in warm product remover and, once softened, scrape the remaining product away with a wooden pusher stick.

Cuticle removers

These are lotions or gels containing approximately 0.4% sodium or potassium hydroxide. The lotion is left in place for 1–3 min and then washed off. Creams containing 1–5% lactic acid (pH 3–3.7) are also used.

Nail hardeners

Nail keratin can be hardened by tissue fixatives such as formaldehyde. These are not commercially available in the USA because of their toxic effects. Nail changes caused by such nail hardeners may include pain, subungual haemorrhage and bluish discoloration of the nail. The nail returns to normal when the offending agent is discontinued. Formaldehyde nail hardeners have been reported as causing onycholysis and allergic contact dermatitis; they may also act as irritants. Patch testing should be with formaldehyde (1% aqueous). Because of its irritant qualities, reactions should be interpreted with caution.

Silicone rubber nail prosthesis [10]

In a wide variety of cases, ranging from deformed nail to complete loss of the terminal phalanx, a silicone rubber, thimble-shaped finger-cover may be indicated. This prosthesis is easily fitted on the finger stump, encasing the entire distal phalanx; it must be fine and flexible to maintain pulp sensitivity and must have the same marking and colouring as the finger. The fixation is excellent and the nail form takes nail varnish well.

Nail cream

This is an ordinary water-in-oil moisturizing cream, with low water (30%) and high lipid content. It is applied, after cleaning the hands, to prevent or diminish brittleness.

Nail buffing

Weekly buffing may be indicated for removing small particles of nail debris, thus enhancing the lustre and smoothness of the nail plate. Buffing creams, which contain waxes and finely ground pumice, and buffing powders are abrasive and should not be overused on thin nails.

Nail whitener

This is a pencil-like device with a white clay (kaolin) core used to deposit colour on the undersurface of the free edge of the nail.

Infection risks

Secondary infection with *Candida* or bacteria is a hazard for anyone with an irritant or allergic contact dermatitis of the periunguium. Where this is associated with artificial nails, the prosthetic nails may be longer than usual and so reduce the ability to keep the area clean. Prosthetic nails are sometimes worn because there are underlying problems with the natural nails, such as cracks or onycholysis. These features may also lower the threshold to certain types of infection.

Medical staff with artificial nails may put patients at risk through carriage of pathogens [11] and it is a common operating theatre rule that artificial nails should not be worn [12]. Nail varnish is also thought to be associated with bacterial carriage when it becomes chipped, although the evidence for this is less strong [13]. Infection through nail salons and the manicuring process is a further factor that adds to the risks for those with artificial nails [14].

Conclusion

Nail beauty therapy may certainly produce an attractive enhancement and disguise unsightly nail conditions but it may also represent a potential hazard due to instrument damage, and is not recommended for psoriatic nails as it may provoke the Koebner phenomenon.

Chapter 63

Disorders of Hair

D.A.R. de Berker, A.G. Messenger & R.D. Sinclair

Anatomy and physiology

[A.G. Messenger, pp. 63.1–63.18]

Introduction

Hair has no vital function in humans, yet its psychological functions are extremely important, as any clinical dermatologist or cosmetician can readily attest from routine daily practice. If the inevitability of scalp baldness makes it reluctantly tolerable to genetically disposed men, in women, loss of hair from the scalp is distressing as is the growth of body or facial hair in excess of the culturally accepted norm.

The evolutionary history of hair is no less enigmatic. Mammals probably evolved from Therapsid reptiles during the Late Triassic period over 200 million years ago (MyA). The earliest direct evidence of hair in mammals comes from fossilized casts and impressions in coprolites and pellets from the Late Paleocene beds of Inner Mongolia [1]. Hairs from at least four extinct mammalian taxa were identified, notably the multituberculate *Lambdopsalis bulla*, all showing striking preservation of the cuticular scale pattern. The three extant mammalian groups—monotremes, marsupials and placental mammals—all possess hair, indicating its presence prior to their divergence which probably took place 115–130 MyA [2]. The multituberculate lineage extends back into the Triassic, suggesting that hair is a very ancient and possibly defining feature of mammals. Whatever its origin, it is clear that the warm-blooded mammals owe much of their evolutionary success to the properties of the hairy pelage as a heat insulator. Paradoxically, Man's movement from the ancestral forest home to populate the globe is linked with a reversion to relative nudity and an ability to keep cool. Moreover, hair serves other purposes: in particular, it is concerned with sexual and social communication by constructing adornments such as the mane of the lion or the beard of the human male, or assisting in the dispersal of scents secreted by complexes of sebaceous or apocrine glands.

For these evolutionary reasons, hair follicles are not all under identical control mechanisms. To match the animal coat to seasonal changes in ambient temperature or environmental background requires moulting and replacement of the hairs. The process appears to involve an inherent follicular rhythm, modified by circulating hormones such as melatonin, prolactin, androgens or thyroxine, whose secretion is geared to environmental cues through the pineal gland, hypothalamus and pituitary.

The control of sexual hair growth must be clearly differentiated from that of the moult cycle. The development of pubic, axillary and other body hair is delayed until puberty because it is dependent upon androgens in both sexes; that 'male' hormones are, in contrast, also a prerequisite

for the manifestation of androgenetic alopecia still defies adequate explanation.

In all mammals, including humans but with the possible exception of the merino sheep and the poodle dog, hair follicles show intermittent activity. Thus, each hair grows to a maximum length, is retained for a time without further growth, and is eventually shed and replaced.

Types of hair

Different types of hair may be produced by different kinds of follicle, and the type of hair produced in any particular follicle can change with age or under the influence of hormones. Animals characteristically have both an overcoat of stiff guard hairs and an undercoat of fine hairs [3], but many kinds of follicle and fibre have been described. Many species also have large vibrissae or sinus hairs, which are sensory and are produced from special follicles containing erectile tissue, but there are no strictly comparable follicles in humans. In humans, a prenatal coat of fine soft unmedullated and usually unpigmented hair, known as *lanugo*, is normally shed *in utero* in the eighth to ninth month of gestation. Postnatal hair may be divided at the extreme into two kinds: vellus, which is soft, unmedullated, occasionally pigmented and seldom more than 2 cm long; and terminal hair, which is longer, coarser and often medullated and pigmented. However, there is a range of intermediate kinds. Before puberty, terminal hair is normally limited to the scalp, eyebrows and eyelashes. After puberty, secondary sexual 'terminal' hair is developed from vellus hair in response to androgens.

Development and distribution of hair follicles

Human hair follicles appear first in the regions of the eyebrows, upper lip and chin at about 9 weeks of embryonic development, and in other regions in the fourth month [4]. Hair over most of the scalp passes through a complete cycle and is shed *in utero*, and follicles in these regions have re-entered anagen by the time of birth. In the occipital scalp, telogen is delayed until after birth and this may give rise to a patch of hair loss in this region in the neonatal period. A fuller account of embryonic development is given in Chapter 3.

In humans, the full complement of hair follicles is probably established by the time of birth. Follicle density is highest in the fetus, when it may be similar across the skin surface. With growth there is a progressive reduction in follicle density, which continues until adult life, as skin surface area increases (Table 63.1). This occurs to a greater degree over the trunk and limbs than over the head so that the reduction in follicle density is less marked on the head than elsewhere [5]. The highest hair follicle densities, in the region of 800/cm^2, are found on the forehead and cheeks, with rather lower values for visible vellus hairs on the forehead in young adults of both sexes, and on the cheeks in women (400–450/cm^2) [6]. Lower hair densities of 50–100/cm^2 are found on the chest and back in both sexes [6,7], and follicle densities of approximately 50/cm^2 on the thigh and leg [5]. Published values for the average scalp hair density in white people vary between 250 and 320 hairs/cm^2 [8–11]. Scalp hair density shows a normal distribution in the population, with a wide range [11]. There is also racial variation in scalp hair density: average hair density in Africans (187/cm^2) [12] and African Americans (171/cm^2) [13] is lower than in white people, and it is lower still in Koreans (128/cm^2) [14].

Table 63.1 Hair follicle density in human fetal and adult skin. In adults, hair follicle density is highest on the head and much lower on the trunk and limbs. At 24 weeks' gestational age hair follicle density is similar in forehead and thigh skin. There is a pronounced reduction in thigh hair follicle density by adult life but only a small fall on the forehead. (Adapted from Szabo [5].)

	Fetal skin					
	24 weeks		Full term		Adult	
	Mean	±	Mean	±	Mean	±
Cheek					830	40
Forehead	1060		1060	110	765	20
Scalp					350	50
Forearm					95	15
Thigh	1010	250	480	40	55	5
Lower leg					45	10
Abdomen					70	15
Chest					75	25

Anatomy of the hair follicle (Fig. 63.1)

Hair is the keratinized product of the hair follicle, a tube-like structure continuous with the epidermis at its upper end. The follicles are sloped in the dermis, and longer follicles extend into the subcutaneous layer. An oblique muscle, the arrector pili, runs from the mid-region of the follicle wall to a point in the papillary dermis close to the dermal–epidermal junction. Above the muscle, one or more sebaceous glands, and in some regions of the body an apocrine gland also, open into the follicle. The hair fibre is made up of three cell layers: an outer cuticle, the cortex (which forms the bulk of the fibre in most hair types) and a variable central medulla, all of which derive from highly proliferative cells in the hair bulb at the base of the follicle. Cells in the hair bulb also give rise to the inner root sheath which surrounds the hair fibre and which disintegrates before the hair emerges from the skin. The inner root sheath is itself enclosed by the outer root sheath, which forms a continuous structure extending from the hair bulb to the epidermis, although the functions and microscopic structure of the outer root sheath vary along the length of the follicle. The hair follicle also has a specialized dermal component, which includes the dermal or connective tissue sheath surrounding the follicle, and the dermal papilla which invaginates the hair bulb.

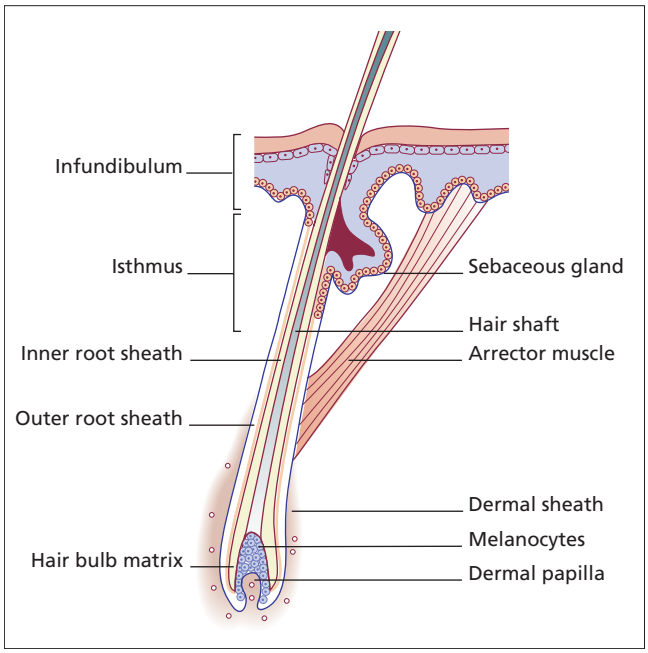

Fig. 63.1 Diagram of an anagen hair follicle.

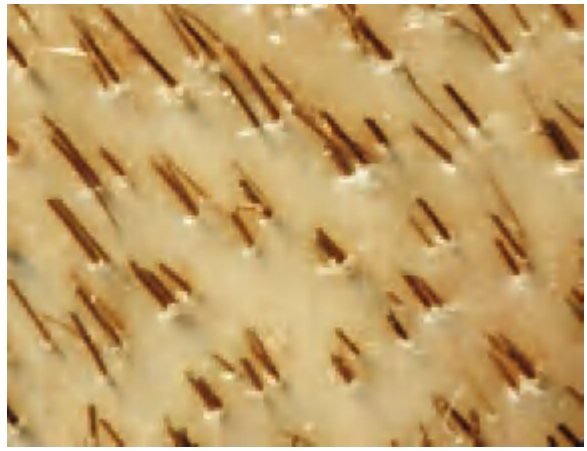

Fig. 63.2 Grouping of hairs in follicular units on human scalp. In some groups, multiple hairs emerge from a single follicular opening.

The hair follicle is conventionally divided into two regions: the upper part consisting of the infundibulum and isthmus and the lower part comprising the hair bulb and suprabulbar region. The upper follicle is a relatively constant structure, whereas the lower follicle undergoes repeated episodes of regression and regeneration during the hair cycle. On the scalp, and some other regions of the skin, hair follicles are arranged in groups of three or more follicles known as follicular units (Fig. 63.2). Several follicles within a follicular unit may coalesce so that hairs emerge through a common infundibulum.

The infundibulum

The infundibulum extends from the skin surface, where it merges with the epidermis, to the opening of the sebaceous duct at the junction with the isthmus. Infundibular epithelium differentiates in a similar manner to epidermis, producing a granular layer and stratum corneum which desquamates into the follicular lumen.

The isthmus

The isthmus extends from the opening of the sebaceous gland duct to the insertion of the arrector pili muscle. It consists of a multilayered outer root sheath that is continuous with the infundibulum but differs in its structure. The innermost cells lack a granular layer and undergo a pattern of differentiation known as trichilemmal keratinization. The keratinized inner root sheath, which lies within the outer root sheath, disintegrates at or about the level of the sebaceous duct. The arrector muscle loops around the follicle in the manner of a sling [1]. Each follicular unit is supplied by a single arrector muscle, which splits to encircle each follicle within the follicular unit [2].

Hair follicle stem cells are thought to reside in the lower part of the isthmus close to the insertion of the arrector

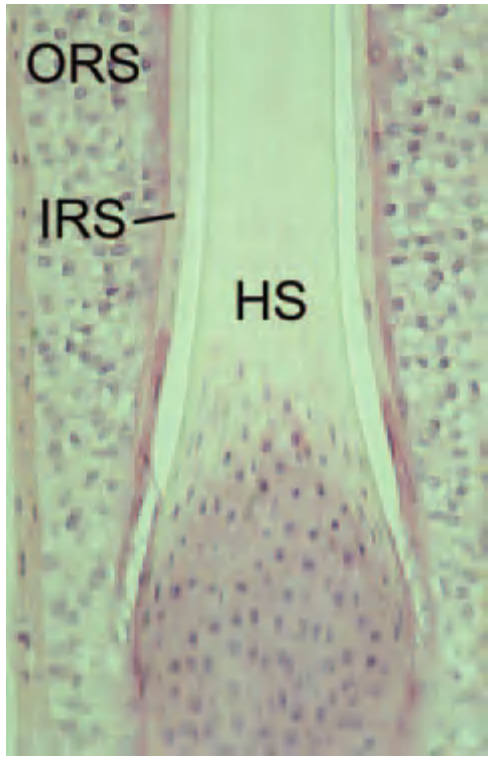

Fig. 63.3 Longitudinal section through suprabulbar region of an anagen follicle showing the keratogenous region of the hair shaft (HS). The inner root sheath (IRS) is keratinized at this level. ORS, outer root sheath.

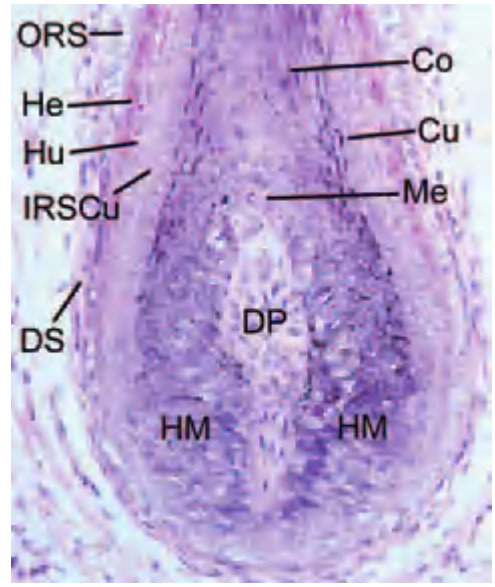

Fig. 63.4 Anagen hair bulb. Co, hair cortex; Cu, hair cuticle; DP, dermal papilla; DS, dermal sheath; He, Henle's layer; HM, hair matrix; Hu, Huxley's layer; IRSCu, inner root sheath cuticle; ORS, outer root sheath.

muscle [3]. During embryogenesis, and in adult follicles in other species, this region shows a distinctive bulge, although a clearly defined bulge is often not seen in human adult hair follicles. Hair follicle stem cells show distinctive biochemical properties, they are slow cycling and proliferate only during the onset of anagen. Daughter cells, known as transient amplifying cells, input into the outer root sheath of the lower part of the hair follicle whence they migrate in a downward direction. On entering the hair bulb matrix, they proliferate and undergo terminal differentiation to form the hair shaft and inner root sheath [4]. The progeny of hair follicle stem cells may also migrate distally to form the sebaceous gland and, under certain circumstances such as wound healing, the epidermis.

The suprabulbar region (Fig. 63.3)

The suprabulbar region of the follicle, below the isthmus and above the hair bulb, is comprised of three layers from outermost to innermost: outer root sheath, inner root sheath and hair shaft. The outer root sheath is a multilayered epithelium enclosing the inner root sheath which, at this level, is a fully keratinized structure. Cells of the hair shaft, at the centre of the follicle, undergo terminal differentiation within the keratogenous zone in the middle part of the suprabulbar region. Keratinization of the inner root sheath precedes that of the hair shaft, suggesting that the inner root sheath has a role in 'moulding' the shape of the hair fibre.

The hair bulb (Fig. 63.4)

In large terminal follicles, the deepest part of the follicle, the hair bulb, is situated in the subcutaneous fat. The hair bulb is invaginated at its base by the dermal papilla, which is connected to the perifollicular dermal sheath by a narrow stalk. The hair shaft and the inner root sheath are derived from epithelial cells surrounding the dermal papilla, a region known as the hair bulb matrix or germinative epithelium. These cells have a high mitotic rate, with a rate of cell turnover similar to that in the bone marrow. Daughter cells migrate in an upward direction and differentiate in a highly ordered fashion to form the concentric layers of the inner root sheath and the hair shaft. The inner root sheath derives from cells in the lower, more lateral part of the matrix, whereas the hair shaft is formed from the upper, centrally situated cells. In pigmented hair follicles, highly melanized melanocytes are situated amongst cells destined to form the hair cortex. Occasional Langerhans' cells may also be found in the matrix region. The outer root sheath surrounds the inner root sheath. At the level of the hair bulb it consists of a single layer of cells, which can be followed almost to the lower tip of the hair follicle.

The dermal papilla

In anagen follicles, the dermal papilla is a flask-shaped structure that invaginates the base of the hair follicle. It is made up of specialized fibroblast-like cells embedded in an extracellular matrix rich in basement-membrane proteins and proteoglycans, and in large follicles the dermal papilla often contains a loop of capillary blood vessels. It is connected to the dermal sheath surrounding the follicle by a narrow stalk. Both the dermal papilla and the dermal sheath are derived from a condensation of mesenchymal cells, which appear at an early stage in follicular embryogenesis. Tissue recombinant studies have shown that the dermal papilla plays an essential part in the induction and maintenance of follicular epithelial differentiation [5–8]. It is responsible for determining the follicle type, so that cultured dermal papilla cells derived from the rat vibrissae follicle induce the formation of a vibrissa-like follicle when implanted into ear skin [9]. The volume of the dermal papilla may also be responsible for controlling the size of the hair follicle, and that of the hair fibre [10,11]. This is of particular relevance to androgen-dependent changes in human hair growth, as the dermal papilla is probably the primary target of androgen action in the hair follicle.

The dermal sheath

The lower part of the hair follicle is enveloped by a collagenous layer known as the dermal or connective tissue sheath. Like dermal papilla cells, fibroblasts of the dermal sheath are highly specialized. In experimental circumstances, these cells can reconstitute the dermal papilla and induce the formation of new hair follicles in adult human skin [12]. As we move distally along the hair follicle, above the level of the arrector insertion, the dermal sheath becomes less distinct, both structurally and functionally, as it merges with the interfollicular dermis.

The inner root sheath

The inner root sheath consists of three layers (from outermost to innermost): Henle's layer, Huxley's layer and the inner root sheath cuticle. Inner root sheath cells accumulate filaments approximately 7 nm thick and, in contrast with the hair cortex, amorphous trichohyalin granules appear in the cytoplasm. As the cells move up the follicle towards the surface, the filaments become more abundant and the number and size of the granules increase. Each of the three layers of the inner root sheath undergoes abrupt keratinization. This occurs at different levels in each layer, although the patterns of change are identical. In the hardened cytoplasm, however, only filaments can be seen. The changes occur first in the outermost Henle's layer, then in the innermost cuticle and lastly in Huxley's layer, which is situated between them. Cells of the inner root sheath cuticle become flattened and overlap, with their free edges pointing downwards to interdigitate with the upwards-pointing cells of hair shaft cuticle, thus anchoring the hair shaft within the hair follicle. The inner root sheath hardens before the presumptive hair within it, and it is consequently thought to control the definitive shape of the hair shaft.

The outer root sheath

The outer root sheath forms the most peripheral layer of hair follicle epithelium, enclosing the inner root sheath. At the lower tip of the hair bulb it consists of a single layer of cuboidal cells, becoming multilayered in the region of the upper hair bulb. The cytoplasm of outer root sheath cells is rich in glycogen, giving a clear appearance with routine histological stains. In some follicles, particularly large beard follicles, there is a distinct single cell layer interposed between the outer and inner root sheaths, known as the companion layer [13]. Companion layer cells are flattened along the axis of the follicle and are relatively devoid of glycogen. They show numerous intercellular connections to the inner root sheath and are thought to migrate distally along with the inner root sheath to be lost in the isthmus region. The direction of movement of outer root sheath cells is unclear but they may migrate downwards towards the hair bulb, the companion layer forming the plane of slippage between the inner and outer root sheaths. The outer root sheath of the suprabulbar region merges imperceptibly with the isthmus where the innermost cells undergo tricholemmal keratinization.

The cuticle

The hair cuticle is formed initially as a single cell layer, but the cells become progressively imbricated (tile-like) as they move peripherally. The cells become flattened, first in a direction at right angles to the plane of the follicle, and then becoming progressively angulated so that the outer edges of the cells point in an upward direction. The flattened cells overlap, their free edges directed towards the tip (Fig. 63.5) and interlocking with the cuticle of the surrounding inner root sheath. In the fully formed hair shaft, the cuticle consists of 5–10 overlapping cell layers, each 350–450 nm thick (Fig. 63.6). The mature cells are thin scales consisting of compact cuticular keratin, associated with ultra-high sulphur proteins, which show three distinct layers by transmission electron microscopy: the outer A-layer, which is particularly rich in cystine; the exocuticle (also cystine-rich); and the inner endocuticle, which is virtually devoid of sulphur. The endocuticle has an irregular substructure of membrane-like elements which are probably the remnants of cytoplasmic structures [14].

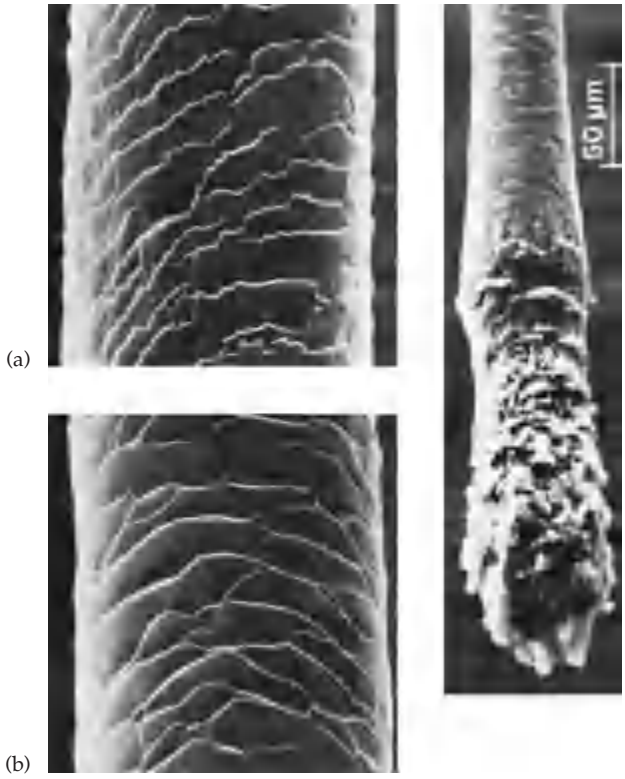

Fig. 63.5 (a) Surface view of weathered cuticular scales in the distal portion of the hair shaft. (b) Surface view of undamaged cuticular scales in proximal part of hair shaft. (Courtesy of Dr D. Jackson, University of Sheffield, Sheffield, UK.)

The outer surface of the cuticle is thought to be coated with long-chain (straight and branched) fatty acids linked to an underlying lipid–protein matrix [15]. This layer is 2–7 nm thick and is known as the fibre cuticle surface membrane or epicuticle. The cuticle has important protective properties. It acts as a barrier to physical and chemical insults, and also maintains the integrity of the hair shaft. Wear and tear (e.g. from cosmetic procedures) leads to gradual degradation of the cuticle ('weathering'), with breaking and lifting of the free margins of cuticular cells. Eventually this process may lead to exposure of the cortex and fracture of the hair shaft.

The cortex

Cells destined to form the cortex gradually become more fusiform in shape as they migrate upwards from the hair bulb. They develop a dense filamentous cytoskeleton in the upper hair bulb to become fully hyalinized in the suprabulbar region (the keratogenous zone) (Fig. 63.7). The hard α-keratin intermediate filaments (α-KIF) are the major structural component of the mammalian hair cortex. The molecule in α-KIF is an obligate heteropolymer containing a type I and a type II polypeptide chain [16,17], in which right-handed α-helices coil round one another in a left-handed manner to form a rod-like dimeric structure (a 'coiled coil') (Fig. 63.8). The 8-nm keratin filaments (microfibrils) are formed from multiple α-KIF molecules, on average 16 molecules or 32 chains in cross-section [18]. Keratin filaments are cross-linked to keratin-associated proteins, which form a matrix between the filaments. More than 60 hair keratin-associated proteins have been found in various species. They are classified into three major families: high sulphur, ultra-high sulphur and high glycine–tyrosine proteins [19]. In some species, notably the sheep, the cortex can be divided into two regions: the orthocortex and paracortex, which differ in the arrangement of KIFs and the proportion of keratin-associated

proteins. In humans, the hair cortex appears to contain mixtures of KIF arrangements within each cell.

The medulla

The medulla is a variable structure in human hairs, where it may be continuous, discontinuous or absent. Large diameter hairs are more likely to contain a medulla, although the relationship between hair diameter and medullation is not clear-cut. The medulla develops quite abruptly around the upper pole of the dermal papilla, without any obvious precursor cell population. Medullary cells contain distinctive eosinophilic granules that eventually form internal coatings within the membranes of mature cells. As these cells develop, arginine residues are converted to citrulline, and isopeptide bonds are formed to yield a highly insoluble protein complex [20]. Mature medulla cells have a spongy structure, with amorphous material bounding air spaces of varying sizes.

Hair follicle innervation

A plexus of longitudinally aligned sensory nerve fibres surrounds the isthmus region. Small nerve fibres may also be arranged in a circular fashion outside the longitudinal fibres. Several different types of nerve endings are found around human hair follicles, including free nerve endings, pilo-Ruffini nerve endings and Merkel nerve endings [21,22]. In other species, lamellated nerve endings are found in richly innervated sinus hair follicles (e.g. vibrissae follicles), which have specialized sensory function [22]. Merkel cells, with or without associated nerve endings, may be found within the bulge region epithelium and the surrounding connective tissue sheath, and it has been postulated that their secretions are involved in regulating the hair cycle [23].

The hair cycle (Fig. 63.9)

Hair follicles undergo a repetitive sequence of growth and rest known as the hair cycle. The timing of the phases of the hair cycle and its overall duration varies between

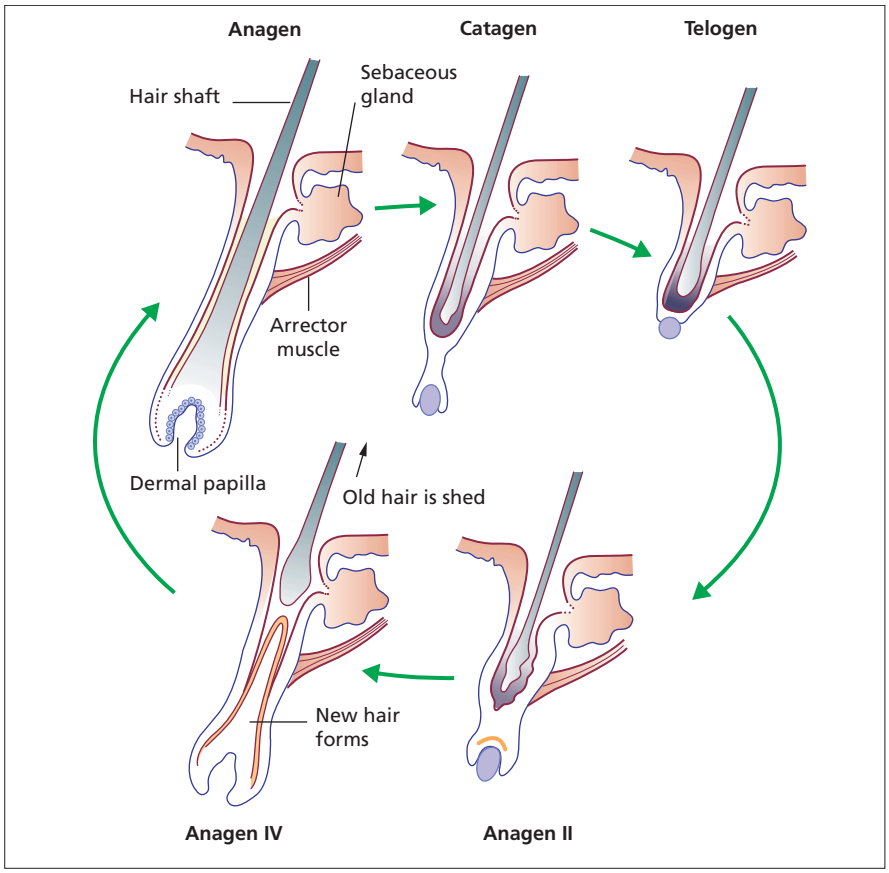

Fig. 63.9 The hair cycle. (From *Disorders of Hair Growth*, McGraw-Hill.)

Fig. 63.10 Scalp hair follicle in Anagen 2 stage of development. The club hair from the previous cycle is still present within the follicle. (Courtesy of Dr A.J.G. McDonagh, Royal Hallamshire Hospital, Sheffield, UK.)

species, between follicles in different regions of the skin in the same species and, in some animals, between different follicle types, such as guard hairs and underhairs, in the same region of the skin.

The period of active hair growth is known as *anagen* and the duration of this phase is responsible for determining the final length of the hair. In most hair follicles in most animals, anagen is relatively brief, lasting a few weeks at most. In some hair follicles, such as those on human scalp, the horse's tail and wool follicles in the merino sheep, anagen may continue for several years, so that very long hairs are produced. Under normal circumstances, 80–90% of hair follicles on the human scalp are in anagen at any one time.

The entry of a resting hair follicle into anagen is heralded by the onset of mitotic activity in epithelial cells overlying the dermal papilla at the base of the follicle (the secondary epithelial germ). In most follicle types (vibrissa follicles are an exception), the lower part of the follicle elongates downwards along a preformed dermal tract (the stele). The developing hair bulb partly envelops the dermal papilla, and epithelial cells start to differentiate to form the inner root sheath and the hair shaft (Fig. 63.10). The dermal papilla expands from a tightly packed ball of cells into a flask-shaped structure where the cells become separated by an extracellular matrix rich in proteoglycans and basement-membrane proteins. A network of capillary blood vessels develops around the lengthening follicle, extending into the dermal papilla in larger follicles. In the fully developed anagen follicle, epithelial cells in the hair bulb undergo vigorous proliferative activity. Their progeny move distally and differentiate in an ordered fashion to form the layers of the inner root sheath and the hair shaft. At the end of anagen, epithelial cell division declines and ceases, and the follicle enters an involutionary phase known as *catagen*. During catagen, the proximal end of the hair shaft keratinizes to form a club-shaped structure and the lower part of the follicle involutes by apoptosis (Fig. 63.11). The basement membrane surrounding the follicle becomes thickened and corrugated to form the 'glassy membrane'. The base of the follicle, together with its dermal papilla, moves upwards, eventually to lie just below the level of the arrector insertion. The period between the completion of follicular regression and the onset of the next anagen phase is termed *telogen*. The club hair lies within an epithelial sac to which it is attached by tricholemmal keratin. The club hair is eventually shed through an active process termed *exogen*. In many species, follicles re-enter anagen prior to shedding of the club hair so that the old hair is not shed until the follicle is well into its next growth phase. This may also be

Fig. 63.12 Bactrian camel in spring moult.

seen in human follicles although it is unusual for a club hair to be retained much beyond the mid-stage of anagen development. In human scalp, hair follicles may remain in a state of latency for a prolonged period after the club hair is shed [1].

Control of the hair cycle

It is thought that hair cycling is controlled primarily within individual hair follicles but that this intrinsic rhythmic behaviour may be modulated by both local and systemic factors. In most newborn mammals, including humans, hair cycles are coordinated in a wave-like fashion (moult waves) across regions of the skin in the neonatal period. Moult waves are regulated within the skin and are accompanied by changes in other skin structures, such as epidermal and dermal thickness. Hence, skin flaps raised on the flanks of rats, rotated through 90–180° and then replaced, continue to moult in their original direction for a prolonged period [2,3]. Homografts between isogenic animals of different ages also retain the moult pattern of the donor, whereas autografts retain that of the recipient [4]. Hair cycles in homografts eventually come into phase with the surrounding skin as do those in rats of different ages joined parabiotically, suggesting that the factors regulating synchrony are able to diffuse into the grafted skin. In many mammals, living in their natural environment in temperate and higher latitudes, moult waves continue into adult life and occur on a seasonal basis. This allows adaptation of the thickness of the coat, and sometimes its colour, to different climatic conditions in summer and winter (Fig. 63.12). In humans, and some other mammals such as the guinea pig, synchronous hair cycling is lost rapidly with increasing age so that, beyond the neonatal period, hair follicles cycle independently of their neighbours. In these circumstances, hair cycling must be regulated by mechanisms intrinsic to the hair follicle.

Seasonal hair growth

Seasonal moulting is regulated by the endocrine system under the influence of environmental signals. The most important of these is change in day length (the photoperiod) [5,6]. Temperature may act as a modifying factor in some species. Changing levels of melatonin production by the pineal gland have a key role in orchestrating endocrine control of seasonal hair growth [7–9]; pinealectomy prevents seasonal moulting, whereas administration of melatonin advances onset of the growth of the winter coat and prevents growth of the summer coat. Prolactin production by the pituitary correlates inversely with melatonin levels, being raised during the summer and falling during the winter. Pinealectomy abolishes the fall in prolactin level in animals kept in short day length conditions and prevents the development of the winter coat [10]. The same response is seen in animals treated with prolactin. Prolactin receptors have been identified in the hair follicle, suggesting that prolactin can affect hair growth directly [11]. Pineal and pituitary hormones may also act indirectly by modulating the activity of peripheral endocrine glands. In rats, estradiol, testosterone and adrenal steroids delay the onset of anagen, whereas gonadectomy and adrenalectomy have the opposite effect [12]. Conversely, thyroid hormones accelerate the onset of follicular activity, whereas thyroidectomy or treatment with propylthiouracil delays it. Seasonal moults are also delayed by testosterone and accelerated by thyroxine in other species [13]. Hormones also act on the anagen phase of hair growth [12]. Estradiol and thyroxine both reduce the duration of anagen in rats, but estradiol decreases the rate of hair growth, whereas thyroxine has the opposite effect, suggesting these hormones have different points of action. In the mouse, oestrogen receptors are expressed in the dermal papilla and the inhibitory effect of exogenous oestrogen on hair growth is prevented by topical treatment with an oestrogen receptor antagonist [14].

Vestiges of seasonal variation in hair growth are present in humans [15], although the magnitude is seldom sufficient to be noticeable. The best example of a systemic influence on the human hair growth cycle is pregnancy (Fig. 63.13) [16]. During pregnancy, there is an increase in the proportion of follicles in anagen, although it is not clear whether this is caused by prolongation of anagen or more rapid shedding of telogen hairs, as there is also a reduction in hair density during the second and third trimesters [17]. Following childbirth, large numbers of follicles enter telogen, leading to increased shedding from about 3 months postpartum (postpartum telogen effluvium). Telogen shedding may also be caused by a number of drugs and by febrile and other catabolic illnesses [18].

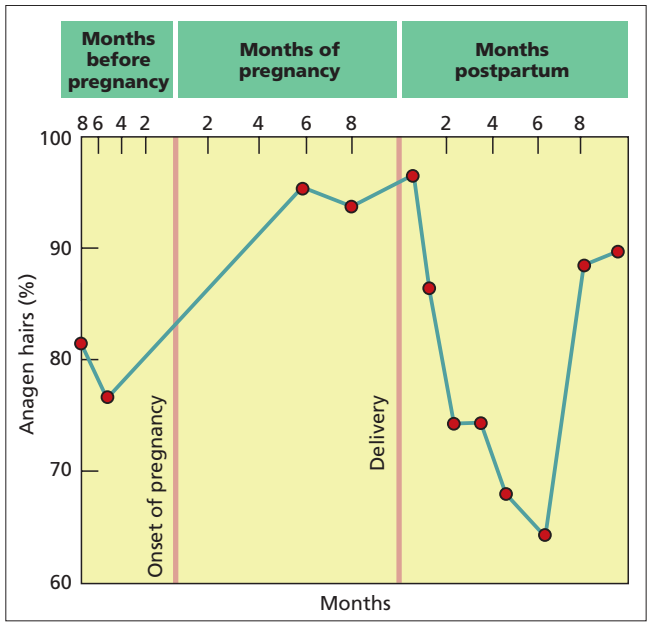

Fig. 63.13 Percentage of anagen hairs in a 25-year-old woman before, during and after pregnancy. (From Lynfield [16].)

Intrinsic control of the hair growth cycle

Although local and systemic factors modulate the hair cycle in some species, in humans and some other mammals hair cycling is asynchronous. Hair follicles in different regions of the skin may also cycle differently. In humans, for example, the duration of anagen on the scalp may last several years, whereas on the eyebrows anagen is very brief. Even in animals showing seasonal hair growth, hair cycles in different follicle types in the same skin region are not necessarily in phase. When scalp hair follicles are transplanted into other regions of the skin they retain the cyclical behaviour of the donor site, indicating that cycle control is determined within the follicle or its immediate tissue environment. Interactions between two key cell populations in the hair follicle, epithelial stem cells in the outer root sheath and mesenchymal cells in the dermal papilla and dermal sheath, are thought to underlie intrinsic control of hair cycling, and a large number of molecules have been implicated in this process. However, the location and the nature of the 'switch' that initiates and terminates anagen growth are unknown.

It has been known for many years that plucking of resting hairs from telogen follicles advances the onset of anagen. This led to the idea that the hair cycle is controlled by a locally active inhibitor which accumulates during anagen causing entry into catagen when present in sufficient concentration (the chalone hypothesis) [19]. The putative inhibitor would disperse during telogen, and plucking resting hairs could accelerate this process. The chalone hypothesis has been disputed because the plucking of resting hairs from follicles that have already entered anagen does not prolong the anagen in progress, although it does advance the onset of the next anagen cycle [12]. There is one report that murine skin contains a factor that inhibits hair growth *in vivo* and *in vitro* [20]. This inhibitory factor, which has not been characterized, appeared to be derived from the epidermis and was present in telogen skin but not in anagen skin.

Cotsarelis *et al.* [21] have suggested that anagen is initiated by signals from the dermal papilla which stimulate mitosis in stem cells in the bulge region of the outer root sheath (the bulge activation hypothesis). As transient amplifying cells, daughter cells have a limited mitotic potential. When this is exhausted, hair growth ceases and the follicle enters catagen, thus determining the duration of anagen and the onset of catagen.

Several other ideas to explain hair cycle periodicity have been proposed [22] but, for the present, these remain at a theoretical level.

Molecular control of hair cycling

A wide variety of molecules and genes have been implicated in controlling the hair cycle (Table 63.2). These include developmental genes, several families of growth factors and their receptors, nuclear receptors, neurotrophins, cytokines and intracellular signalling pathways. These molecules have generally been studied in isolation, although they undoubtedly operate in a complex milieu of interactions and cross-talk about which little is currently known. The expression level of many of these molecules fluctuates during the hair cycle, and it is difficult to know whether this is of functional significance or is secondary to the metabolic and structural cycle-related changes in the hair follicle. However, there are some examples where there is convincing evidence of a physiological role.

The origin of the signals that initiate anagen has not been identified, and it is not known whether these signals are negative, as proposed in the chalone hypothesis, or positive, or both. Locally synthesized parathyroid hormone-related peptide (PTHrp) is a possible inhibitor of anagen, as injection of a PTHrp antagonist into murine skin accelerates the onset of anagen and delays catagen. Several growth factors appear to be involved in promoting anagen, including insulin-like growth factor 1 (IGF-1), hepatocyte growth factor, keratinocyte growth factor and vascular endothelial growth factor. The *sonic hedgehog* gene and its receptor *patched* also promote anagen in adult follicles as well as being essential for follicular development. Anagen development is a time of extensive remodelling of the follicle and its tissue environment. Follicles grown *in vitro* synthesize a variety of metalloproteinases, suggesting that this process involves degradation of the surrounding extracellular matrix. Hair follicles also express tissue inhibitor of matrix metalloproteinase 3 (TIMP-3) in the outer root sheath during anagen, implying

Table 63.2 Molecular mediators of hair cycle control.

Growth factor	Location	Function
FGF5	ORS	Terminates anagen [23]
FGF7 (KGF)	DP	Induces hair growth in athymic nude mice [24] Hair shaft defect in KGF deficient mice [25]
EGF/TGF-α		Inhibits hair development and growth [26,27] Stimulates ORS proliferation *in vitro* [28]
EGF-R	Hair bulb and ORS	Wavy hair in EGF-R deficient mice [29]
TGF-α		Wavy hair in TGF-α deficient mice [30]
TGF-β1, 2, 3		Inhibits hair growth *in vitro* [31] TGF-β mRNA expressed in skin during anagen/catagen transition [32]
TGF-β receptors		TGF-β receptors expressed in hair follicle—maximal during anagen/catagen transition [33] Delayed catagen in TGF-β1 null mice [34]
IGF-1	DP, hair bulb	Maintains hair follicle growth *in vitro* [35]
IGF-1 receptors	DP, pre-cortex, ORS	Down-regulated in catagen [36]
IGF BP-3, -4, -5	DP and DS [37]	
HGF		Stimulates hair growth when injected into mouse skin [38] Expression in skin varies during hair cycle: high in anagen, low in telogen [39]
VEGF	DP, ORS	Probably regulates perifollicular angiogenesis. Increased follicle size in transgenic mice which overexpress VEGF in ORS. Systemic VEGF antibody retards hair growth in mice [40]
IL-1α, IL-1β		Inhibit hair growth *in vitro* [41]
TNF-α		Inhibits hair growth *in vitro* [41]. TNF-α receptor mRNA expression increased in late anagen [36]
Sonic hedgehog (SHH)		Overexpression in skin accelerates entry into anagen [42] SHH antibody inhibits pelage (but not vibrissae) follicle development in mice. Inhibits anagen in postnatal cycles [43]
Hairless		Required for normal catagen [44]
PTHrp	Follicle epithelium	Inhibits initiation and maintenance of anagen. PTHrp antagonist induces and prolongs anagen [45]
RXR		Required for normal catagen? [46]
Vitamin D receptor	DP, ORS	Variable expression during hair cycle [47] Alopecia in vitamin D receptor knockout mice [48] and in human vitamin D-resistant rickets [49]
Oestrogen receptor	DP	Oestrogen inhibits hair growth in mice [50]
Neurotrophins	Follicle epithelium	NGF, brain-derived neurotrophic factor, neurotrophin-3, neurotrophin-4, and p75 neurotrophin receptor, TrkB receptors promote progression of catagen [51,52]
Mast cells		Increased degranulation at end of anagen and fall in number during telogen. May be involved in control of catagen [53]

DP, dermal papilla; DS, dermal sheath; EGF, epidermal growth factor; FGF, fibroblast growth factor; HGF, hepatocyte growth factor; IGF, insulin-like growth factor; IGF BP, IGF binding proteins; IL-1, interleukin-1; KGF, keratinocyte growth factor; ORS, outer root sheath; PTHrp, parathyroid hormone-related peptide; RXR, retinoid X receptor; TGF, transforming growth factor; TNF, tumour necrosis factor; VEGF, vascular endothelial growth factor.

that remodelling involves a carefully controlled sequence of positive and negative influences.

The end of anagen and transition into catagen is a key period in the hair cycle, as its timing determines the final length of the hair. Catagen may be initiated as a passive process through exhaustion of the mitotic potential of transient amplifying cells in the hair bulb or the loss of action of growth promoting agents. Also, several growth factors and cytokines, including transforming growth factor-β (TGF-β), interleukin-1α (IL-1α) and tumour necrosis factor-α (TNF-α) have an inhibitory effect on hair growth and may be actively involved in triggering catagen. Transgenic mice with a null mutation in the gene for fibroblast growth factor 5 (*FGF5*) show a delay in the onset of catagen and grow abnormally long hair. The phenotype is identical to the naturally occurring *angora* mouse which has a mutation in the *FGF5* gene, suggesting that this growth factor has an active role in terminating anagen

[23]. *FGF5* is expressed in the outer root sheath towards the end of anagen, in keeping with this idea. However, although anagen is delayed in *FGF5*-deficient mice, it is not delayed indefinitely, indicating that other factors must also be involved.

Catagen proceeds in an orderly fashion as cells are deleted from the regressing epithelial column by apoptosis. The expression levels of several proto-oncogenes associated with apoptosis, including c-*myc*, c-*jun* and c-*myb*, change immediately prior to or coincident with the onset of catagen [32]. The apoptosis-inhibitory proto-oncogene *bcl*-2 is expressed in cycling follicular epithelium during anagen, disappears during catagen and is absent in telogen. *Bcl*-2 is expressed in the dermal papilla throughout the hair cycle, suggesting a possible protective role in this site [54].

For the follicle to maintain the ability to cycle, it must maintain its integrity during catagen regression. In the *hairless* mouse, the first coat develops normally but the pelage is then lost. Towards the end of the first anagen phase, cells in the hair bulb undergo extensive premature apoptosis, and formation of the epithelial column is disrupted during catagen. The dermal papilla loses contact with the base of the hair follicle epithelium and the follicle is unable to re-enter anagen. Follicular remnants subsequently undergo cystic degeneration [44]. A similar pattern of hair loss is seen in the human disorder, atrichia with papular lesions, in which there is a mutation in the human homologue of the mouse *hairless* gene [55]. The function of *hairless* in the hair follicle is not fully established but there is some evidence that it acts as a co-repressor of the thyroid receptor (TR). Atrichia with papules also occurs in some families with vitamin D-resistant rickets [48], which is caused by a mutation in the vitamin D receptor (VDR) gene. Like the TR, the VDR is a transcription factor and a member of the nuclear hormone receptor superfamily. Both TR and VDR bind to response elements in target genes as heterodimers with the retinoid X receptor (RXR), another nuclear hormone receptor. Transgenic mice with a null mutation in the RXR gene also show a *hairless* phenotype [46], suggesting there is a common pathway involving nuclear hormone receptors that regulates entry into catagen.

Although generally regarded as a state of quiescence, it is possible that active mechanisms are also needed to maintain a follicle in telogen. For example, expression of the oestrogen receptor in dermal papillae of murine hair follicles is increased during telogen, and oestrogens inhibit entry into anagen [56], although the physiological relevance of this observation is unknown. Release of the club hair from the follicle, a process that has been termed *exogen* [57], does not necessarily coincide with re-entry of the follicle into anagen, and this has led to the idea that shedding is controlled separately from the hair cycle. The club root lies embedded in tricholemmal keratin and its release presumably requires local proteolysis. The cells surrounding the club root are also rich in desmosomes. Transgenic mice with a null mutation in the gene for the desmosomal protein desmoglein 3 show defective anchorage of the club hair [58].

Role of the immune system in hair cycling

Cells in the lower part of the hair follicle, below the arrector insertion, show reduced or absent expression of class I major histocompatibility complex (MHC) molecules [59]. In rat skin the expression of class I MHC in follicular epithelium increases during catagen, and this is associated with a perifollicular accumulation of activated macrophages and loss of the proteoglycan-rich extracellular matrix [60]. These observations led to the suggestion that an immune process mediated by macrophages contributes to control of the hair cycle but other studies have failed to confirm these findings [61]. However, there is experimental support for the idea that the lower part of the hair follicle is an immunologically 'privileged' site not subject to classic immune surveillance [62,63]. This is relevant to disease states, such as alopecia areata, which may be explained by a breakdown of putative immune privilege.

Rate of hair growth

The rate of hair growth varies from species to species, and within one species from region to region, as well as with sex and age. For example, in the rat it can be more than 1 mm/24 h [64] and in the guinea pig up to 0.6 mm/24 h, whereas in humans it is much less. The rate has been determined by direct measurement of marked hairs *in situ* [65], by shaving and clipping at selected intervals [66,67] or by pulse labelling with ^{35}S-cysteine [68–70]. Most investigators now use macrophotographic methods (phototrichography), which may be analysed using computerized systems. Comparable measurements are obtained by all methods. The average rate of growth of human hair has been stated to be approximately 0.03 mm/24 h for the vellus on the male forehead [71], 0.21 mm/24 h on the female thigh and 0.38 mm/24 h on the chin of a young male. On the crown of the scalp it averaged approximately 0.5 mm/24 h, being slightly less on the margins. In another study in which graduated capillary tubes were fitted around the growing hairs, the average growth in males was as follows: vertex 0.44 mm/24 h; temple 0.39 mm/24 h; chest 0.44 mm/24 h; beard 0.27 mm/24 h [72]. The average rate on the vertex of women was 0.45 mm/24 h and there were no variations diurnally or during the menstrual cycle. Although scalp hair grows faster in women than in men [72,73], the rate before puberty is greater in boys than in girls [74]. The average rate over the whole body is greater in men than in women [67]. Irrespective of

sex, growth appears to be highest in the two decades between 50 and 69 years of age [67]. From studies on the guinea pig, it seems clear that the growth rate depends upon the time for which the activity of the follicle has been in progress [75].

There is agreement that shaving has no effect on the rate of growth [72,76]. Various endocrine factors have been shown to influence the rate of hair growth in animals; for example, oestrogens reduce it [64,77] and thyroxine increases it [78].

Hair pigment and melanogenesis in the follicle

See p. 63.108.

Androgens and hair growth

Androgens influence hair growth in several ways. First, they participate in the endocrine control of moulting in animals that show seasonal hair growth [1]. Secondly, in some mammals, androgens stimulate the growth of hair follicles in certain regions of the skin following sexual maturity. Thirdly, in humans and some other primates, androgens are necessary for the development of balding on the scalp.

Androgen-stimulated hair growth

The growth of obvious facial, trunk and extremity hair in the male, and of pubic and axillary hair in both sexes, is clearly dependent on androgens. The development of such hair at puberty is, in broad terms and at least initially, in parallel with the rise in levels of androgen from testicular, adrenocortical and ovarian sources, which occurs in both sexes and is somewhat steeper in males. That testosterone from the interstitial cells of the testis is responsible for growth of beard and body hair in male adolescence and that testicular activity is itself initiated by gonadotrophic hormones of the pituitary is unquestioned. However, the findings that growth-hormone-deficient boys and girls are less than normally responsive to androgens, and that growth hormone is necessary as a synergistic factor to allow testosterone to be fully effective with respect to hair growth [2], as well as protein anabolism and growth promotion, suggest that hypophysial hormones also have a more direct role. Direct evidence of the role of testicular androgen is that castration reduces growth of the human beard [3], whereas testosterone stimulates it in eunuchs and elderly men. The role of androgen is further demonstrated in the treatment of hirsute women with the antiandrogen cyproterone acetate [4], which reduces the definitive length, rate of growth, diameter and extent of medullation of the thigh hairs [5].

At puberty, terminal hair gradually replaces vellus, starting in the pubic regions. In both sexes the first pubic hair is sparse, long, downy, slightly pigmented and almost straight. It later becomes darker, coarser, more curled and extends in area to form an inverse triangle. A British study showed that boys had the first recognizable pubic hair at an average age of 13.4 years, and the full adult 'male' pattern at 15.2 years, approximately 3.5 years after the start of development of the genitalia [6]. The corresponding mean ages for girls were considerably earlier, namely 11.7 years and 13.5 years [7]. In approximately 80% of men and 10% of women the pubic hair continues spreading until the mid-twenties or later; there is no absolute distinction between male and female patterns, only one of degree.

Axillary hair first appears approximately 2 years after the start of pubic hair growth. The amount, as measured by the weight of the fully grown mass, continues to

increase until the late twenties in males as well as in females, in whom, however, it is less at any age [3]. The mean amounts grown per day increase from late puberty until the mid-twenties and thereafter decrease steadily.

Facial hair in boys first appears at about the same time as the axillary hair, starting at the corners of the upper lip, and spreading medially to complete the moustache and then the cheeks and beard.

Terminal hair development is continued in regular sequence on the legs, thighs, forearms, abdomen, buttocks, back, arms and shoulders [8]. The extent of terminal hair tends to increase throughout the years of sexual maturity, but most patterns occur over a wide age range. The adult pattern is not achieved until the fourth decade, when the androgen levels are already somewhat lower than in early adult life. Moreover, aural hairs do not appear until late middle age, and a study of coarse sternal hair in men showed that the hairs continue to increase in length and number from puberty to the fifth or sixth decade.

There is considerable racial variability in androgen-dependent hair growth. The growth of facial and body hair is greater in European men than in Chinese men [3] and there is also variation within these broad racial categories—southern European men tend to be hairier than men from northern Europe [9].

Androgenetic alopecia

It has been known since ancient times that eunuchs do not go bald. Hippocrates noted that 'eunuchs are not subject to gout nor do they become bald' (Aphorisms VI, 28). The role of testosterone in male balding was first recognized by James Hamilton, a US anatomist [10]. He observed that men castrated before puberty retain a prepubertal hairline and do not go bald. Of 12 such men who were treated with testosterone, four developed typical male hair loss. Castration later in life halted the progression of hair loss but did not result in regrowth of hair.

The prevalence and severity of male balding increase with age. All races are affected but the prevalence is higher in white males, reaching at least 80% in men aged over 70 years, than in African American [11] and in Japanese men [12]. Chinese and Korean men are also less likely to show frontal recession [13,14]. Genetic factors undoubtedly predispose to the development of male balding, but little is known of the genes involved and the mode of inheritance is also uncertain.

The loss of hair in male balding is the result of a gradual reduction in the duration of anagen and a prolongation of the latent period of the hair cycle [15], and miniaturization of terminal hair follicles [16].

Androgen synthesis and metabolism

The initial stages in the synthesis of steroid hormones from cholesterol occur exclusively in the gonads and the adrenal glands. Circulating androgens are also derived from the peripheral conversion of weak precursor hormones into potent androgens, a process that takes place in many tissues including the skin and hair follicles. The majority of androgens in the circulation are bound to plasma proteins, principally sex hormone-binding globulin (SHBG), with approximately 20% bound to albumin. The remaining 1–2% circulates in a free unbound form and this comprises the biologically active pool. Androgen bound to albumin dissociates readily and can replenish the free pool. SHBG binds androgen with high affinity and its plasma concentration therefore has an important effect on the free and albumin-bound pools. High levels of SHBG reduce the biologically active androgen level and low levels of SHBG have the reverse effect. Free androgen is thought to enter cells by passive diffusion where it binds to a specific intracellular androgen receptor.

Testosterone is the major circulating androgen, but in most body sites the effect of testosterone on hair growth is mediated by its more potent metabolite 5α-dihydrotestosterone (DHT). The conversion of testosterone to DHT is catalysed by the enzyme 5α-reductase. There are two isoforms of 5α-reductase, which are encoded by different genes [17]. Although both enzymes catalyse the conversion of testosterone to DHT they differ in their pH optima, substrate affinities and tissue distributions. Type 1 5α-reductase is widely distributed in the skin, but expression of the type 2 isoform is restricted to androgen target tissues such as the prostate and the epididymis. Much of our knowledge of the biological role of DHT in hair growth comes from studies of men with 5α-reductase deficiency (type II pseudohermaphroditism, pseudovaginal perineoscrotal hypospadias) [18,19], which is caused by mutations in the 5α-reductase 2 gene [20]. In this autosomal recessive disorder, genetic males (46XY) are born with normally differentiated but usually undescended testes. The external genitalia are ambiguous with a small hypospadic phallus, a bifid scrotum and a blind vagina. Partial virilization of the genitalia occurs at puberty, the voice deepens and the musculature assumes a typical male distribution. Circulating testosterone levels are within or above the normal male range but DHT levels remain low, with testosterone : DHT ratios 3.5–5 times higher than normal. Subjects show a female pattern of androgen-dependent hair growth, with terminal hair largely restricted to the axillae and the lower pubic triangle, suggesting that hair growth in these sites responds to less potent androgens. In the large group of subjects studied in the Dominican Republic, beard growth was absent or sparse. More facial hair has been observed in affected men from other parts of the world, perhaps reflecting underlying racial differences in normal androgen-dependent hair growth, although this was reduced compared with normal males in the same communities [21,22]. None of the cases studied has shown

temporal recession of the hairline or balding. A role for DHT in balding is supported by studies in macaques in which treatment with 5α-reductase inhibitors prevented the development of balding [23] or increased scalp hair growth in balding animals [24], and a large clinical trial of the 5α-reductase type 2 inhibitor finasteride in balding men. This latter study showed that the progression of balding was prevented in almost all men taking finasteride orally, and about two-thirds showed an increase in hair growth [25].

Hair follicles possess 5α-reductase activity, suggesting that DHT acts as a paracrine or intracrine hormone (it is synthesized within or close to the target cell). It is possible that circulating DHT also contributes to androgen effects on hair growth. Other steroid metabolizing enzymes, including 3β- and 17β-hydroxysteroid dehydrogenase which interconvert weak and potent androgens, and aromatase which converts androgens to oestrogens, are also expressed in the hair follicle [26,27], but their role in hair growth is not currently known.

The androgen receptor

The tissue effects of androgens are mediated through binding to the intracellular androgen receptor. The androgen receptor is a nuclear hormone receptor [28], and like other members of the nuclear hormone receptor superfamily it acts as a gene transcription factor following ligand binding. Mutations in the androgen receptor gene are responsible for the androgen insensitivity syndrome [29]. Individuals with the complete form of the syndrome, in which there is failure of functional androgen receptor expression, have intra-abdominal testes but female external genitalia, breast development and psychosocial development. After puberty, circulating testosterone is in the normal or elevated male range but pubic and axillary hair fail to develop, there is no beard growth and no balding.

Mechanism of androgen action on the hair follicle

Hamilton [10] reported that balding did not progress following castration in older men but neither did it promote regrowth of hair. Similarly, although beard growth was prevented by castration before puberty and stimulated by subsequent treatment with testosterone, there was only partial regression of the beard in postpubertal men castrated before the age of 20 years and no effect in older men [3]. Hamilton's observations were relatively crude by modern standards and it is now clear from clinical trials of 5α-reductase inhibitors that some reversal of male balding is possible. However, the response is far from complete, indicating that androgens induce changes in gene expression in hair follicles that are only partially reversible in the absence of androgen and probably not at all once these changes are fully expressed.

The specificity of the response of hair follicles to androgens is determined within the skin. Hair follicles in occipital skin, a site that shows little or no response to androgens, retain their site-specific behaviour when transplanted into balding areas on the frontal scalp [30]. Conversely, hair follicles from balding scalp continue to regress when transplanted into skin of the forearm [31]. The success of micrografting techniques, in which individual follicles are transplanted, shows that androgen responsiveness is determined at the level of the follicle or its immediate tissue environment. Three lines of evidence suggest that the dermal papilla is the primary target of androgen action in the hair follicle.

1 Androgen receptor expression in the lower part of the follicle is restricted to dermal papilla cells [32,33]

2 The size of the hair follicle is probably determined by the volume of the dermal papilla [34–36]

3 Dermal papillae express 5α-reductase type 2 whereas hair follicle epithelium expresses only 5α-reductase type 1 [37].

However, it is not yet known how androgen action on dermal papilla cells causes changes in hair follicle size and hair cycling. Hence androgens may act on hair growth by altering the number of cells in the dermal papilla and its extracellular matrix [36]. Cells cultured from dermal papillae of human beard hair follicles also release growth factors in response to androgens that stimulate proliferation of keratinocytes [33,38], and the pattern of androgen metabolism by cultured and intact dermal papilla cells is consistent with that expected from their site of origin [39,40]. However, the molecular mechanisms whereby androgens inhibit hair growth on the scalp but stimulate growth in most other body sites are not yet understood.

Alopecia

Common baldness and androgenetic alopecia

SYN. MALE PATTERN HAIR LOSS; FEMALE PATTERN HAIR LOSS; PATTERNED OR PREMATURE BALDNESS

[R.D. Sinclair, pp. 63.18–63.36]

Nomenclature. Common baldness is the result of a progressive patterned hair loss that only occurs in genetically predisposed individuals. The lack of balding in eunuchs, pseudohermaphrodites and individuals with androgen insensitivity syndrome confirms that androgens are a prerequisite for common baldness. As the pattern of hair loss differs between men and women, the terms male pattern hair loss and female pattern hair loss are also commonly used [1]. Whether someone is considered bald, and in particular prematurely bald, is in part a subjective assessment. The process by which common baldness occurs is androgen-mediated conversion of susceptible terminal hairs into vellus hairs, and has been termed androgenetic alopecia (AGA).

Aetiology. Most vertebrates show regional specificity in the induction and arrangement of skin appendages. The determinants of this are only beginning to be understood [2–4].

Four separate but interrelated factors determine whether an individual will become bald: susceptibility to AGA, age of onset, rate of progression and pattern of hair loss.

Hamilton [5] defined the progressive pattern of male baldness and produced the first useful grading scale. This classification was modified by Norwood [6], who added grades IIIa, III vertex, IVa and Va (Fig. 63.14). Although the grades are imprecise measures of the continuum of hair patterns that are seen in adult males, they are useful as diagnostic aides and in the classification of extent of hair loss in clinical investigations.

It is important to keep in mind that there is no gold standard for the diagnosis of early baldness. While it is safe to assume agreement that men with Hamilton–Norwood stage I are not balding and men with Hamilton–Norwood stage III are going bald, the fate of men who develop stage II pattern of scalp hair has not been followed prospectively.

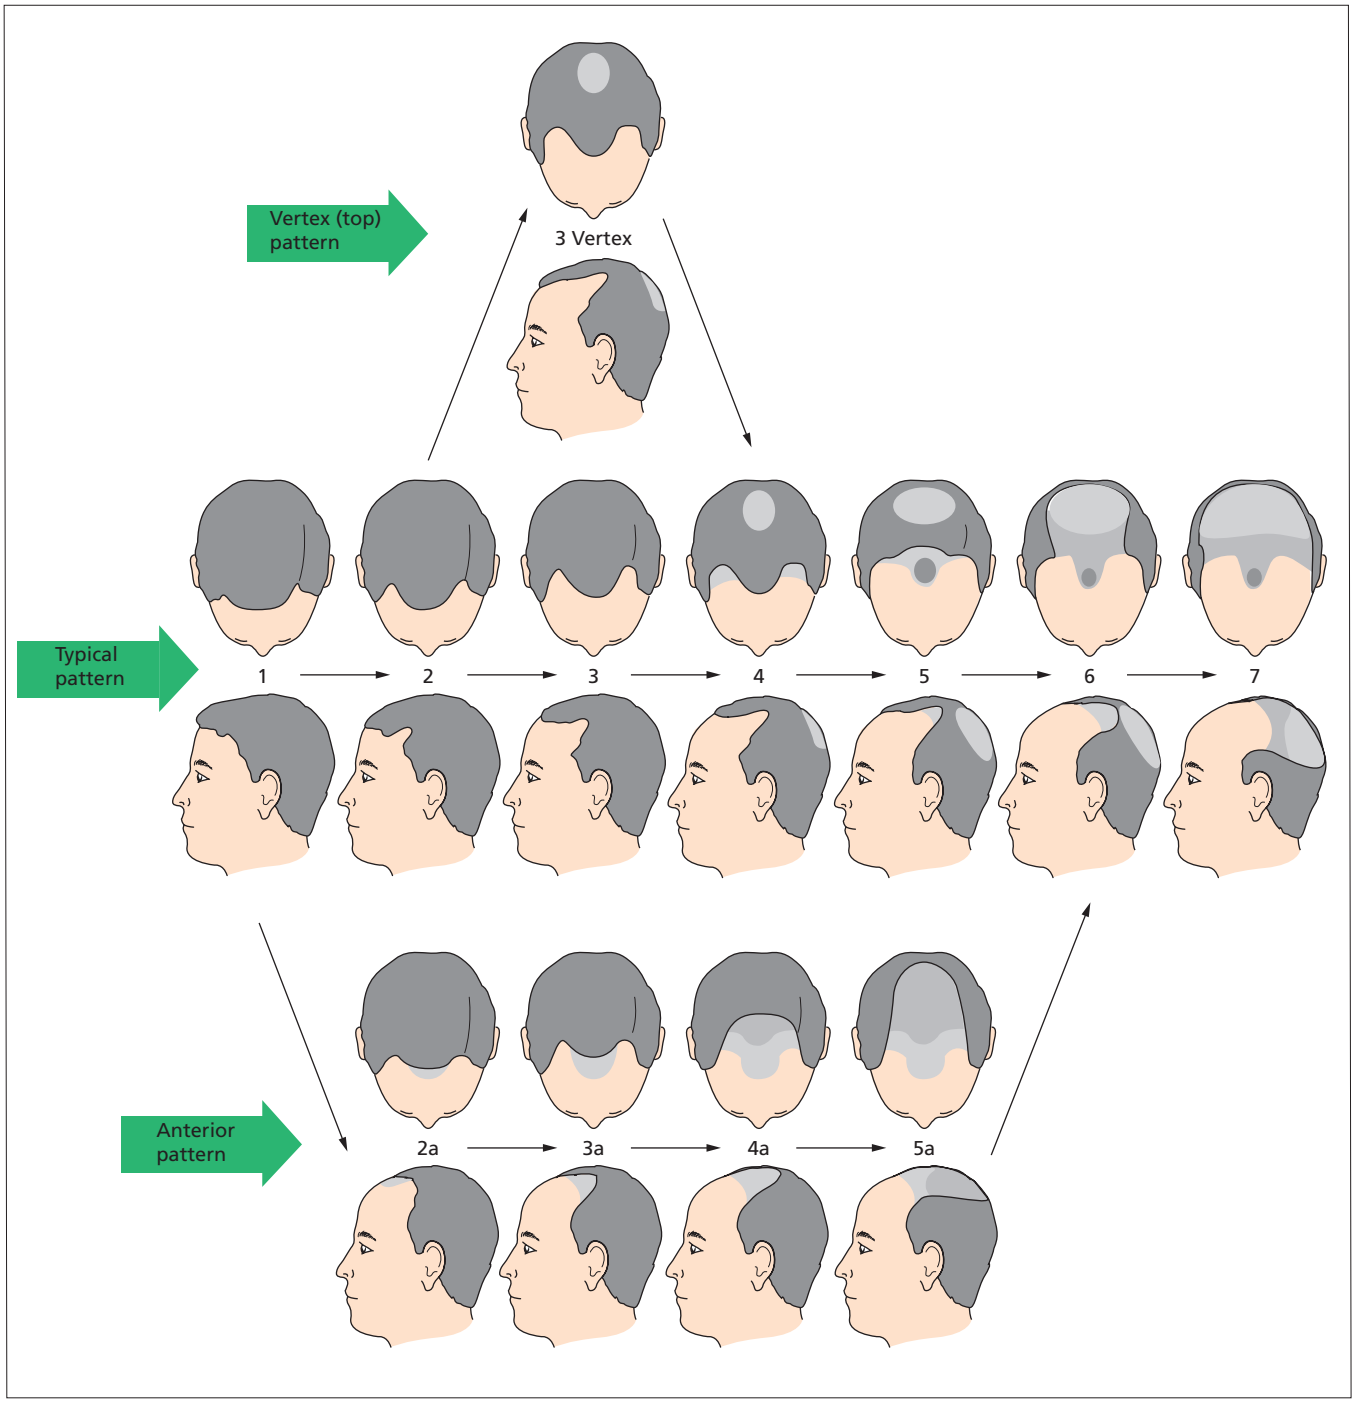

Fig. 63.14 Hamilton–Norwood scale for grading male patterned hair loss [2].

The lifetime risk of male pattern baldness (MPB) can be defined by studying hair patterns in men aged 80 years and above. In Norwood's cohort [6], 16% had a type I hair pattern and by definition are not bald. Fourteen per cent had a type 2 hair pattern, and although demonstrating at least some degree of AGA, would not be considered bald. The remaining 70% had a type III (16%), IV (12%), V (12%), VI (13%) or VII (17%) pattern of hair loss and would be considered to demonstrate MPB.

At least 94% of adult men develop some degree of frontoparietal recession of the hairline after puberty [5]. As the histology of this hair loss shows increased vellus hairs, and as Hamilton observed that three males castrated at the age of 15 and 16 years failed to develop even minimal recession along the frontal hairline, it is likely that this hair

loss occurs by androgen-mediated miniaturization of terminal follicles, and by definition is AGA [7]. However, 16% of 80-year-old men still have stage I hair density. Therefore, limited frontoparietal AGA does not always progress, and may be a benign manifestation of sexual maturity rather than a precursor of MPB.

The age of onset of MPB can also be determined by extrapolation of Norwood's data [6]. Sixty per cent of men aged 18–29 years, 36% aged 30–39 years, 33% aged 40–49 years, 28% aged 50–59 years, 19% aged 60–69 years, 17% aged 70–79 years and 16% of men aged 80 years or above were assessed as having no evidence of AGA. If early MPB is defined as stage II hair pattern, then 40% begin to develop MPB between the ages of 18 and 29, a further 24% first develop MPB in their thirties, 3% in their forties, 5% in their fifties, 9% in their sixties, 2% in their seventies and 1% at or beyond the age of 80 years. If this extrapolation of Norwood's data is valid, then a man with stage I hair at the age of 40 years has almost a 50% likelihood of still having stage I hair at the age of 80 years.

There is wide individual variation in the rate of progression of hair loss in MPB. A small number of men achieve type V or VI hair loss in their twenties, indicating a very rapid rate of progression. In contrast, approximately 25% of men with MPB show no visible hair loss on standardized clinical photographs over a 5-year period [8]. Norwood's data [6] also support the common observation that early-onset MPB progresses more rapidly. Men who develop MPB in their twenties tend to advance 1–2 stages per decade, whereas men with late-onset MPB may take two decades to progress a single stage. As stated above, not every man with AGA goes bald. Although 40% of men start losing their hair in their twenties, only 30% ever reach stage VI or VII. Hence, even for those with early-onset AGA complete baldness is not automatic.

Twin concordance studies in males indicate that susceptibility, age of onset, pattern and rate of progression of MPB are all under genetic influence [9,10]. The lower age-related prevalence of MPB and higher proportion of men with a Ludwig pattern hair loss among Koreans also confirms the profound influence of genes on susceptibility, age of onset and pattern of hair loss [11].

Patterned balding occurs in women, but the susceptibility, age of onset, rate of progression and pattern are different from men. Thirty-two per cent of women aged 80 years and above show no evidence of female pattern hair loss (FPHL). The age of onset of FPHL is later than that seen in men. Only 3% first develop clinically detectable FPHL by age 29 years, a further 13% first develop it by age 49 years, a further 8% by age 69 years and a further 6% after the age of 70 years. In addition, because many women wear their hair long, they are more aware of fluctuations in daily hair shedding. Women with AGA-related increased hair shedding often present prior to the development of reduction in hair volume over the crown (FPHL).

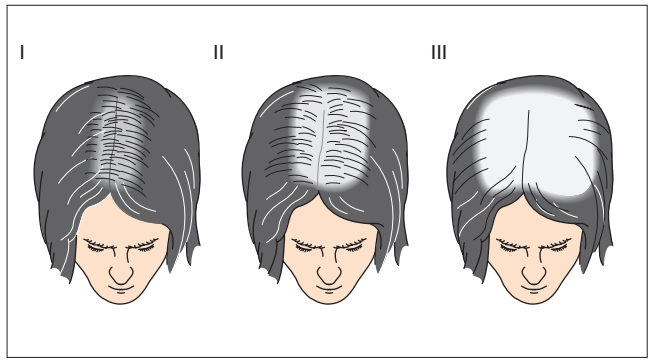

Fig. 63.15 Ludwig scale for grading female patterned hair loss [12].

Fewer than 1% of women progress to Hamilton–Norwood stage IV or above (equivalent to Ludwig stage III). Severe bitemporal recession (Hamilton–Norwood III) is uncommon and, as Ludwig pointed out, the most common pattern of hair loss seen in women is diffuse reduction of hair density over the crown with complete or near complete preservation of the frontal hairline [12]. Olsen observed the so-called Christmas-tree pattern, with widening of the central parting line most noticeably in the mid-frontal scalp. She also pointed out that the hair loss in women is often not confined to the crown but may extend ear to ear (Figs 63.15 & 63.16) [13].

The histology of the hair loss seen in women is indistinguishable from that seen in men. The process of FPHL involves androgen-mediated miniaturization of terminal hair follicles and therefore is AGA. The only caveat to this is that hair loss in an identical pattern has been observed in a female without androgens, indicating that other non-androgen-dependent mechanisms can produce hair loss that mimics AGA [14].

Minor bitemporal recession also occurs in more than 25% of women in their twenties and, as in men, is not necessarily a precursor of baldness, even though biopsy from these areas reveals AGA [15].

Inheritance. A familial tendency to MPB is well recognized, as is racial variation in the age-related prevalence of balding. A polygenic model of inheritance has been evoked in an attempt to explain the high prevalence of MPB in the population, the finding that baldness risk increases with the number of affected family members and, in particular, the high frequency of baldness in the fathers of balding men [16]. Of the 54 father–son relationships in the Victorian Family Heart Study, 81.5% of balding sons had fathers who had cosmetically significant balding.

Definition of MPB, particularly in its early stages, has confounded attempts to identify causative genes. By comparing DNA from young bald men with that of old non-bald men, Ellis *et al.* [17] identified an association of MPB

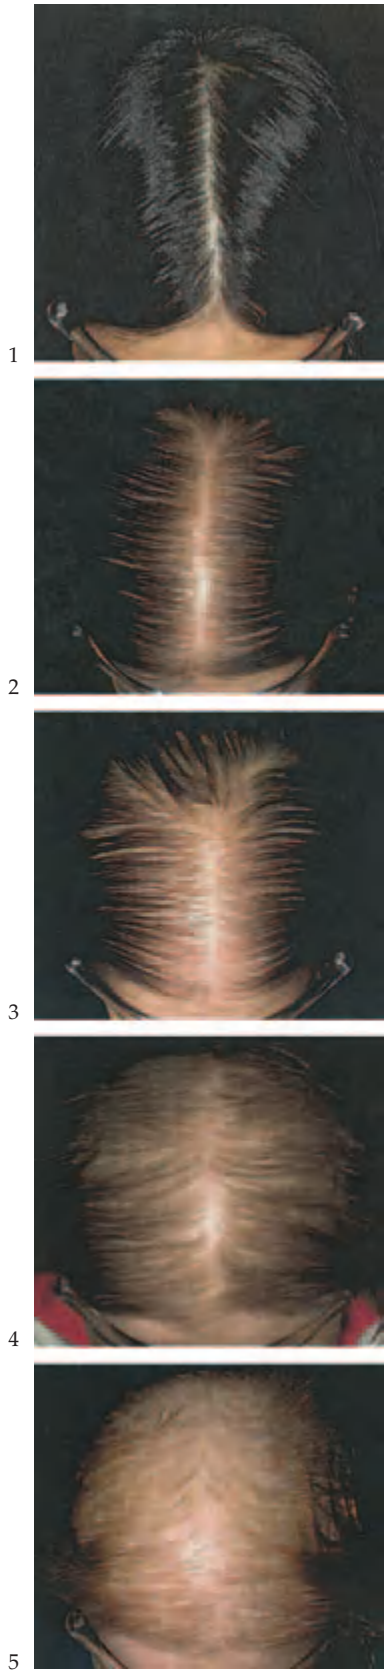

Fig. 63.16 Pattern of frontal hair loss in women with androgenetic alopecia. Stage 1 is normal.

with a polymorphism of the androgen receptor gene on the X chromosome. The androgen receptor gene *Stu1* restriction fragment length polymorphism (RFLP) was found in almost all (98.1%) young bald men, and most older bald men (92.3%), but only in 77% of non-bald men. This polymorphism appears to be necessary for the development of AGA, but its presence in non-bald men indicates that it is not sufficient for the development of AGA [17]. In addition, several shorter triplet repeat haplotypes were found in higher frequency in bald men than in normal controls. These RFLPs appear to be associated with a functional variant of the androgen receptor gene that is part of the polygenic inheritance of male common baldness. Of note is that the androgen receptor gene is located on the X chromosome, which is passed from the mother to a male child.

Current modelling suggests the involvement of at least four genes that combine to modify the age of onset, pattern of loss and rate of progression of MPB [16]. Other candidate gene and chromosomal regions have been examined. They include *SRDA1* and *SRDA5*, coding for the two variants of the 5α-reductase enzymes [18], the insulin gene [19], the aromatase gene, the gene for the Erα oestrogen receptor, the non-recombinant area of the Y chromosome and the type II IGF genes [16]. Thus far, no association has been found between any of the above-mentioned genetic areas and MPB.

Although a positive association between vertex balding and prostate cancer [20] has been identified, there is no clear association between MPB and dense hair patterns on the trunk [21], number of children [22] or coronary artery disease [23].

Regarding FPHL, Harrison examined DNA from 136 women with histologically proven AGA and compared them with 100 elderly female controls without hair loss, and suggested a possible role for both androgen receptor gene polymorphisms and polymorphisms in the aromatase gene in the development of FPHL [24].

Hormonal influences

Systemic hormonal effects (see p. 63.15)

A number of studies have tried to identify increased circulating androgens in balding males, but no differences between patients and controls have been consistently found. Pitts [1] found elevated serum dihydroepiandrosterone sulphate (DHEA) but normal testosterone levels in 18 balding males compared with non-balding controls. A case–control study of 159 cases and 156 controls found a positive association between free testosterone and frontal and vertex baldness, compared with men who had only minimal hair loss [2]. The association with testosterone was also found in a cross-sectional study [3]. A positive association between IGF-1 and vertex balding has also been reported [4]. Sreekumar *et al.* [5] investigated a subset of patients with early-onset and advanced AGA and found no difference between patients and controls in the absolute levels of any androgens; however, the ratio of DHT : testosterone was elevated. All these studies suffer from a lack of reproducibility, and although differences in mean levels have been variously detected, the substantial overlap in the absolute levels of all androgens between cases and controls demonstrates that normal male levels of androgen are sufficient to make manifest the degree of baldness determined genetically for the individual.

The situation in women is more complex, as androgen-secreting tumours can trigger a sudden onset and rapidly progressive baldness [6]. Although hyperandrogenism was identified in 42 out of 109 women referred to an endocrinologist for hormonal evaluation of diffuse vertex alopecia, most of the abnormalities detected were inconsequential. For this survey, hyperandrogenism was defined as an increase in any plasma androgen. Of those 42 women, only 18 had polycystic ovary syndrome [7]. In contrast, no clinically significant hormone abnormality was found in 166 consecutive women with biopsy-proven AGA seen in a dermatology clinic [8].

Although the vast majority of women with FPHL have no discernible endocrine abnormality, in some women the hair loss may be accelerated by elevated circulating androgen levels [9–11]. Stated differently, androgens in the normal female range are sufficient to induce early baldness in women with a strong genetic predisposition. In women with a less strong genetic predisposition, balding will not occur until later in life unless androgen production is increased or drugs with androgen-like activity are taken. Some women with even grossly abnormal levels of androgen do not develop clinically significant baldness, although such patients are generally hirsute.

As there is no clear association between levels of circulating androgens and MPB, it is likely that the normal level of systemic androgen is adequate for the maximal production of dihydrotestosterone, and local factors determine individual susceptibility and severity of baldness. In females, local factors determine susceptibility, but severity is influenced by both local and systemic hormone factors.

Local hormonal effects

Beard dermal papilla cells are known to secrete growth-inducing autocrine growth factors in response to testosterone, leading to an increase in dermal papilla size and enlargement of the hair follicle and hair cortex. This response is not seen with occipital scalp hair follicles when subjected to the same testosterone challenge [12,13]. IGF-1 has been identified as a major component of secreted cytokines [14]. Similar investigations performed on dermal papilla cells from the balding scalp of the stump-tailed macaque showed that testosterone inhibited the growth and proliferation of keratinocytes [15]. TGF-β1 has been identified as a major component of the secreted cytokines in the vertex scalp and neutralizing anti-TGF-β1 antibody will reverse the androgen-induced inhibition of keratinocyte proliferation. It has been postulated that the androgen-induced anti-TGF-β1 derived from the dermal papilla cells mediates hair growth suppression in androgenetic alopecia [16]. Studies examining distribution and expression of androgen receptors have shown varying results. Two studies showed that androgen receptors are only found in the nuclei of dermal papilla cells [12,17].

However, another study found more extensive follicular distribution of receptors, including the hair bulb [18]. Comparing different anatomical sites, there appear to be higher numbers of androgen receptors in the pubic hair follicles and beard dermal papilla cells, with occipital scalp follicles expressing lower levels [19].

Hair loss on the scalp progresses in an orderly and reproducible pattern, and is a function of factors intrinsic to each hair follicle. *In vitro* experiments have shown that the hair follicles are able to self-regulate their response to androgens by regulating the expression of 5α-reductase and androgen receptors [20,21]. This self-regulation is postulated to produce the quantifiable difference in androgen receptor numbers [19,22] and 5α-reductase activity [20,23] that is observed between balding and non-balding areas of the scalp. This intrinsic regulation is best demonstrated in hair transplantation experiments; occipital hairs maintain their resistance to AGA when transplanted to the vertex, and scalp hairs from the vertex transplanted to the forearm miniaturize at the same pace as hairs neighbouring the donor site [24].

Hair cycle dynamics

In AGA, the duration of anagen decreases with each cycle, whereas the length of telogen remains constant or is prolonged. This results in a reduction of the anagen : telogen ratio. Balding patients often describe periods of excessive hair shedding, most noticeable while combing or washing. This is a result of the relative increase in numbers of follicles in telogen.

As the hair growth rate remains relatively constant, the duration of anagen growth determines hair length. Thus, with each successively foreshortened hair cycle, the length of each hair shaft is reduced. Ultimately, anagen duration becomes so short that the growing hair fails to achieve sufficient length to reach the surface of the skin, leaving an empty follicular pore. In addition, the latent phase is prolonged, reducing hair numbers, and further contributing to the balding process [25].

Hair follicle miniaturization

In addition to the changes in hair cycle dynamics, there is a stepwise miniaturization of entire follicles. It is not clear whether the same factors control the miniaturization and hair cycle changes. A significant proportion of men and women bald without ever being aware of increased hair shedding, but increased hair shedding can occur in the context of chronic telogen effluvium without associated follicular miniaturization.

As the dermal papilla is central to the maintenance and control of hair growth, it is likely to be the target of androgen-mediated events leading to follicle miniaturization and hair cycle changes [26–28]. The constant geometric relationship between the dermal papilla size and the size of the hair matrix [29] suggests that the size of the dermal papilla determines the size of the hair bulb and ultimately the hair shaft produced.

A greater than 10-fold reduction in overall cell numbers is likely to account for the decrease in hair follicle size [30]. The mechanism by which this decrease occurs is unexplained, and may be the result of either apoptotic cell death, cell displacement with loss of cellular adhesion leading to dermal papilla fibroblasts dropping off into the dermis, or migration of dermal papilla cells into the dermal sheath associated with the outer root sheath of the hair follicle [30].

In overall volumetric terms, change in the follicular extracellular matrix is unlikely to greatly affect follicle size. However, being a potential source of biologically active molecules, small changes in its volume may have significant effects on hair follicle function [31].

Smaller follicles result in finer hairs. The calibre of hair shafts reduces from 0.08 mm to less than 0.06 mm [32]. This is also followed by a reduction in pigment production. On the balding scalp, transitional indeterminate hairs represent the bridge between full-sized and miniaturized terminal hairs [33].

Follicular miniaturization has been traditionally thought to occur in a stepwise fashion. The cross-sectional area of individual hair shafts remains constant throughout fully developed anagen [31], indicating that the hair follicle, and its dermal papilla, remain the same size through each individual anagen stage of the cycle. Thus, miniaturization occurs between rather than within cycles.

In catagen, the entire bulb undergoes apoptosis and the base of the hair follicle retracts upwards to the level of the hair bulge. Entry into anagen occurs when the slow cycling stem cells in the bulge are activated, probably in response to signals from the dermal papilla. Daughter transient amplifying cells migrate downwards along the follicular stella, renew contact with the dermal papilla, and reform a new hair bulb and ultimately its differentiated cell product—the hair. This early part of the anagen cycle is the most likely point in time for miniaturization, and results in the stepwise reduction in follicle size between successive cycles [34].

Birch *et al.* [35] studied hair diameter in women in relation to hair density. The distribution of hair diameters showed wide variation between individual subjects, but narrow hair diameter was not associated with low hair density. They were not able to demonstrate a progressive reduction in the diameter of individual hairs with falling hair density, and concluded that miniaturization in FPHL occurs rapidly, possibly in the space of a single cycle.

Follicular miniaturization leaves behind stellae as dermal remnants of the full-sized follicle. These stellae, also known as fibrous tracts or streamers, extend from the subcutaneous tissue up the old follicular tract to the

miniaturized hair and mark the formal position of the original terminal follicle. Arao–Perkins bodies may be seen with elastic stains within the follicular stellae. An Arao–Perkins body begins as a small cluster of elastic fibres in the neck of the dermal papilla. These clump in catagen and remain situated at the lowest point of origin of the follicular stellae. With the progressive shortening of anagen hair seen in AGA, multiple elastic clumps may be found in stellae, like the rungs of a ladder [36].

Follicular miniaturization is also a prominent feature of the histology of alopecia areata. It has been postulated that inflammation and fibrosis within the follicular stellae of AGA account for the difficulty of reversing the miniaturization in AGA.

Clinical features. The essential clinical feature of balding in both sexes is patterned hair loss over the crown. Pigmented terminal hairs are progressively replaced by finer hairs, which are short and virtually non-pigmented. This process may begin at any age after the onset of adrenarche and may precede pubarche.

Males. The clinical appearance of male androgenetic alopecia is instantly recognizable in most cases. The progression of the hair loss occurs in an orderly manner and has been well documented by Hamilton [1] and Norwood [2] (Fig. 63.14). The posterior and lateral scalp margins are spared, even in the most advanced cases, and even in old age. Twin concordance studies indicate that variations in the pattern are governed, at least in part, by genetic factors, as is the rate of progression [3].

The main significance of hair relates to socialization,

and hair is an essential part of an individual's self-image. Thus, the consequences of AGA are predominantly psychological. Bald men are likely to have fewer lifetime sexual partners than non-bald men, which may be a reflection of their physical attractiveness to the other sex [4]. Several studies have shown that the negative self-perception of balding patients appears to be consistent between Western [5,6] and Asian cultures [7]. The negative impact of AGA is often trivialized or ignored by the non-bald [8]. However, there is evidence that perception by others may compound the psychological problems suffered by balding men. A Korean study [7] of the perception of balding men by women and non-balding men found that their negative perception of men with AGA was similar to the psychosocial effects reported by the patients themselves. Of note was that a perception of bald men looking less attractive was found in more than 90% of subjects surveyed. Importantly, this view was more common in women than non-balding men. Such negative perceptions may further impair the social functioning of balding men.

However, it is important to note that most affected men cope well with AGA, and it does not have significant impact on their psychosocial function. Thus, those who do seek help are likely to be in greater emotional distress and to have been dissatisfied with any treatment they have received.

The most distressed balding men are those with more extensive hair loss, those who have very early onset, and those who regard their balding as progressive (often arising from observation of their father) and socially noticeable [5].

Females. The pattern of hair loss and the clinical presentation of AGA in women differ from men. Women may present with either an episodic or continuous increase in hair shedding without any noticeable reduction in hair volume, increased hair shedding with loss of hair volume over the crown or diffuse thinning over the crown with no history of hair shedding [9]. Women with FPHL commonly underestimate the severity of their loss [10]. Asking women with a loss of hair volume over the crown about the thickness of their ponytail often enables them to estimate and communicate the degree of hair loss. Diffuse thinning over the crown can be best detected when the hair is parted centrally. Widening of the central parting (part) often follows a Christmas tree pattern and can be used to grade the hair loss [11].

Ludwig [12] described the most common pattern of loss in women and his illustrations have been used as a grading scale. The earliest change (Ludwig grade I) is a rarefaction of the hair on the crown. This produces an oval area of alopecia encircled by a band of variable breadth with normal hair density. Frontally the fringe is narrow (1–3 cm) and at the sides the margin is 4–5 cm wide. Progression to Ludwig grade II results in further rarefaction of the crown, with preservation of the fringe. Grade III is near-complete baldness of the crown. As Ludwig only produced three illustrations (Fig. 63.15), other validated scales with more images should prove more useful for patient grading (Fig. 63.16) [13].

The relative incidence of Ludwig versus Hamilton pattern alopecia among balding women has been determined. Ludwig pattern I–III occurred in 87% of premenopausal women and Hamilton stage II–IV occurred in 13%. Among postmenopausal women, Ludwig I–III occurred in 63% and Hamilton II–V occurred in 37% [14].

In most women the hair loss is confined to the vertex scalp, but in a significant proportion hair loss also occurs diffusely over the parietal scalp. Generalized hair loss may preclude women from hair transplantation procedures because of a diminished donor population.

Most women who present with hair loss have no other evidence of virilization. However, if the hair loss is of sudden onset, rapidly progressive and advanced, a full medical history and examination, and endocrinological investigation are desirable to exclude virilization, which can rarely be caused by a virilizing tumour. Investigation is also indicated in women with AGA of gradual onset accompanied by menstrual disturbance, hirsutism or recrudescence of acne [15].

The principal differential diagnosis of early AGA is chronic telogen effluvium (CTE) [16]. Women with CTE present with chronic diffuse hair shedding without noticeable widening of the central parting. They may describe a loss in volume of the ponytail of up to one-third, and there is commonly mild bitemporal recession. Scalp biopsy of women who present in this fashion reveals AGA in approximately 60% of cases and CTE in 40% [13]. Scalp biopsy is not required in women who present with loss of hair volume either alone or associated with increased hair shedding.

Pathology. The key elements of the histology of AGA are a marked reduction in terminal hairs, an increase in secondary vellus hair with associated angiofibrotic streamers, an increase in telogen and catagen hairs, and a mild or moderate perifollicular lymphohistiocytic infiltrate, with or without concentric layers of perifollicular collagen deposition (Fig. 63.17) [1].

A mild lymphohistiocytic inflammation is found in approximately one-third of cases of AGA and a similar number of controls, and is non-specific. In contrast, a moderate lymphohistiocytic inflammation is found in another one-third of cases of AGA, but in only 10% of controls [2]. Occasional eosinophils and mast cells can be seen. The cellular inflammatory changes also occur around lower follicles in some cases and occasionally involve follicular stellae. The diagnostic and prognostic significance of the degree of the inflammation is not known.

Many of these changes are best seen on horizontally sectioned scalp biopsies. Horizontal sections reveal numerous pseudovellus hair follicles in the papillary dermis, reflecting a miniaturization process. In the vast majority of cases there is no genuine reduction in the number of follicles, and follicular fibrosis is seen in less than 10% of cases. The presence of arrector pili muscles and angiofibrotic streamers distinguishes them from true vellus hairs. There is a change in the ratio of terminal : vellus hairs from greater than 8 : 1 to less than 4 : 1. Also, the anagen : telogen hair ratio reduces from 12 : 1 to 5 : 1 [3]. The increased proportion of catagen and telogen hairs reflects the shortened duration of anagen and the relative increase in telogen hairs.

As the balding scalp loses its protective covering of hair, solar degenerative changes may be seen. A reduction of blood supply has been observed [4], but whether it follows or precedes the hair loss is unknown.

The reduction in the size of the affected follicles, which is the essential histological feature of AGA, necessarily results in a reduction in the diameter of the hairs they produce. This reduction is said to be greater in women than in men [5,6]. Balding patients showed a wide spread of hair-shaft diameters, with peaks at 0.04 mm and 0.06 mm, whereas non-bald subjects showed a symmetrical distribution with a single peak at 0.08 mm. Increased hair

Pathogenesis. Any unifying hypothesis for AGA has to explain the following: the occurrence in humans and simian species; strong familial tendency; the involvement of both sexes; geographical patterning of hair loss on the scalp; the paradoxical effect of circulating and local androgens on scalp and body hairs; the phenomenon of donor dominance in hair transplantation; the alteration of hair cycle dynamics; follicular miniaturization; perifollicular inflammation; and the coexistence of greasy skin, acne and hirsutism in some women.

Treatment

Twenty-five years ago patterned baldness was thought to be irreversible, and although oral antiandrogens were advocated to arrest further hair loss for women, there were no medical treatments available for men. There are now a number of effective treatments to arrest the progression of the hair loss and stimulate regrowth in a significant proportion of individuals. Although the degree of regrowth achieved is often minor, a small proportion of men have a dramatic response to therapy.

As baldness is not life-threatening and the morbidity is variable, most people do not seek treatment. Some patients simply attend for a diagnosis, and when the currently available therapies are discussed, decline treatment. Without therapy baldness is progressive, although the rate of progression is extremely variable. Twenty-five per cent of men will have no visible progression after 5 years. Some will achieve Hamilton stage VII within 5 years, whereas others may take 50 years.

Before any patient embarks on therapy he or she should be counselled carefully and made aware of the need for maintenance therapy. It is preferable that advice is given by qualified medical practitioners who are fully aware of all the treatment options so that vulnerable individuals may be kept away from commercial centres where profit is the only motivation.

Surgery

All surgical procedures are attempts to spread parietal and occipital hairs thinly over the rest of the scalp. Hair can be redistributed using autografts or flaps. Either procedure can be performed alone or in combination with reduction of the bald area by excision and closure. Grafts may be as large as 4 mm in diameter, but better results are achieved with much smaller 'micrografts', which can be manipulated to produce a natural-looking frontal hairline. Reduction of the bald area by removal of an ellipse from the vault or repeated such operations may cover the top of the head by stretching the remaining parietal scalp. Expansion techniques have been used successfully to restore post-traumatic alopecia [1]. Hair transplantation techniques are constantly undergoing revision and improvement. They have been recently reviewed [2]. Artificial fibre implantation has been used for AGA but foreign body reactions and infections are potentially serious complications [3,4]. Use of artificial fibres has been banned in a number of countries.

Surgery is often performed long before the ultimate pattern of hair loss is clear. Without adjunctive medical therapy to prevent progression of the balding process, an unnatural appearance can evolve over time that may require further surgery to correct.

Camouflage and wigs

Camouflage is the simplest, easiest and cheapest way of dealing with mild AGA. Balding becomes most noticeable when the scalp can be seen through the hair. Camouflage treatments involve either adding small fibres held in place electrostatically or dyeing the scalp the same colour as the hair to create the illusion of thicker hair. Numerous brands are available, each in a range of colours. Although many of the newer agents are water-resistant, if the hair becomes wet in the rain the dye may still run.

Wigs are an alternative to scalp surgery. For many women, an alternative to a full wig is a smaller hair piece that can either be interwoven with existing hair or worn over the top of existing hair. Interwoven wigs tend to lift as the hair beneath grows, and they require periodic adjustment.

Wig hair is composed of either a synthetic acrylic fibre that withstands wear and tear very well, or natural fibre (usually Asian or European human hair). Natural fibre wigs look better, are easier to style and last longer, but are considerably more expensive. Wigs can be styled and washed, and modern wigs provide excellent coverage that looks natural. A drawback of wigs is that the head may be hot in the summer, and some patients find them difficult to wear for this reason.

Excellent advice on wigs is available from the alopecia patient support groups that exist in the UK, USA and Australia. In the UK, the National Health Service subsidizes wigs for 'medical hair loss'.

Medical management

Currently available medical management for women consists of oral antiandrogens and topical minoxidil. Antiandrogens may feminize males and therefore are not appropriate for use in balding men. They are potential teratogens, and women should be advised to take appropriate precautions to avoid pregnancy while taking these medications. Pharmacological therapy for men includes topical minoxidil and the 5α-reductase inhibitors finasteride and dutasteride. Finasteride and dutasteride are both teratogens with very long biological half-lives, and so should be avoided in women with child-bearing potential, as even if these agents were stopped as soon as a woman discovered she had become pregnant, activity may persist into the critical second trimester.

Medical treatment should be continued indefinitely, as the benefit is not maintained when therapy is stopped. Up to 1 year of treatment may be required before any clinical response is noticeable. The monitoring of this response can be problematic. Patients inspect their hair on a daily basis and subtle changes over time may not be readily observable. Doctors are essentially reliant upon the patient's subjective assessment of their hair density over time. Baseline photographs are helpful, but unlikely to detect changes of less than 20% in hair density. Periodic photography is useful for monitoring and maximizing patient compliance [5].

Management of male pattern baldness. Many therapies given systemically for other reasons may produce general hypertrichosis and concurrent improvement in AGA (e.g. ciclosporin and psoralen with UVA therapy [PUVA]), but these cannot be used as treatment. Only minoxidil has been shown to enhance regrowth significantly when used topically. Minoxidil is a piperidinopyrimidine derivative and a potent vasodilator that is effective orally for severe hypertension. When applied topically as a 2% solution in an alcohol and water base containing 10% propylene glycol, minoxidil has shown conversion of vellus to terminal hair in up to 30% of individuals [6,7]. Terminal hair appeared to regrow at the margins, but complete covering of the bald areas was seen in less than 10% of responders. De Villez [8] suggested that bald men who responded best to minoxidil were those in whom the balding process was at an early stage, with a maximum diameter of the bald area of less than 10 cm and in whom the pretreatment hair density was in excess of 20 hairs/cm^2. There is a slight increase in benefit if the concentration is increased to 5%. The benefit is most pronounced in the first 6 months of therapy and thereafter is marginal.

Topical minoxidil appears to be a safe therapy with side effects only of local irritation and hypertrichosis of the temples, and there is a low incidence of contact dermatitis [9]. If treatment is stopped clinical regression occurs, after 3 months, to the state of baldness that would have existed if treatment had not been applied [10]. Patients should be warned that in order to maintain any beneficial effect, applications must continue twice daily for the rest of their lives [7]. Whether the benefits are maintained in the longer term is uncertain [11].

Finasteride is a synthetic aza-steroid that is a potent and highly selective antagonist of 5α-reductase type 2. Being a non-competitive antagonist, it binds irreversibly to the enzyme and inhibits the conversion of testosterone to DHT. Thus, although the pharmacokinetic half-life is about 8 h, the biological effect persists for much longer. The underlying principle for its use is the reduction of DHT production and thus limitation of the miniaturization of scalp hair follicles. A scalp biopsy study of patients with AGA found that after 12 months of finasteride treatment, terminal hair counts increase and vellus hair counts decrease, demonstrating the ability of finasteride to reverse the miniaturization process and to encourage the growth of terminal hairs [12].

An oral dosage of 1 mg/day reduces scalp DHT by 64% and serum DHT by 68% [13]. Finasteride is also approved for the treatment of benign prostatic hypertrophy in a dosage of 5 mg/day. Dose-ranging studies have found no significant difference in clinical benefit between 5 and 1 mg/day regimens [14], nor is there any significant further reduction of scalp or serum DHT levels.

At the end of 1 year, patients on finasteride have a 10% increase in the mean number of terminal hairs compared with baseline counts. After 5 years of continuous therapy, hair counts remained close to the 1-year level, whereas the counts in the placebo patients had dropped by 30%. Using global photography to assess scalp coverage, 48% of patients taking finasteride had increased hair density, compared with 7% of the placebo group at the end of 1 year. At 2 years [15], coverage continued to improve in the finasteride group, with 66% having increased density, whereas only 7% of the placebo subjects had increased coverage. By 5 years [16], 10% of treated patients had a lowered hair density, 42% had no change, and 22%, 21% and 5% were assessed as moderately, markedly and greatly improved, respectively. In contrast, 19%, 31% and 25% of patients in the placebo group were greatly, markedly or moderately worse. Nevertheless, 25% of the patients in the placebo group showed no deterioration over the 5-year period, reflecting the variable rate of progression of balding among males.

These data suggest that the maximal number of finasteride-responsive follicles are recruited by the end of 1 year, and further improvement in scalp coverage results from increase in hair length, diameter and pigmentation [16]. At the end of the first year, some finasteride patients

were changed to placebo, resulting in a decrease in their hair counts after 12 months. Some in the placebo group were also crossed over, receiving finasteride for the second year; these subjects had an increase in their hair counts, although the average increase was less than that seen in the original group, indicating the potential for regrowth diminishes as the AGA progresses.

Studies using hair weight as the objective measure of outcome indicate that men on placebo had a reduction in hair weight of 9.2% of their hair at 48 weeks and 15.4% at 96 weeks, compared with the men on active treatment who had an increase of 25.6% at 48 weeks and 35.8% at 96 weeks. Factors that affect hair weight include the number of hairs, hair growth rate and hair thickness [17].

Work examining the effect of finasteride on frontal hair loss also confirmed efficacy here, albeit the magnitude of regrowth appears less [18].

Few adverse effects were reported in the phase III studies [15,16]. In the finasteride group, loss of libido was reported in 1.8% and erectile dysfunction in 1.3%. The placebo groups reported these same events, with frequencies of 1.3% and 0.7%, respectively. These events appeared to resolve on cessation of the drug and, in some cases, with continued treatment. It has been suggested that even these figures overstate the true incidence of sexual dysfunction [19].

Of note is that older men on finasteride experienced a 50% reduction in serum prostate-specific antigen (PSA) levels, which could result in an underestimation of prostatic cancer risk. It has been shown in the urology literature that PSA levels remain valid while patients are taking finasteride, but the value should be doubled to correct for the finasteride effect [20,21]. Men between 18 and 41 years of age have a negligible decrease in measured PSA [22].

Topical finasteride has been investigated as an alternative means of drug delivery. Although a 0.05% finasteride solution applied to the scalp was well absorbed and produced a 40% reduction in serum DHT, it had no effect on hair regrowth. One explanation is that inhibition of prostatic DHT production is an important factor in preventing hair loss with finasteride; a significant reduction in circulating DHT is required in addition to the local blockade of 5α-reductase at the hair follicle [23].

Finasteride is a teratogen. Male rats exposed to finasteride *in utero* develop hypospadias with cleft prepuce, decreased anogenital distance, reduced prostate weight and altered nipple formation [24]. As the drug is secreted in the semen and can be absorbed through the vagina during intercourse, it was originally advocated that men taking finasteride should avoid unprotected intercourse with pregnant women. In practice, the concentration of finasteride in the semen is well below the minimum effect dosage, and no recommendations regarding the use of condoms are made in the product information leaflet [25]. There are no reports of adverse pregnancy outcomes among women exposed to finasteride taken by their partners [26]. Finasteride has no effect on spermatogenesis or semen production [27].

With regard to long-term safety, finasteride has now been in widespread use for over 10 years. Many recipients are elderly men taking 5 mg/day. Very few side effects have been observed [28]. There is no effect of long-term use on bone mineral density [16,29]. Reversible painful gynaecomastia has been reported [30] and the incidence is thought to be approximately 0.001% [31]. The prostate cancer prevention trial has demonstrated that 5 mg daily of finasteride will reduce the incidence of prostate cancer by 25% among men aged 55 and over. More of the reduction occurred in low-grade prostate cancers (Gleason stage 2–6), whilst the incidence of high-grade cancers (Gleason stage 7–10) was increased [32].

Dutasteride is a combined type 1 and 2 5α-reductase inhibitor. There is a dose-dependent reduction in scalp DHT levels. At 0.5 mg/day a 53% reduction is scalp DHT is seen, and at 2.5 mg/day the reduction is 83%. The percentage reduction in scalp DHT seems to be the best indicator of clinical response. The drug is currently marketed at a 1 mg dosage for benign prostatic hypertrophy. Sexual side effects are more common with dutasteride than with finasteride, and are also dose related, but appear to be reversible on cessation.

Management of female pattern hair loss. Topical minoxidil has been demonstrated to either arrest hair loss or to induce mild to moderate hair regrowth in approximately 60% of women [33]. It may be used alone or in combination with oral antiandrogen therapy [34].

Oral antiandrogen therapy with cyproterone acetate, spironolactone and flutamide are of benefit in arresting AGA in women [35]. Most studies with these drugs have been performed in hirsutism and only a small number in AGA [36].

Spironolactone is a synthetic steroid, structurally related to aldosterone, which acts by competitively blocking cytoplasmic receptors for DHT. It also weakly inhibits androgen biosynthesis. Its primary use is as a diuretic and antihypertensive and many of its side effects and numerous drug interactions relate to this. Several studies have demonstrated the efficacy of spironolactone in the treatment of hirsutism [36], and some have found that it is also of benefit in AGA [37]. Dosage ranges from 100 to 300 mg/day, but most women require a minimum of 200 mg/day [38]. Side effects are dose related and include menstrual irregularities, postmenopausal bleeding, breast tenderness or enlargement, and fatigue [39]. Spironolactone has the potential to feminize a male fetus and women should not become pregnant while taking spironolactone. Concomitant use of oral contraceptives will reduce the hormonal side effects. The antialdosterone effect can result in an elevation of serum potassium and a slight reduction in blood pressure, although this is rarely significant in the absence of renal impairment. Rare cases

of hepatocellular carcinoma and hepatitis have been reported, but with substantially higher doses [40,41].

Cyproterone acetate is an androgen receptor blocker and potent progestin [42]. It also has an antigonadotrophic effect. It has been in common usage for over 40 years. It has been shown to be of benefit in AGA [43] and is widely used to treat it in women. However, it appears more effective at arresting progression than stimulating hair regrowth [44]. Although low-dose therapy with 2 mg/day cyproterone acetate may be useful in hirsutism [45], higher doses, in the order of 100 mg/day for 10 days of each menstrual cycle, seem to be required in AGA [46]. For postmenopausal women, cyproterone acetate may be used continuously, with or without oestrogens. The average dosage required is 50 mg/day.

The side effects of cyproterone acetate are dose dependent and include lassitude, weight gain, breast tenderness, loss of libido, depression and nausea [47]. Shortness of breath is an uncommon side effect [48]. Feminization of a male fetus may occur and so patients should be advised to cease the medication before conception. The combination of cyproterone acetate and oral oestrogen therapy provides effective contraception and stabilizes menstrual irregularities.

Flutamide is a non-steroidal antiandrogen that acts by inhibiting androgen uptake and by inhibiting nuclear binding of androgen within the target tissue. One study suggested that flutamide is superior to cyproterone acetate and finasteride in the treatment of androgenetic alopecia [49]. However, rare but potentially fatal hepatotoxicity limits the use of flutamide for this condition [36].

In a double-blind placebo-controlled study involving almost 100 postmenopausal women, 1 mg finasteride was found to be no better than placebo [50]. Subsequently, a case report and a case series have shown idiosyncratic benefit [51,52].

Disturbances of hair cycle

Telogen effluvium

SYN. TELOGEN DEFLUVIUM

Definition. The term telogen effluvium, first coined by Kligman in 1961 [1], refers to the loss of club (telogen) hair in disease states of the follicle. Kligman's hypothesis was that whatever the cause of the hair loss, the follicle tends to behave in a similar way; the premature termination of anagen. 'The follicle is precipitated into catagen and transforms into a resting stage that mimics telogen.' The observation of increased telogen hair shedding does not infer a cause. To establish a cause, one requires a history to identify known triggers, biochemical investigation to exclude endocrine, nutritional or autoimmune aetiologies and, in persistent cases, histology to identify the earliest stages of AGA. The duration of the hair shedding at presentation helps predict those patients in whom further investigation will have the greatest yield.

Follicular cycling within anatomical regions is synchronous in infancy, in that all neighbouring hairs grow together, involute together and are shed together, producing a moult wave. Whereas the moult wave persists indefinitely in many animals, in humans synchronous hair growth disappears in childhood. Rather than periodically shedding all 100 000 scalp hairs over the course of a few months, adult humans tend to lose a few hairs each day, and therefore are never normally bald [2].

Scalp trichography reveals 86% of plucked hairs are in anagen, 1% in catagen and 13% are in telogen, whereas data from analysis of horizontal scalp biopsies puts these figures at 93% of follicles in anagen and 7% in telogen [3]. Based on biopsy data, if the average number of scalp hairs is 100 000, then 7000 hairs should be in telogen at any one time. As the approximate duration of telogen is 100 days, 77 hairs should be shed each day, but most people are not aware of shedding anywhere near this amount. Although this number is likely to correspond to the absolute number of hairs that are shed each day, it still remains to be defined what amount is normally noticed and how introspection heightens one's powers of detection [4].

Pathogenesis. Headington [5] described five functional types of telogen effluvium based on different phases of the follicular cycle: immediate anagen release, delayed anagen release, short anagen syndrome, immediate telogen release and delayed telogen release.

Immediate anagen release is a short-onset effluvium where follicles are stimulated to leave anagen and enter telogen prematurely, resulting in increased hair shedding at the end of telogen approximately 2–3 months later. It is common after a physiological stress such as severe illness, and with drug-induced hair loss. Reversal is associated with resumption of the normal cycle. Delayed anagen release is the cause of postpartum hair loss. During pregnancy, hairs remain in prolonged anagen rather than cycling into telogen. If a large number of follicles are involved, postpartum telogen conversion will be accompanied by increased shedding some months later. Short anagen syndrome is caused by an idiopathic shortening of the duration of anagen and can cause a persistent telogen hair shedding in some individuals [5].

It is not known precisely how long a telogen hair remains in the follicle, but it is believed that club hairs are released 4–6 weeks after the onset of anagen. This may explain the different anagen : telogen rates seen on trichogram versus biopsy. Immediate telogen release results from a shortening of normal telogen, with release of club hairs as the follicles are stimulated to re-enter anagen. Drugs such as minoxidil can precipitate immediate telogen release. Delayed telogen release occurs after a prolonged telogen followed by transition to anagen. It occurs in animals with synchronous hair cycles during shedding

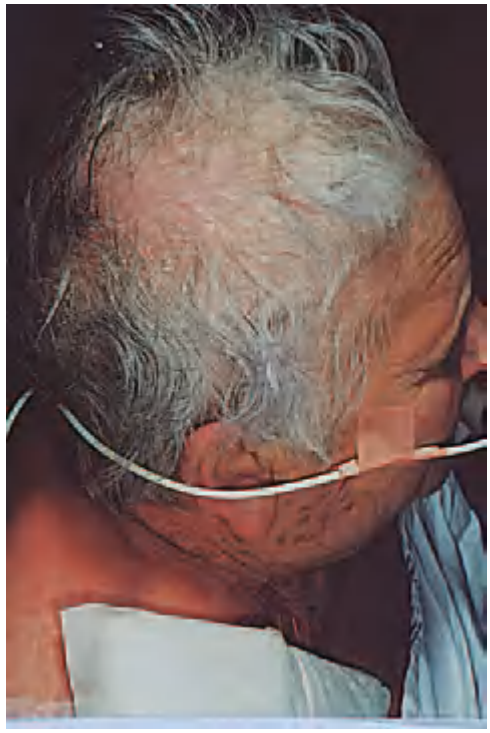

Fig. 63.18 Acute telogen effluvium.

of their winter coats. It may occur seasonally in some humans.

Acute telogen effluvium. Acute telogen effluvium is an acute-onset scalp hair loss that occurs 2–3 months after a triggering event such as a high fever, surgical trauma, sudden starvation or haemorrhage [2,4–6]. In approximately 33% of cases of acute telogen effluvium, no trigger can be identified. Acute telogen effluvium is commonly attributed to emotional stress, but the evidence for this is weak and there is no evidence that suggests the stresses of everyday life are sufficient to induce diffuse hair loss. The functional mechanism of shedding is immediate anagen release.

The patient may be particularly aware of increased loss on the brush or comb, or during shampooing. The daily loss ranges from under 100 to over 1000. If the lower rates of shedding are continued for only a short period there may be no obvious baldness, but if shedding occurs at higher rates, diffuse reduction in hair density is produced (Fig. 63.18). It may be severe but is never total. Unless the trigger is repeated, spontaneous complete regrowth occurs within 3–6 months. The proportion of follicles affected, and hence the severity of the subsequent alopecia, depends partly on the duration and severity of the precipitating cause and partly on unexplained individual variations in susceptibility.

Telogen gravidarum refers to the telogen hair loss seen 2–3 months after childbirth [7,8]. It is an example of delayed anagen release. It is universal to some degree, but is often subclinical. Most cases of telogen gravidarum resolve; however, a small proportion of women may experience persistent episodic shedding that may be diffuse or localized. It has been suggested that after pregnancy some hairs may not revert to an asynchronous growth pattern seen in normal adult hair follicles [5]. A similar state of affairs prevails when the contraceptive pill is discontinued after it has been taken continuously for some time [8,9].

Diagnosis. The diagnosis is usually simple. Abrupt-onset telogen effluvium is likely to be related to a specific event or trigger 6–16 weeks earlier. The hair pull test is positive, with normal club hairs. The hair loss is always diffuse and never total. Gradual onset or prolonged hair loss is more difficult to assess. Increased shedding of club hairs is a variable but often very obvious symptom of early AGA. Other differential diagnoses are discussed below under the heading of chronic diffuse telogen hair loss.

The hair pull test is notoriously difficult to interpret. In acute telogen effluvium, it is usually strongly positive for telogen hairs at the vertex and the scalp margins. However, a negative hair pull test does not exclude the diagnosis of telogen effluvium [10]. The trichogram from a hair pluck sample usually shows more than 25% of telogen hairs in acute telogen effluvium [2]. When an obvious explanation exists for a recent-onset telogen effluvium, expectant management and observation is appropriate. Shedding can be expected to cease within 3–6 months and thereafter recovery should be complete [2]. Histological examination shows no abnormality other than an increase in the proportion of follicles in telogen.

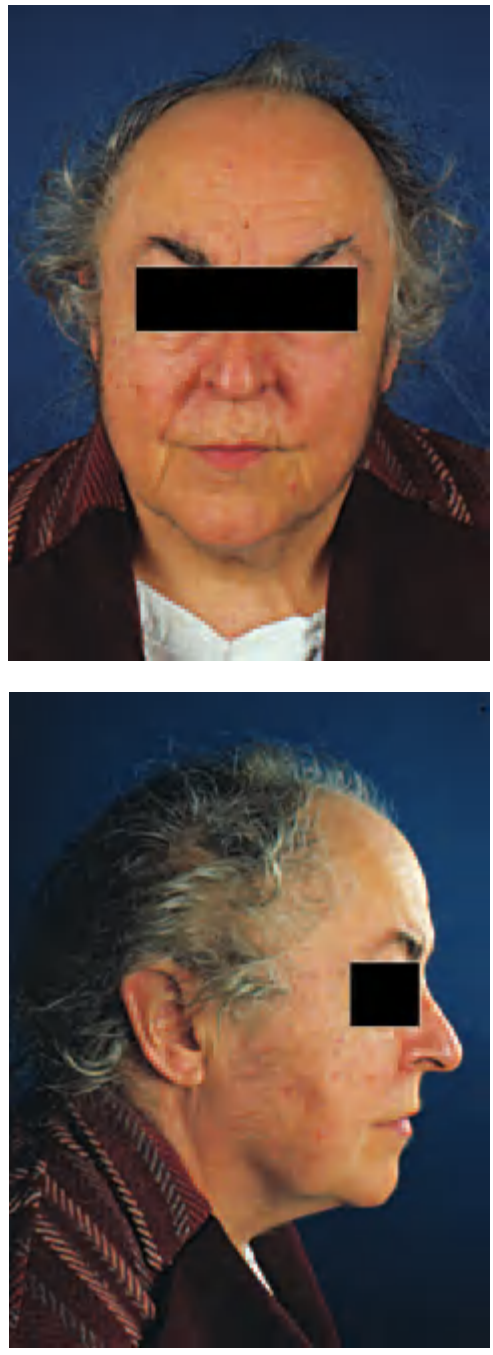
Chronic diffuse telogen hair loss. A short-lived insult usually produces a sudden-onset diffuse shedding. If the insult is prolonged or repeated, shedding can develop insidiously. Chronic diffuse telogen hair loss refers to

telogen hair shedding persisting for longer than 6 months. It can be a result of a primary chronic telogen effluvium or be secondary to a variety of causes. To be a true cause of chronic diffuse telogen hair loss, the relationship between the trigger and the hair loss must be reversible and reproducible. The requirements of proof include exclusion of other known causes of shedding, in particular AGA, reversal of the hair loss following correction of the causative factor, and relapse on rechallenge.

Accepted causes of chronic diffuse telogen hair loss are thyroid disorders (Fig. 63.19), profound iron deficiency anaemia, acrodermatitis enteropathica and malnutrition [1]. Both hyperthyroidism and hypothyroidism (including drug-induced hypothyroidism) cause a diffuse telogen hair loss in approximately 50% and 33% of patients, respectively [2,3]. The mechanism of telogen hair shedding in thyroid disorders still remains unclear [4]. Hair loss is reversible when the euthyroid state is restored, except in long-standing hypothyroidism where the hair follicles are said to have atrophied [3]. If replacement therapy fails to correct the hair loss, alternate causes should be sought [5].

Profound iron-deficiency anaemia can cause a diffuse telogen hair loss that is corrected by iron replacement. It is thought that hair follicles that have shed their hair at the end of telogen may temporarily fail to re-enter anagen —leading to a slow-onset diffuse hair loss [6]. The relationship between iron deficiency with no anaemia or only mild anaemia and chronic diffuse hair loss is, however, more complex and controversial [7–9]. Depending on how it is defined, low iron stores are a common finding in women of child-bearing age. AGA is also common in this age group and the shedding in the early stages of female AGA can be diffuse and episodic, and mimic a telogen effluvium. It is important not to focus on the treatment of a subclinical iron deficiency while neglecting the underlying AGA, especially when therapy for female AGA is more reliable in arresting hair loss than stimulating regrowth. It is not uncommon for women presenting with increased telogen hair shedding caused by AGA to coincidentally have low iron stores. As the telogen hair loss in AGA can be episodic, it may even appear to abate with iron replacement. However, in patients with AGA the shedding tends to be chronic and relapsing, and recovery is generally incomplete. A punch biopsy can usually clarify the diagnosis.

Acrodermatitis enteropathica and acquired zinc deficiency (Fig. 63.20) brought about by long-standing parenteral nutrition can lead to a severe telogen effluvium [1,10]. However, low zinc levels found on routine blood biochemistry screening in patients being investigated for diffuse telogen hair loss are probably an incidental finding. Diffuse hair loss alone, with no other symptoms or signs, is never a result of dietary zinc deficiency [9]. Correction of a subclinical zinc deficiency often does not stop the increased hair shedding, and other forms of alopecia such as AGA or chronic telogen effluvium should be considered.



(a) (b)

Fig. 63.19 Diffuse alopecia in association with hypothyroidism.

Crash dieting with severe protein-calorie restriction can precipitate hair loss [11,12]. Chronic starvation, especially marasmus, causes a diffuse telogen hair loss often accompanied by hair shaft abnormalities [13]. Hypoproteinaemia of metabolic as well as dietary origin can cause hair loss [1]. Pancreatic disease and other forms of

Fig. 63.20 Acquired zinc deficiency resulting from prolonged parenteral feeding and inadequate zinc supplementation.

Fig. 63.21 Hair loss and photosensitivity caused by systemic lupus erythematosus.

malabsorption also cause a diffuse telogen hair loss [14], as do the essential fatty acid deficiencies seen in prolonged parenteral nutrition and hypervitaminosis A [15,16]. Metabolic disturbances such as liver disorders [1,17] and chronic renal failure can produce sparse scalp hair [18]. Hair loss in advanced malignant disease may be a result of hypoproteinaemia rather than the malignancy itself, but alopecia has occurred as an early sign of Hodgkin's disease [19]. Systemic lupus erythematosus (Fig. 63.21) and dermatomyositis can also cause telogen hair loss [20]. Diffuse hair loss may occur in secondary syphilis, but the characteristic moth-eaten appearance is not always present [21].

Drug-induced diffuse telogen hair loss usually starts 6–12 weeks after instigation of treatment and is progressive while the drug is continued [22,23]. It is most commonly a result of immediate anagen release [6]. The diagnosis of drug-induced telogen hair loss is made by demonstrating compatible chronology of drug exposure and the onset of the hair loss, and exclusion of the other causes of alopecia. Shedding can recur with drugs that are chemically unrelated, suggesting that true cross-reactivity is rare, and individual susceptibility exists to drug-induced telogen effluvium. CTE and AGA are important differential diagnoses. If a particular drug is suspected, testing involves stopping it for at least 3 months. Regrowth following discontinuation and recurrence on re-exposure to the drug supports the conclusion that the drug caused the alopecia. Many drugs have been said to cause a diffuse telogen hair loss but few have fulfilled the above criteria. A dose-related diffuse telogen hair loss is common with etretinate [24] and acitretin, but less common with isotretinoin. The retinoids appear to cause a telogen anchorage defect and reduce the duration of anagen. Occasionally, continued shedding is noted after retinoid-induced telogen effluvium, but such cases may be caused by coincidental AGA. Minoxidil has been reported to cause a short-lived telogen shedding by immediate telogen release [6,25].

Chronic telogen effluvium. CTE has become a term used to describe a pattern of presentation in middle-aged women that is distinct from androgenetic hair loss and is distinguished from chronic diffuse telogen effluvium and its organic causes [1,2]. It is described as an idiopathic self-limiting condition with increased telogen shedding of at least 6 months' duration, but with no widening of the central parting, and no miniaturization of hair follicles on scalp biopsy [1]. CTE contrasts with acute telogen effluvium by its prolonged fluctuating course and much less frequent occurrence. It is common in females between 30 and 50 years of age [2]. Hair shedding is much less obvious in males with short hair, and for unknown reasons few males with long hair present with increased hair shedding [3]. Although some cases of CTE follow an acute telogen effluvium with a known trigger, such as pregnancy or systemic illness, in most cases a trigger cannot be identified. Any of the functional types of telogen effluvium could account for CTE, but it is believed to be related to shortening of the anagen phase of the hair cycle [4].

The diagnosis of CTE is made by exclusion of other causes of diffuse telogen hair loss. A thorough history is required, including a detailed drug and dietary history. A full clinical examination should be performed, including scalp examination and hair pull testing. The routine work-up includes full blood count and thyroid function tests. Syphilis serology, antinuclear antibody titre, serum zinc levels and other investigations of nutritional status should be performed if clinically warranted.

Affected women commonly present with persistent severe shedding that runs a fluctuating course over several years [4] (Fig. 63.22). They often give a history of the ability to grow their hair very long in childhood, suggestive of a long anagen phase, and report a high hair density prior to the onset of hair loss [5,6]. They usually have a negative family history of AGA. Clinical examination reveals marked bitemporal recession, but no widening of the central hair parting, which if present would support the diagnosis of AGA. However, these criteria are not absolute, and AGA can mimic this presentation. A positive hair pull test is common over the vertex and occipital scalp, and patients may describe a reduction in the thickness of their ponytail volume, stating it has decreased by up to 50% [4]. A negative hair pull test does not exclude the diagnosis of CTE.

Fig. 63.22 Idiopathic chronic telogen effluvium.

CTE has to be distinguished clinically from AGA as women with early AGA may present with periods of increased hair shedding without a discernible pattern to the loss. The mechanism of increased hair shedding in AGA is probably related to shortening of the anagen duration [7]. In an evaluation of 600 women presenting with chronic diffuse telogen hair shedding with little or no reduction of visible hair density, 60% were found on scalp biopsy to have hair miniaturization consistent with a diagnosis of AGA and 40% had CTE [8].

The natural history, prognosis and treatment of CTE and AGA differ [9]. The diagnosis of CTE can usually be suspected from the history and examination, but scalp biopsy is required to differentiate reliably between the two conditions [1]. The optimal scalp biopsy is a 4-mm punch biopsy taken from the vertex of the scalp for horizontal embedding. The vertex is the chosen site because AGA is a patterned disease that preferentially affects the vertex of the scalp, so diagnostic yields are greatest in this area. Histology of a scalp biopsy in CTE resembles normal scalp, but shows an anagen : telogen ratio of 8 : 1

compared with the ratio of 14 : 1 on normal scalp biopsies [1]. The total number of hairs in CTE is the same as that found in normal scalps and the terminal : vellus-like hair (miniaturized) ratio is similar in both, averaging eight terminal hairs per vellus-like hair [1]. These findings differ considerably from AGA. The mean terminal : vellus-like hair ratio in AGA is 1.9 : 1 [1].

Despite the assertion that CTE is a self-limiting process that does not evolve into AGA, its natural history remains poorly characterized, with only one published longitudinal study [9].

Alopecia in central nervous system disorders

Alopecia has been described in association with a number of diseases of the central nervous system, but in many instances the association was probably fortuitous. There are four forms of hair loss in which the association appears to be valid, although the mechanism is unknown.

1 Total and permanent alopecia has accompanied lesions of the mid-brain and brainstem [1]—a glioma in the region of the hypothalamus or post-encephalitic damage to the mid-brain.

2 Temporary diffuse alopecia may follow head injuries, particularly in children [2], and may be associated with reversible hirsutism.

3 Total loss of hair occurred at approximately annual intervals for 20 years in a patient with syringomyelia and syringobulbia [3].

4 Androgenetic baldness occurs early in myotonic dystrophy [4]. A genetic linkage rather than a direct effect of the neurological changes is probably concerned.

Piloerection [5]

Episodes of piloerection may occur in patients with lesions close to the hypothalamus or involving some portion of the limbic system, but the symptom has no precise localizing value.

Alopecia areata

[A.G. Messenger, pp. 63.36–63.46]

Alopecia areata is a chronic inflammatory disease that involves the hair follicle and sometimes the nails. Current evidence indicates that hair follicle inflammation in alopecia areata is caused by a T-cell-mediated autoimmune mechanism occurring in genetically predisposed individuals. Environmental factors may be responsible for triggering the disease.

In the only formal population study of alopecia areata, from Olmsted County, Minnesota, USA, the incidence rate was 0.1–0.2% with a projected lifetime risk of 1.7% [1]. Several large case series of alopecia areata have been reported from Europe [2], North America [3,4] and Asia [5,6], but these have generally been drawn from hospital clinic attenders and no accurate indication of variation in disease rates between populations is available.

Aetiology

Genetic factors

The importance of genetic factors in alopecia areata is underlined by the high frequency of a positive family history in affected individuals [7]. In most reports, this ranges from 10 to 20% of cases, but mild cases are often overlooked or concealed and the true figure may be greater. The lifetime risk of alopecia areata in the children of a proband is approximately 6% [8]. Price and Colombe [9] found a family history of alopecia areata was more common in those with disease onset before the age of 30 years (37% compared with 7.1% in patients with onset after 30 years). There have been several case reports of alopecia areata in twins [10–12], but only a single study looking at concordance rates in monozygotic and dizygotic pairs [13]. In this investigation, there was a concordance rate of 55% for alopecia amongst monozygotic twins with no concordance among the dizygotic pairs. However, the numbers studied were insufficient to allow a precise estimate of the genetic contribution in alopecia areata. Except in occasional families, alopecia areata is not inherited in a simple Mendelian fashion and the genetic basis appears to be multifactorial.

Major histocompatibility complex genes. No consistent associations with MHC class I antigens have been reported, but several studies have shown an association between alopecia areata and the MHC class II antigens HLA-DR4, DR11 (DR5) and DQ3. Earlier studies using serological typing techniques suggested that DR4 and DR5 were associated with severe forms of alopecia areata [7]. This severity association was subsequently confirmed by molecular typing. Colombe *et al.* [14] found an increase in the broad antigen DQ3 in all patients in their study, suggesting this may act as a susceptibility factor. The DQB1*0301 allele (a subtype of DQ3 that is in linkage disequilibrium with DR5) was associated with severe alopecia but not with newly diagnosed patchy disease. There was also a strong association between alopecia totalis and universalis and the DR11 allele DRB1*1104 (relative risk 30.2), which was absent in milder disease. The association with DQB1*0301 had previously been reported by Morling *et al.* [15] and Welsh *et al.* [16]. The latter group also showed an increase in the frequency of DQ3, which was greater in alopecia totalis and universalis than in patchy alopecia. De Andrade *et al.* [17] confirmed the importance of DQB1*03 alleles, which were present in 85% of alopecia areata patients compared with 46% of controls. In the only family-based study of HLA association and linkage in alopecia areata, these authors reported an association between alleles of HLA-DQB1*0302, *0601, *0603 and HLA-DR4, DR6 using the transmission disequilibrium test [17]. Linkage analysis in 75 families supported linkage between alopecia areata and HLA class II loci, with maximal LOD scores of 2.42 for HLA-DQB at 5% recombination and 2.34 for HLA-DR at 0% recombination.

Cytokine genes. IL-1 is a primary cytokine involved in mediating inflammatory responses. The IL-1 gene cluster on chromosome 2 includes genes for the pro-inflammatory IL-1 proteins, their cell membrane receptors, the anti-inflammatory IL-1 receptor antagonist (*IL1RN*) and its homologue, *IL1F5* (*IL1L1*). Associations between the severity of alopecia areata and polymorphisms in *IL1RN* and *IL1F5* have been reported [18,19]. *IL1RN* variants are also associated with the severity of several other inflammatory autoimmune diseases, including ulcerative colitis, lichen sclerosus, psoriasis, myasthenia gravis, multiple sclerosis and rheumatoid disease. However, a later family-based study by Barahamani *et al.* [20] using 131 trios, failed to confirm the association of *IL1RN* genotypes with alopecia universalis.

Like IL-1, TNF-α has a potent inhibitory effect on hair growth *in vitro* [21]. TNF-α is encoded by a gene in the HLA class III region and a polymorphism of this gene has been shown to be strongly associated with certain autoimmune/inflammatory diseases including systemic lupus erythematosus (SLE), rheumatoid arthritis, dermatitis herpetiformis and coeliac disease. TNF-α polymorphisms were investigated in alopecia areata in a small study of 50 cases by Galbraith and Pandey [22], who demonstrated a significant difference in TNF-α genotypes between patients with patchy disease and those with alopecia totalis and universalis. However, there was no difference between disease and control groups overall.

Chromosome 21. The frequency of alopecia areata is increased in Down's syndrome, with up to 8.8% of patients affected [23,24], suggesting possible involvement of genes on chromosome 21. There is an even stronger association with the autosomal recessive disorder autoimmune polyglandular syndrome type 1 (APS-1, autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy), in which approximately 30% of patients have alopecia areata [25]. The defective gene in APS-1 maps to the Down's critical region on chromosome 21 [26,27]. A potentially functional exonic polymorphism in the APS-1 gene has been associated with alopecia universalis [28].

Atopy. Several studies have reported an association between alopecia areata and atopic disease [4,5,29,30], and have suggested that alopecia areata in atopic subjects tends to have an earlier age of onset and be more severe than in non-atopic subjects. However, none of these studies has used a control group to which the same criteria for defining atopy have been applied, and the association has been disputed in a study from India [31].

Autoimmunity

The idea that alopecia areata is an autoimmune disease was first suggested by Rothman following a paper presented by Van Scott [32]. Alopecia areata is associated with other autoimmune diseases, such as myxoedema and pernicious anaemia [4,33]. Intriguingly, the frequency of type 1 diabetes mellitus is increased in the relatives of patients with alopecia areata but not in the patients themselves [34], suggesting that the predisposition to alopecia areata protects against the development of diabetes. In most published series, patients with alopecia areata have had an increased frequency of circulating organ-specific and non-organ-specific autoantibodies compared with normal subjects, and a variety of non-specific abnormalities in peripheral T-cell numbers and function have also been reported (reviewed in [7]). Circulating autoantibodies to hair follicle tissue have been found in patients with alopecia areata [35]. These antibodies also occur in normal subjects but less frequently and at lower titre. They recognize various epithelial compartments within the hair follicle and appear to be targeted against intracellular antigens [36]. Antibody binding has not been demonstrated *in vivo* in humans, and their role in the pathogenesis is unclear. Passive immunization with alopecia areata serum failed to induce hair loss in human skin grafted on to nude mice

[37]. However, one study reported that serum from a horse with alopecia areata-like hair loss caused local inhibition of hair growth when injected into murine skin, whereas serum from a normal horse did not [38].

The most convincing evidence implicating circulating immune factors in the pathogenesis of alopecia areata comes from the transplantation experiments carried out by Gilhar *et al*. They first showed that hair growth recovered in alopecic skin transplanted on to athymic nude mice [39]. In their later experiments (in which SCID rather than athymic nude mice were used as graft recipients), alopecia was induced in grafted skin by the injection of autologous T lymphocytes incubated with hair follicle extracts and antigen-presenting cells [40]. T cells not incubated with hair follicle extracts failed to cause hair loss. Taken together with the immunopathological features of the disease, and with the T-cell depletion studies on the Dundee experimental bald rat (DEBR) model (see below) [41,42], the results of these experiments suggest that alopecia areata is a T-cell-mediated disease.

Environmental factors

The idea that alopecia areata is caused by infection, either directly or as a consequence of a remote 'focus of infection', has a long history and still cannot be ruled out. It was the predominant aetiological theory until well into the twentieth century, and sporadic reports connecting alopecia areata with infective agents continue to appear. Skinner *et al*. [43] reported finding mRNA for cytomegalovirus in alopecic lesions, but this was not confirmed in a subsequent study from Italy [44]. There are also reports of alopecia areata in husband and wife, although this may be coincidence [45,46]. The 'external' factor most frequently implicated in triggering alopecia areata is psychological stress [47–50]. The significance of such an association is difficult to establish because of the problems in performing a controlled investigation. The published evidence is also conflicting, with some studies failing to show any relationship between stressful events and onset of hair loss [51,52], to the extent that no firm conclusion can be reached.

Despite the anecdotal nature of much of the evidence it is possible that environmental factors are responsible for triggering alopecia areata in some patients. If so, it seems likely that a diversity of factors can operate in this way.

Pathogenesis

Pathology

Anagen follicles at the margins of expanding patches of alopecia areata characteristically show a perifollicular and intrafollicular inflammatory cell infiltrate, concentrated in and around the hair bulb (Fig. 63.23). The inflammatory infiltrate is composed mainly of activated T lymphocytes, with a preponderance of CD4 cells, and an admixture of macrophages and Langerhans' cells [1,2]. In contrast with the inflammatory scarring alopecias, little or none of the inflammatory infiltrate is seen around the isthmus of the hair follicle, the site for hair follicle stem cells [3]. This may explain why follicles are not destroyed in alopecia areata. Lymphocytic infiltration of the dermal papilla and bulbar epithelium may be accompanied by increased expression of HLA class I and II antigens and of intercellular adhesion molecule-1 (ICAM-1) [4–6], which are thought to be secondary to the local release of T-cell cytokines. Normal

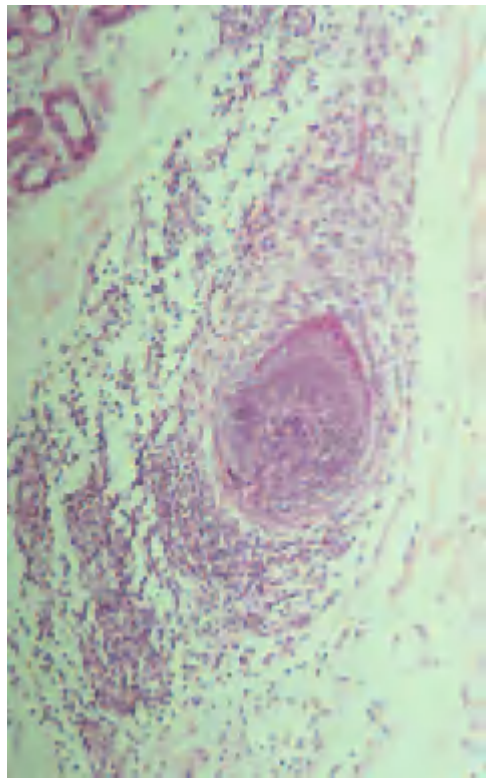

Fig. 63.23 Lymphocytic inflammatory infiltrate surrounding an anagen hair bulb in alopecia areata.

numbers of follicles are found in established bald patches and in alopecia universalis. Both anagen and telogen follicles are found in these sites, with a higher proportion in telogen than in normal scalp. Follicles are smaller than normal and anagen follicles do not develop beyond the Anagen 3–4 stage, when the hair shaft starts to be formed [7]. The inflammatory infiltrate tends to be less pronounced than in early lesions and is associated mainly with anagen follicles.

Pathodynamics

Eckert *et al*. [8] studied anagen : telogen ratios in hairs plucked from demarcated concentric zones around the periphery of expanding bald patches. They concluded that the initial event in alopecia areata is precipitation of anagen follicles into telogen. Less severely affected follicles may remain in anagen for a time but they produce a dystrophic hair and eventually also undergo telogen conversion. In keeping with these observations, biopsies from the margins of expanding lesions of alopecia areata show most follicles in catagen or telogen [9]. It is not clear whether follicles attain telogen via normal catagen. Exclamation mark hairs may have a well-formed club root identical to that of a normal telogen hair. However, the root is frequently narrowed and club hairs fall out more

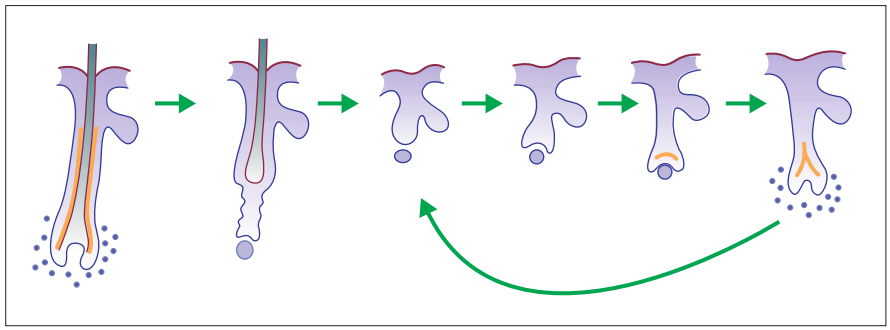

Fig. 63.24 Proposed pathodynamic changes in alopecia areata. An inflammatory attack on anagen follicles precipitates follicles into telogen. Follicles re-enter anagen but development is halted in Anagen 3–4 and follicles return to telogen prematurely.

readily than normal, suggesting that anchoring of the hair within the follicle is defective.

Van Scott [7] studied biopsies from patches of alopecia areata and found an average of 58% of follicles in anagen, suggesting that re-entry into anagen takes place. In early lesions there was a reduction in the size of the lower follicle, with preservation of the upper part of the follicle and the sebaceous gland. In long-standing disease, the entire follicle became smaller. The matrix of these miniaturized anagen follicles was mitotically active and produced a normal inner root sheath. However, the cortex was incompletely keratinized. Van Scott interpreted these changes as indicating arrest of follicle development in Anagen 4. A later study supported these findings and proposed that, while the disease is active, follicles are unable to develop beyond Anagen 3–4 and then return prematurely to telogen (Fig. 63.24) [9]. Follicles may pass through repeated truncated cycles until the disease activity subsides, and are then able to progress further into anagen.

Except in very long-standing alopecia, hair follicles are retained, even in clinically hairless scalp. When alopecia areata has persisted for many years, particularly in the universal form, there may be a decline in follicle density, possibly associated with fibrosis of the perifollicular connective tissues.

The hair follicle target

The inflammatory infiltrate in alopecia areata is concentrated in and around the bulbar region of anagen hair follicles. Cells of several different types and differentiation pathways are found in the hair bulb, but which of these is the primary focus of the pathology is unknown. Trichocytes in the hair bulb matrix undergoing early cortical differentiation may show vacuolar degeneration (Fig. 63.25) [10,11] and are also the predominant cell type showing aberrant class I and II MHC expression [4]. However, increased MHC expression is also seen in the dermal papilla, and pathological changes have been described in dermal papillae in clinically non-lesional sites [12]. Hence, it is possible that changes in the epithelial compartment of the hair follicle are secondary to dysfunction of the dermal papilla. The sparing of white hair sometimes seen in alopecia areata has raised the possibility that alopecia areata is primarily a disease of hair bulb melanocytes. Alopecia areata may show other pigmentary features including reduced pigmentation in regrowing hairs and an association with vitiligo [13,14]. However, the melanocyte hypothesis does not explain why sparing of white hair is often a relative phenomenon and is sometimes absent.

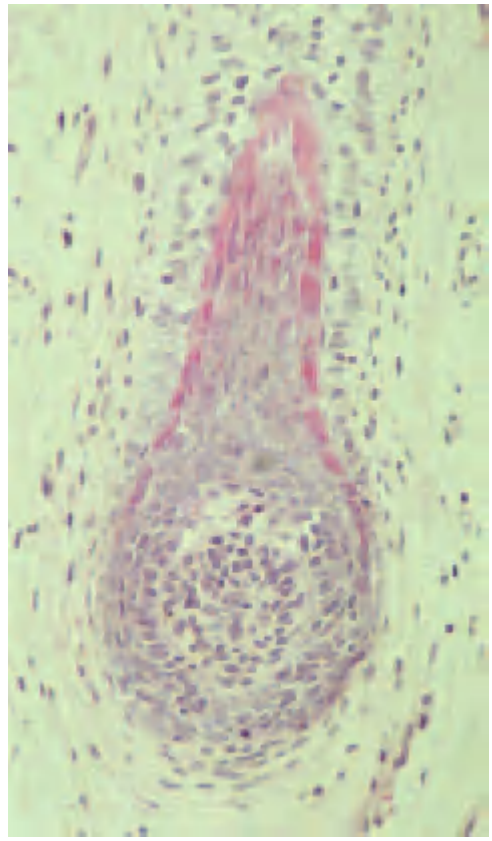

Fig. 63.25 An early anagen follicle in alopecia totalis showing vacuolation in the hair matrix epithelium around the upper pole of the dermal papilla.

Animal models

Alopecia areata occurs in mammals other than humans, including chimps, dogs, horses, rats and mice. Two rodent

strains, in which alopecia areata is common, the Dundee experimental bald rat (DEBR) and the CH3/HeJ mouse, have been used as experimental models of the disease.

Dundee experimental bald rat

In this strain of the brown hooded rat, animals grow a normal first coat of hair but then become progressively hairless [15]. Skin histological examination confirms the persistence of hair follicles, mostly in a dystrophic anagen state. Perifollicular and intrafollicular lymphocytic infiltration is a prominent feature and vacuolar degeneration occurs in the cortex of some lesional anagen follicles. Increased expression of HLA class I and II molecules in the dermal papilla and precortical matrix is seen in a pattern similar to human alopecia areata [16]. Hair regrowth in DEBR alopecia can be stimulated by photochemotherapy (PUVA), topical minoxidil, systemic ciclosporin [17] and topical tacrolimus [18]. Partial regrowth can also be induced by depletion of circulating CD4 or CD8 cells using monoclonal antibodies, suggesting that T cells have an active role in the pathogenesis [19,20].

C3H/HeJ mouse

A diffuse non-scarring alopecia with clinical and pathological features similar to alopecia areata was reported by Sundberg *et al*. [21] in a large production colony of C3H/HeJ mice. On the dorsal skin, the alopecia developed in circular areas, with disease involvement restricted to anagen follicles. Pedigree analysis suggested the disease was inherited. Alopecia was more common in ageing animals, and the frequency was highest in mice selectively bred for inflammatory bowel disease. Subsequent studies have revealed considerable similarity in histopathology, immunological features and response to therapeutic agents between C3H/HeJ alopecia and human alopecia areata.

Clinical features

The onset of alopecia areata may be at any age, peaking between the second and fourth decades. The sex incidence is probably equal. The characteristic initial lesion is a circumscribed, totally bald, smooth patch (Fig. 63.26). It is often noticed by chance by a parent, hairdresser or friend. The skin within the bald patch appears normal or slightly reddened. Short, easily extractable broken hairs, known as exclamation mark hairs, are often seen at the margins of the bald patches during active phases of the disease (Fig. 63.27). Subsequent progress is very varied; the initial patch may regrow within a few months, or further patches

Fig. 63.26 Patch of alopecia areata. Broken 'exclamation mark hairs' are seen towards the margins of the patch.

Fig. 63.27 Exclamation mark hairs.

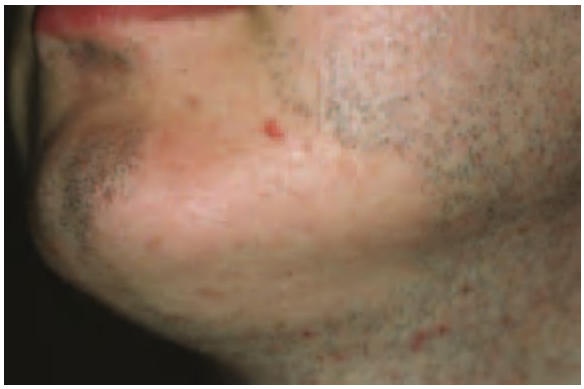

Fig. 63.28 Alopecia areata affecting the beard.

may appear after an interval of 3–6 weeks and then in a cyclical fashion. These intervals are of varying duration. A succession of discrete patches may rapidly become confluent by the diffuse loss of remaining hair. In some cases the initial hair loss is diffuse, and total denudation of the scalp has been reported within 48 h. However, diffuse hair loss may occur over part or the whole of the scalp without the development of bald areas. Regrowth is often at first fine and unpigmented, but usually the hairs gradually resume their normal calibre and colour. Regrowth in one region of the scalp may occur while the alopecia is extending in others.

The scalp is the first affected site in most cases, but any hair-bearing skin can be affected. In dark-haired men, patches in the beard are conspicuous and in such individuals are often the first to be noticed (Fig. 63.28). The eyebrows and eyelashes are lost in many cases of alopecia areata and may be the only sites affected. The term alopecia totalis is applied to total or almost total loss of scalp hair, and alopecia universalis is the loss of all body hair. The extension of alopecia along the scalp margin is known as ophiasis (Fig. 63.29).

An intriguing feature of alopecia areata is the sparing of white hairs. In patients with grey hair, which is an admixture of pigmented and non-pigmented hair, the disease process appears preferentially to affect pigmented hair, so

Fig. 63.29 The ophiasis pattern of alopecia areata.

Fig. 63.30 Regrowth of hypopigmented hair in alopecia areata.

that non-pigmented or white hair is spared. This may result in a dramatic change in hair colour if the alopecia progresses rapidly, and is probably the explanation for historical accounts of people 'going white overnight'. Sparing of white hair is a relative phenomenon and it is clear that the white hairs, although less susceptible to the disease, are not immune. During the regrowth phase hairs may be non- or hypopigmented (Fig. 63.30) but hair pigmentation usually recovers completely. In exceptional cases where regrowing hairs remain non-pigmented the possibility of concurrent vitiligo should be considered.

In 10–15% of cases referred for specialist opinion alopecia areata also involves the nails, usually in the context of severe hair loss. Classically, alopecia areata causes fine stippled pitting of the nails (Fig. 63.31), but some cases show less well-defined roughening of the nail plate (trachyonychia) or a non-specific atrophic dystrophy. For some patients, the latter problem is the most troublesome aspect of the disease.

Differential diagnosis

In children the main sources of difficulty are tinea capitis

Fig. 63.31 An organized pattern of pitting present on all fingernails 8 months prior to onset of alopecia areata. Pits are highlighted with mascara.

and trichotillomania. Tinea capitis should always be considered in children presenting with patchy hair loss. There is usually evidence of scalp inflammation but this may be limited to mild scaling. The hair loss in trichotillomania may be asymmetrical or occur in artificial shapes. Broken hairs are usually present across the areas of hair loss, giving a bristly texture and, unlike exclamation mark hairs, are firmly anchored in the scalp. In most cases the true diagnosis will become evident with time; a biopsy is useful when doubt remains. Occasionally, the early stages of scarring alopecia can resemble alopecia areata. The diffuse form of alopecia areata is perhaps the most difficult to identify. A history of previous episodes of hair loss, nail dystrophy and the usually rapid progression may provide clues, but other causes of diffuse hair loss, such as SLE, may need to be excluded by appropriate serological tests and a scalp biopsy. Secondary syphilis sometimes presents with diffuse or patchy hair loss.

Prognosis

Alopecia areata does not destroy hair follicles, and the potential for regrowth of hair is retained for many years and is possibly lifelong. In some patients, patches of hair loss occur at infrequent intervals interspersed with long periods of normal hair growth. In others, alopecia areata is more persistent, so that new patches of hair loss continue to develop at the same time as regrowth occurs elsewhere. In a relatively small number of patients, hair loss progresses to involve all of the scalp (alopecia totalis) or the entire skin surface (alopecia universalis); in these cases, spontaneous recovery is the exception rather than the rule.

Data from secondary and tertiary referral centres indicate that 34–50% of patients will recover within 1 year, although almost all will experience more than one episode of the disease, and 14–25% progress to alopecia totalis or alopecia universalis, from which full recovery is unusual (less than 10%) [1,2]. One study from Japan reported that spontaneous remission within 1 year occurred in 80% of patients with a small number of circumscribed patches of hair loss [3]. The prognosis is less favourable when onset occurs during childhood [1,4–6] and in ophiasis [6]. The concurrence of atopic disease has been reported to be associated with a poor prognosis [3,6], but this was not found in a study from India [7].

Management

A number of treatments can induce hair growth in alopecia areata, but none has been shown to alter the course of the disease. The high rate of spontaneous remission makes it difficult to assess efficacy, particularly in mild forms of the disease. Some trials have been limited to patients with severe alopecia areata where spontaneous remission is unlikely. However, these patients tend to be resistant to all forms of treatment and the failure of a treatment in this setting does not exclude efficacy in mild alopecia areata. Few treatments have been subjected to randomized controlled trials and, except for contact immunotherapy, there are few published data on long-term outcomes. These difficulties mean that counselling of the patient and, where relevant, of their family, are of paramount importance. This should include discussion of the nature of the disease and its natural history, the treatments available and their chances of success. Some patients have great difficulty coping with alopecia areata and require considerable support. Sources of support may include the physician, other patients, formal patients' sup-

port groups and, in some circumstances, professional counselling services.

Treatment. Leaving alopecia areata untreated is a legitimate option for many patients. Spontaneous remission occurs in up to 80% of patients with limited patchy hair loss of short duration (less than 1 year) [1]. Such patients may be managed by reassurance alone, with advice that regrowth cannot be expected within 3 months of the development of any individual patch. The prognosis in long-standing extensive alopecia is less favourable. However, all treatments have a high failure rate in this group and some patients prefer not to be treated, other than wearing a wig if appropriate.

Corticosteroids. Intralesional depot corticosteroids have a small but useful role in the management of alopecia areata [2,3]. They can be used to accelerate regrowth in a circumscribed patch of alopecia areata that is cosmetically disfiguring or difficult to conceal, and can be useful for maintaining regrowth of the eyebrows in alopecia totalis; but great care must be exercised to avoid steroid side effects in the eye. Hydrocortisone acetate (25 mg/mL) and triamcinolone acetonide (5–10 mg/mL) are commonly used, either by needle injection or jet injection. Localized atrophy is a common complication, particularly if triamcinolone is used, but this is temporary and recovers within a few months.

Potent topical corticosteroids are widely used to treat alopecia areata but there is little evidence that they produce significant regrowth of hair. In some cases, a troublesome folliculitis may result.

Long-term daily treatment with oral corticosteroids will produce regrowth of hair in some patients. One small, partly controlled study reported that 30–47% of patients treated with a 6-week tapering course of oral prednisolone (starting at 40 mg/day) showed more than 25% hair regrowth [4]. Unfortunately, in most patients, continued treatment is needed to maintain hair growth and the response is usually insufficient to justify the risks [5]. There are several case series reporting response to high-dose pulsed corticosteroid treatment employing different oral and intravenous regimens [6–8]. However, these studies were uncontrolled and, although none reported significant side effects, the potential toxicity of systemic corticosteroids remains a serious concern.

Contact immunotherapy. Contact immunotherapy was introduced by Rosenberg in 1976 [9] and is the most effective and best-documented treatment for alopecia areata, but problems associated with its use mean that it is available in only a few centres. The patient is sensitized to a potent allergen and the same allergen is then applied to the scalp, usually at weekly intervals, in a concentration sufficient to induce a mild contact dermatitis. The contact allergens that have been used in the treatment of alopecia areata include dinitrochlorobenzene (DNCB), squaric acid dibutylester (SADBE) and diphenylcyclopropenone (DPCP). Most centres now use DPCP [10]. A review of all the published studies of contact immunotherapy concluded that 50–60% of patients achieve a worthwhile response, but the range of response rates was very wide (9–87%) [11]. Patients with extensive hair loss are less likely to respond [12,13]. Other reported adverse prognostic features include the presence of nail changes, early onset and a positive family history [11]. In most studies treatment was discontinued after 6 months if no response was obtained. In one case series from Canada, clinically significant regrowth occurred in approximately 30% of patients after 6 months' treatment, but this increased to 78% after 32 months of treatment, suggesting that more prolonged treatment is worthwhile [14]. The response in patients with alopecia totalis and universalis was less favourable at 17% and this was not improved by treatment beyond 9 months. Relapses may occur following or during treatment. In the Canadian series, relapse following successful treatment occurred in 62% of patients. Two case report series of contact immunotherapy in children with alopecia areata reported response rates of 33% [15] and 32% [16]. A third study found a similar short-term response in children with severe alopecia areata, but less than 10% experienced sustained benefit [17].

Most patients will develop occipital and/or cervical lymphadenopathy during contact immunotherapy. This is usually temporary but may persist throughout the treatment period. Severe dermatitis is the most common adverse event, but the risk can be minimized by careful titration of the concentration. Uncommon adverse effects include urticaria [18], which may be severe [19], and vitiligo [20,21]. Cosmetically disabling pigmentary complications, both hyper- and hypopigmentation (including vitiligo), may occur if contact immunotherapy is used in patients with racially pigmented skin. Contact immunotherapy has been in use for 20 years and no long-term side effects have been reported.

The mode of action of contact immunotherapy is unknown. Happle [22] suggested that the contact allergen competes for CD4 cells, attracting them away from the perifollicular region ('antigenic competition'). Other suggested mechanisms include the non-specific stimulation of a local T-suppressor-cell response [23] and increased expression of TGF-β in the skin, which acts to suppress the immune response [24].

Photochemotherapy. There are several uncontrolled studies of photochemotherapy (PUVA) for alopecia areata, using all types of PUVA (oral or topical psoralen, local or whole body UVA irradiation) [25–28], claiming success rates of up to 60–65%. Two retrospective reviews have reported low response rates [29] or suggested that the response

was no better than the natural course of the disease [30], although these observations were also uncontrolled. The relapse rate following treatment is high and continued treatment is usually needed to maintain hair growth, which may lead to an unacceptably high cumulative UVA dose.

Minoxidil. An early double-blind study reported a significantly greater frequency of hair regrowth in patchy alopecia areata in patients treated with topical 1% minoxidil compared with placebo [31]. Subsequent controlled trials in patients with extensive alopecia areata using 1% or 3% minoxidil failed to confirm these results [32–34]. Two of these studies reported a treatment response during an extended but uncontrolled part of the trial [33,34]. In one study comparing 5% and 1% minoxidil in extensive alopecia areata, regrowth of hair occurred more frequently in those receiving 5% minoxidil, but few subjects obtained a cosmetically worthwhile result [35]. Topical minoxidil is ineffective in alopecia totalis and universalis.

Dithranol. There are a small number of case report series of the use of dithranol (anthralin) or other irritants in the treatment of alopecia areata [36–38]. The lack of controls makes the response rates difficult to evaluate but only a small proportion of patients seem to achieve cosmetically worthwhile results. In one open study, 18% of patients with extensive alopecia areata achieved cosmetically worthwhile hair regrowth [36]. The published data indicate that dithranol needs to be applied sufficiently frequently and in a high enough concentration to produce a brisk irritant reaction in order to be effective.

Summary

Alopecia areata is difficult to treat and few treatments have been tested in randomized controlled trials. The tendency to spontaneous remission and the lack of adverse effects on general health are important considerations in management, and counselling, with no treatment, is the best option in many cases. Intralesional corticosteroids can be helpful in disease of limited extent, especially in cosmetically obvious sites. Topical corticosteroids, minoxidil lotion and dithranol are widely used but there is little convincing evidence of efficacy. Contact immunotherapy is the most effective treatment for extensive alopecia areata, although it is not widely available, and the response rate in alopecia totalis and universalis is low. The place of systemic corticosteroids is controversial. In view of the lack of evidence of sustained efficacy and the potential hazards, their routine use in alopecia areata cannot be recommended.

Alopecia areata may cause considerable psychological and social disability and, in some cases, particularly those seen in secondary care, it may be a chronic and persistent disease causing extensive or universal hair loss. If the prognosis is poor (e.g. in a prepubertal atopic child with total alopecia), a full explanation and help in adjusting to the problems of hair loss will be of far greater value than the raising of unwarranted hopes.

Acquired cicatricial alopecia

[R.D. Sinclair, pp. 63.46–63.61]

Hair follicles are self-regenerating organs. A new and distinct hair bulb is produced for every anagen phase of the hair cycle. Stem cells located within the outer root sheath (ORS) at the level of insertion of the arrector pili muscle have the potential to induce not only hair bulb regeneration, but also sebaceous gland formation and re-epithelialization of the epidermis [1]. Selective damage to the ORS in the isthmus that destroys hair follicle stem cells will ultimately lead to loss of the entire pilosebaceous unit and replacement by a fibrous tract or stella. Other non-selective forms of hair follicle damage can produce a similar outcome.

Cicatricial alopecia is the generic term applied to permanent areas of hair loss that are associated with destruction of hair follicles. Following recovery from the initial injury or inflammatory insult, there is little if any potential for hair regrowth. Histologically, the follicles are replaced by fibrous stellae, but as there is no scar *per se* the alternative generic term *scarring alopecia* is not favoured [2]. Replacement of follicular structures by fibrous tissue is the common final pathway for a number of diverse conditions and it is commonly not possible to infer the cause of the hair loss.

Cicatricial alopecia is by no means rare. In Whiting's series of 5860 patients presenting with hair loss between 1989 and 1999, 427 (7.3%) had cicatricial alopecia [3]. One of the earliest descriptions of cicatricial alopecia was by Brocq in 1885 [4]. He described what later became known eponymously as pseudopelade of Brocq [5], which is now regarded as a syndrome in which destruction of follicles leading to permanent patchy baldness is not accompanied by any clinically evident inflammatory pathology. Quainquad [6] described folliculitis decalvans, a form of scarring alopecia in which pustular folliculitis of the advancing margin was a conspicuous feature.

Cicatricial alopecia may result from a disease that affects the follicles primarily or a disease process external to the follicle that damages them secondarily. Secondary causes include trauma, as in burns or radiodermatitis, infections such as favus, tuberculosis or syphilis, or benign or malignant tumours. Chemicals used to straighten or curl hair may also cause a secondary cicatricial alopecia in susceptible persons.

Once the preliminary diagnosis of cicatricial alopecia has been made, the scalp should be examined for other clues as to the cause of the hair loss such as folliculitis, follicular plugging or broken hairs. These signs may help to establish the cause of a cicatricial alopecia, but no single sign is pathognomonic for a particular disease, and clinicopathological correlation is usually needed to make a specific diagnosis. An occasional sterile pustule can even be seen in some cases of lichen planopilaris and chronic cutaneous lupus. Hairs, even if grossly normal in appearance, should be extracted from the edge of the bald area for microscopy and culture. Any pustule should be swabbed and the fluid cultured. If no firm diagnosis is achieved, general examination of the skin, nails and oral mucosa should be carried out. Up to 40% of patients with scalp lichen planus and 30% of patients with discoid lupus of the scalp will have cutaneous disease elsewhere either at presentation or during follow-up.

In most cases, a diagnostic biopsy is indicated. The site for biopsy must be carefully selected and an early lesion is preferable. Several punch biopsies are preferable to a single elliptical biopsy; in this way, the biopsies can be orientated along follicles, and different stages of the disease process can be investigated. Ideally, at least one 4-mm biopsy should be taken from a clinically active area, prepared for horizontal section and stained with haematoxylin and eosin. If vertical sections or immunofluorescence are desired, a second 4-mm biopsy specimen from an area of similar clinical activity should be obtained. Additional biopsies from the centre of a patch of alopecia to establish whether follicular loss has occurred or to assess potential regrowth are optional, as are further biopsies for special stains (e.g. elastin, mucin, periodic acid–Schiff [PAS]) [2].

Classification of the primary causes of cicatricial alopecia is difficult because of changing clinical and histological features as these conditions evolve. The most common identifiable causes among white people are lichen planopilaris (LPP), folliculitis decalvans and discoid lupus erythematosus. Among black people, especially in North America and Europe where hair-straightening procedures are common, the most common cause is central centrifugal alopecia (see p. 63.54). Tumours, in particular metastatic nodules from renal, breast and lung carcinomas, should not be forgotten as a rare but important cause of cicatricial alopecia.

Despite multiple investigations a specific diagnosis is not always possible and a generic diagnosis of cicatricial alopecia is the best that can be done. In such cases, a trial of oral steroids or antimalarials may be considered to assess the potential for regrowth. Surgical correction of small areas can be considered once the underlying disorder has burned out. This can be done either by follicle transplantation or excision of the area. Larger areas may require the prior use of tissue expanders [7].

Classification [2]. The causes of cicatricial alopecia are classified here into broad groups, and the individual causes then considered in greater detail. Many of the causes are discussed in other chapters where appropriate.

1 *Primary cicatricial alopecia*

Inflammatory	Lymphocytic	Chronic cutaneous lupus erythematosus
		Lichen planopilaris (LPP)
		Classic LPP
		Graham-Little syndrome
		Frontal fibrosing alopecia
		Pseudopelade of Brocq
		Central centrifugal cicatricial alopecia
		Alopecia mucinosa
		Keratosis pilaris spinulosa decalvans
		Morphoea/scleroderma
	Neutrophilic	Folliculitis decalvans (including tufted folliculitis)
		Dissecting cellulitis/folliculitis
	Mixed	Acne keloidalis
		Acne necrotica
		Erosive pustular dermatosis
	Non-specific or end-stage cicatricial alopecia	

2 *Secondary cicatricial alopecia*

Traumatic	Radiodermatitis
	Mechanical trauma
	Postoperative (flap necrosis)
	Burns
	Accidental alopecia
	Dermatitis artefacta
	Traction alopecia
	Hot comb alopecia
Sclerosing disorders	Morphoea
	Scleroderma
	Lichen sclerosus
	Sclerodermoid porphyria cutanea tarda
	Chronic graft-versus-host disease
Granulomatous	Sarcoidosis
	Necrobiosis lipoidica
	Infectious granulomas
Infectious	Bacterial: Folliculitis
	Bacterial: Carbuncle/furuncle
	Fungal: Kerion
	Fungal: Favus
	Fungal: Tinea capitis (rarely scarring)
	Viral: Shingles
	Viral: Varicella
	Viral: HIV
	Protozoal: Leishmaniasis
	Protozoal: Syphilis
	Mycobacterial: Tuberculosis
Neoplastic	Benign: Cylindroma
	Benign: Other adnexal tumours
	Malignant: Primary: Basal cell carcinoma
	Malignant: Primary: Squamous cell carcinoma
	Malignant: Primary: Cutaneous T-cell lymphoma
	Malignant: Secondary: Renal, breast, lung, gastrointestinal
	Malignant: Secondary: Lymphoma, leukaemia

Developmental defects and hereditary disorders

Aplasia cutis
Facial hemiatrophy (Romberg's syndrome)
Epidermal naevi
Hair follicle hamartomas
Incontinentia pigmenti
Focal dermal hypoplasia of Goltz
Porokeratosis of Mibelli
Ichthyosis
Epidermolysis bullosa
Polyostotic fibrous dysplasia
Conradi–Hünermann syndrome (chondrodysplasia punctata)

Non-specific cicatricial alopecia

Aetiology. This is by far the most common diagnosis made among patients presenting with cicatricial alopecia. In Whiting's series of 358 patients who were biopsied because of cicatricial alopecia this was the diagnosis made in 32% of cases [1]. Although often called pseudopelade, this term is best avoided because of confusion with pseudopelade of Brocq, a specific and distinct clinical disease. This entity of non-specific cicatricial alopecia encompasses a range of idiopathic non-inflammatory irregular permanent alopecias that are often slowly progressive. Many primary cicatricial alopecias ultimately burn out and the final common pathway is an irregular area of cicatricial hair loss of the scalp with no distinguishing clinical or histological features. Various authorities have estimated that between 15% and 90% of cases of non-specific cicatricial alopecia result from LPP, but there is no way of confirming this. That a small minority of patients initially diagnosed as having non-specific cicatricial alopecia later develop associated cutaneous lichen planus confirms significant overlap between this condition and LPP.

Pathology. The histology is variable and non-specific. Scalp biopsies taken from hairy skin at the edge of a scarred patch may be either completely normal or show a non-specific lymphocytic infiltrate around follicular infundibulum and mid-follicle, with or without a light superficial perivascular infiltrate. Follicles may be depleted and replaced by fibrous tracts, and sebaceous glands and follicular units may be disrupted. In the centre of areas of alopecia, follicles are absent or dramatically diminished in number and the epidermis is atrophic. Concentric lamellar fibrosis and follicular atrophy is seen around residual follicles. The adjacent dermis is sclerotic. Follicle rupture can produce hair granulomas or pustules.

Clinical features. The initial patch often occurs over the crown, but may occur anywhere on the scalp. The lesions tend to be oval, and several foci may coalesce to form irregular bald areas. There is usually no erythema and the patches are smooth, shiny and slightly depressed. Within any patch, a small number of terminal hairs may persist. These are often irregularly twisted and sometimes easily extracted. Folliculitis is rarely seen. The hairs at the edge of the patch of alopecia are also often irregularly twisted and easily extracted, even when in anagen, which indicates active extension of the alopecia.

Prognosis. The prognosis is extremely variable and unpredictable. Some patches extend almost imperceptibly over many years, whereas others enlarge rapidly. Whether this condition ever truly burns out, or merely extends too slowly to be noticed is uncertain.

Treatment. Much has been tried empirically, but nothing has been shown to be effective.

Lichen planus (see Chapter 42)

SYN. LICHEN PLANOPILARIS; FRONTAL FIBROSING ALOPECIA

Aetiology. Lichen planus is an idiopathic inflammatory disease that may affect the skin, hair and nails. There are numerous cutaneous variants of lichen planus. On the scalp it tends to produce a cicatricial alopecia. Three variants of cicatricial alopecia resulting from lichen planus are recognized: LPP, Graham-Little syndrome and frontal fibrosing alopecia. In each of these conditions the scalp may be affected alone or in conjunction with lichen planus elsewhere.

Lichen planus occurs throughout the world, but there are marked regional variations in its incidence and in its clinical manifestations. In the USA, lichen planus accounts for at least 10% of cases of cicatricial alopecia and the mean age of onset is 44 years [1]. In Europe and Australia, where follicular degeneration syndrome is less common, the incidence is higher. Although drug-induced lichen planus is well recognized, drug-induced LPP is not recognized.

Pathology [2]. The initial abnormality is in the epidermis; fibrillar changes in the basal cells lead to the formation of colloid bodies and at an early stage these, and macrophages containing pigment, may be seen in the dermis. By immunofluorescence, fibrin and immunoglobulin M (IgM) may be detected in the upper dermis, and various components of complement in the basement-membrane zone. The damaged basal cells are continually replaced by the migration of cells from neighbouring normal epidermis. In the established lesion, the horny layer and granular layer are thickened and there is irregular acanthosis. Flattening of the rete pegs gives rise to a saw-tooth configuration. There is liquefaction degeneration of the basal cells. Close up against the epidermis is a dense infiltrate of lymphocytes and some histiocytes. In many sections, colloid bodies can be seen. If the process involves hair follicles, the infiltrate extends around them and the hairs are replaced by keratin plugs. The follicles may ultimately be totally destroyed (Figs 63.32 & 63.33).

AGA with associated fibrosis may be confused with patterned LPP, especially as mild to moderate lymphohistiocytic inflammation is commonly seen in AGA [3].

Clinical features [4]. Lichen planus occurs at any age, but in over 80% of cases the onset is between 30 and 70 years [5]. Significant involvement of the scalp is relatively infrequent—only 10 of 807 patients in one series [5]—but the incidence is probably rather higher than such figures suggest, because they tend to exclude those patients in whom alopecia, classified as pseudopelade, was the only

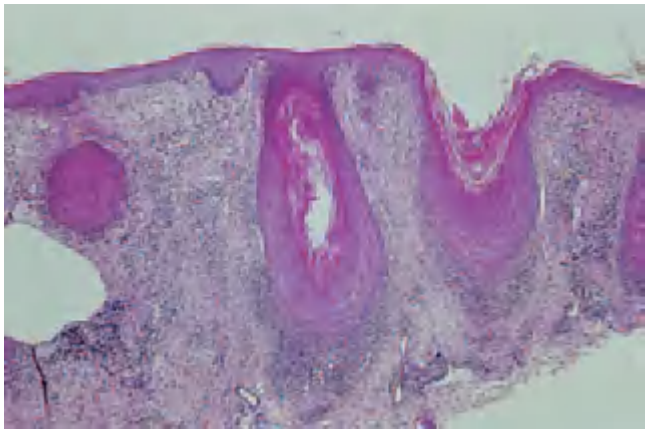

Fig. 63.32 Low-power photomicrograph showing lichen planopilaris. There is follicular plugging and a peri-appendageal inflammatory infiltrate.

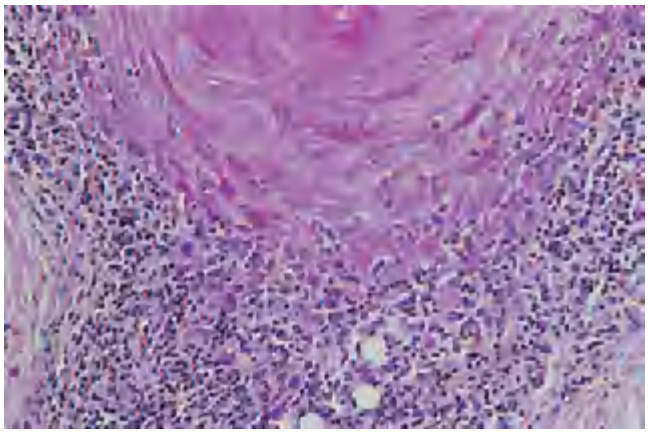

Fig. 63.33 Base of the hair follicle shows hydropic degeneration of the basal layer and a lichenoid mononuclear cell infiltrate.

Fig. 63.34 Scarring alopecia caused by lichen planus showing active lesions.

Fig. 63.35 More advanced lichen planus showing follicular plugs and scarring.

manifestation of the disease. Scalp involvement occurs in over 40% of patients with either of two unusual variants of lichen planus: the bullous or erosive form and LPP. Most patients seen with scalp lesions are middle-aged women, but a girl aged 13 years with scarring has been reported [6].

Recent scalp lesions may show violaceous papules, erythema and scaling (Fig. 63.34) [7]. These papules are replaced quickly by follicular plugs and scarring (Fig. 63.35). Eventually, the plugs are shed from the scarred area, which remains white, smooth and atrophic. Follicular orifices are absent within the area of alopecia. If the patch is extending, horny plugs may still be present in follicles around its margins, and the hair pull will be positive at the margins, with twisted anagen hairs being easily extracted by gentle traction.

Patients commonly present with pseudopelade-like patches of scarring that are non-specific. The diagnosis of lichen planus can be made only in the presence of unquestionable lesions elsewhere and lichen planus histology. These may take the form of bullous lichen planus with shedding of nails [8], of bullous lesions associated with typical lichen planus of the skin and mucous membranes [9], or of lichen planus of very limited extent involving, for example, the nails only [10].

One clinical variant of LPP is frontal fibrosing alopecia (Fig. 63.36) [11]. This condition superficially resembles AGA with frontal recession, but on close inspection there is loss of follicular orifices, and perifollicular erythema and hyperkeratosis at the marginal hairline. It typically occurs in postmenopausal women, although it can occur earlier. In contrast with AGA, the frontal hairline recedes in a straight line rather than bitemporally.

The natural history of frontal fibrosing alopecia is slow progression over many years. There is no effective treatment [11].

Prognosis. In some patients, the course of lichen planus of the scalp is slow and only a few inconspicuous patches are present after many years. However, particularly if the skin lesions are of bullous or planopilaris type, they may rapidly result in extensive and permanent baldness.

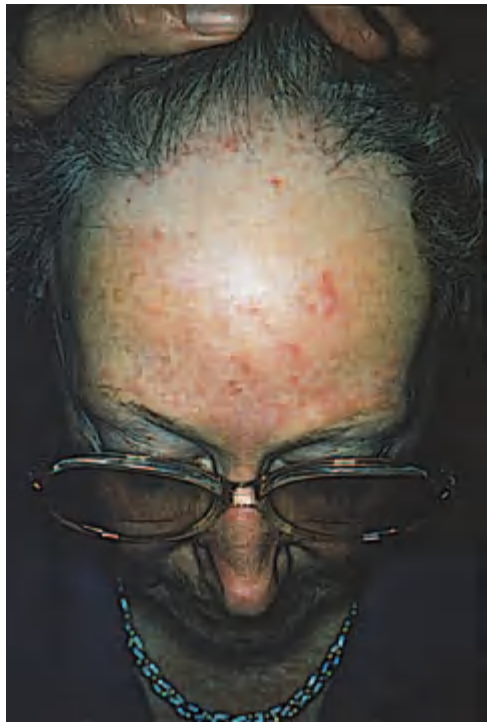

Fig. 63.36 Frontal fibrosing alopecia of Kossard.

Treatment. In some cases, a short course of systemic treatment with a corticosteroid may be desirable. In other cases, intralesional corticosteroids are helpful, but only at a stage when active inflammatory changes are still present. Potent topical steroids such as clobetasol propionate ointment twice daily usually relieve associated symptoms such as itch or pain, and may slightly inhibit the process [12]. Hydroxychloroquine and acitretin have been tried with variable success. Ciclosporin is very effective for cutaneous lichen planus, and has been reported as useful in Graham-Little syndrome [13], as has thalidomide [14,15].

Graham-Little syndrome [1,2]

In 1915, Graham-Little reported the case of a woman aged 55 years who had suffered for 10 years from slowly progressive cicatricial alopecia and for 5 months from groups of horny papules [3]. Since then many further cases have been reported. Whether this syndrome is or is not a form of lichen planus is still unresolved, although the immunofluorescence in typical cases strongly suggests lichen planus [4]. However, whatever its cause or causes, the syndrome is distinctive. It is known eponymously and variously as the Graham-Little, Lassueur–Graham-Little or Piccardi–Lassueur–Little syndrome.

Pathology. In the scalp, the mouths of affected follicles are filled by horny plugs. The underlying follicle is progressively destroyed and eventually an atrophic epidermis covers sclerotic dermis. In the axillae and pubic region, the follicles are likewise destroyed, although the skin does not appear clinically to be atrophic.

Clinical features. Most patients are women between the ages of 30 and 70 years. The essential features of the syndrome are progressive cicatricial alopecia of the scalp, loss of pubic and axillary hair without clinically evident scarring, and the rapid development of keratosis pilaris [5].

In most patients, the earliest change has been patchy cicatricial alopecia of the scalp. In general, the scalp alopecia precedes the widespread keratosis pilaris by months or years [6]. In some patients, the alopecia and the keratosis pilaris appear to have developed more or less simultaneously, or the keratosis pilaris has preceded the discovery of the alopecia [7].

The scalp changes are commonly described simply as patches of cicatricial alopecia. Some authors specifically mention associated follicular plugging of the scalp [7]; others refer to ‘scaly red patches’.

The keratosis pilaris is referred to in early case reports as lichen spinulosus, which emphasizes that the horny papules are prolonged into conspicuous spines. In most cases they have developed aggressively over a period of weeks or months and have been grouped into plaques,

often on the trunk, or the trunk and limbs, but occasionally involving the eyebrows and the sides of the face. Pruritus is an inconstant symptom; it was noted in several reported cases [8]. Thinning and ultimately total loss of pubic and axillary hair has been noted in many cases.

Treatment. None is universally effective. Ciclosporin was reported as useful in a single case [9].

Discoid lupus erythematosus [1]

Lupus erythematosus (LE) is an autoimmune connective tissue disease characterized by the presence of circulating non-organ-specific autoantibodies to cell nuclear antigens. Three different forms of LE are described: systemic (SLE), subacute and discoid (DLE) lupus. However, only DLE regularly produces cicatricial alopecia. Inflammation of the infundibular region of the hair follicle that contains the stem cells is thought to be the basis of the scarring alopecia that occurs in DLE, but this does not explain why the identical pattern of inflammation seen in SLE does not scar. The diffuse hair shedding that accompanies SLE is believed to be an acute telogen effluvium.

Pathology [2]. The histology of DLE, in common with SLE, shows hyperkeratosis with follicular plugging, a perivascular and periadnexal lymphoid infiltrate, which may be sparse, moderate or heavy, and the essential feature of focal basal layer vacuolar degeneration (Figs 63.37–63.39). This may be associated with colloid body formation, pigmentary incontinence, papillary dermal oedema, thickening of the basement-membrane zone and exocytosis of lymphocytes into the epidermis and follicular epithelium. Mucin can be seen in the dermis as a faint blue tinge between widely separated collagen bundles. Scarring only occurs in DLE and manifests as homogenized collagen fibres running parallel to the surface, a loss of appendages and lone arrector pili muscles. Staining for elastin shows that elastic fibres are absent from the scar.

Hypergranulosis, saw-toothed rete ridges, perifollicular fibrosis and clefts are not seen in lupus, and this helps to distinguish it from lichen planus. However, frequently it is not possible to separate these two conditions on routine histological examination and in such cases

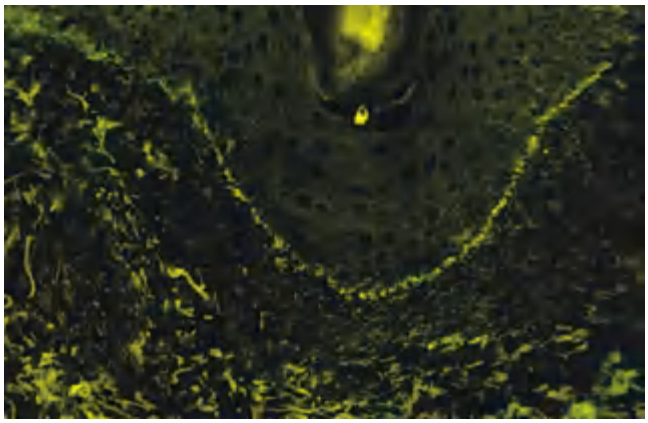

Fig. 63.40 Positive linear immunofluorescence to IgG: the lupus band test. (Courtesy of Dr G. Mason, Melbourne, Australia.)

immunofluorescence may be decisive. There is linear staining of deposits of complement (C3), IgM and IgG on the basement membrane in more than 80% of cases of LE, but not in lichen planus. Direct immunofluorescence is also positive in non-lesional skin in approximately 50–75% of cases of SLE, depending on whether sun-exposed or non-exposed skin is chosen. Only approximately 20% of cases of DLE will have positive immunofluorescence of uninvolved skin. A weak false-positive immunofluorescence to IgM can occur on the head and neck and is a source of confusion. Only positivity to IgG or very strong positivity to IgM (Fig. 63.40) should be used as supportive evidence of lupus on the scalp, as this only rarely occurs in the absence of lupus.

In old burnt-out lesions, the histology and immunofluorescence may be inconclusive and in such cases a non-specific diagnosis such as scarring alopecia is all that can be made.

Fig. 63.41 Discoid lupus erythematosus producing cicatricial alopecia.

Clinical features [2]. DLE occurs most commonly in women (8 : 1 for SLE and 2 : 1 for DLE) and is about three times more common in African Americans than in white people. The incidence is approximately 1 in 2000. Familial cases occur in approximately 10%. The peak age of onset is around 40 years.

Scarring alopecia occurs in 20% of men and 50% of women affected with DLE, and the scalp is the only area affected in a significant number of patients. Patches on the scalp are often itchy. Areas of erythema and scaling with follicular plugging extend irregularly across the scalp and produce scarring (Fig. 63.41). Sometimes patches of scarring alopecia develop with little in the way of preceding inflammation and then resemble pseudopelade of Brocq. Ultimately, large areas of alopecia may form. Some cases burn out after 1–2 years, but others continue to progress for many years.

Pigmentary disturbance, particularly in dark-skinned people is common. Rarely, calcification occurs in the patches. Squamous cell carcinoma has been reported in chronic cicatricial LE of the scalp [3].

Antinuclear antibody (ANA) is positive in approximately 35% of patients with DLE. Anti-Ro antibodies are found in 10%. DLE may occur on its own or associated with SLE. If the initial DLE is confined to the head and neck, the risk is 1–2%, whereas if the lesions are generalized the risk is 22%. SLE first presents with DLE in 10% of cases and DLE can be found at some stage during the course of SLE in 33%.

Treatment [4]. Potent topical corticosteroids, intralesional triamcinolone and systemic prednisolone (1 mg/kg) may halt progression of active DLE. Antimalarials form the mainstay of treatment in chronic cases refractory to topical steroids. Hydroxychloroquine in a regimen of 200–400 mg/day produces a remission within 3 months in the majority and the dosage can then be tapered gradually. Scarring is permanent, but early treatment may produce a surprising amount of regrowth. Chloroquine, acitretin, dapsone, thalidomide or a combination of these medications may be useful in refractory cases. Cyclophosphamide, methotrexate and ciclosporin have also been used in severe, rapidly progressive cases where all other treatments have failed.

Pseudopelade of Brocq [1]

Pseudopelade of Brocq is an idiopathic, chronic, slowly progressive, patchy cicatricial alopecia that occurs without any evidence of inflammation. It is primarily an atrophy rather than an inflammatory folliculitis. The term pseudopelade was first used by Brocq to distinguish this condition from the 'pelade' of alopecia areata. The French term pelade had been in use at that time for more than 200 years and is derived from *pelage*—the fur, hair, wool, etc. of a mammal. In recent times, the term pseudopelade has been used to describe a generic scarring alopecia, the end result of any number of different pathological processes, and the interchangeable use by some of 'pseudopelade' and 'pseudopelade of Brocq' has led to confusion in the literature.

Pathology [2]. Early lesions may have a light lymphocytic infiltrate around the upper two-thirds of the hair follicle (including the hair bulge) that spares the epidermis and eccrine glands [3]. This infiltrate invades the walls of the follicles and sebaceous glands and eventually destroys the entire pilosebaceous unit. Single hairs may survive within a patch for many years.

Later patches are smooth, soft and slightly depressed and histological examination reveals only a thin atrophic epidermis overlying a sclerotic dermis containing fibrotic streams extending into the subcutis. There are no inflammatory changes at this stage. These fibrotic streams are follicular 'ghosts'. Arrector pili muscles may be seen inserting into these fibrous remnants of hair follicles. Elastic stains are important in differentiating pseudopelade of Brocq from lichen planus, DLE and other scarring alopecias. With an acid–alcohol orcein stain, elastic fibres are seen around the lower part of the follicle, whereas in all the other scarring alopecias the scar tissue consists of collagen devoid of elastin.

Clinical features [1]. Pseudopelade of Brocq may occur in both sexes at any age. Most commonly, women over 40 years are affected. Childhood cases are rare [4]. The aetiology and pathogenesis are unknown. The condition is almost always sporadic, but the occurrence in two brothers suggests a genetic factor may be important. There is no doubt that lichen planus can produce a very similar clinical picture and there are some authorities who maintain, on the basis of associated skin lesions and histopathological findings, that 90% of cases of 'pseudopelade' are caused by lichen planus [5].

The alopecia is asymptomatic and is often discovered by chance. It always remains confined to the scalp. The initial patch is often on the vertex but may occur anywhere (Fig. 63.42). On examination, the affected patches are smooth, soft and slightly depressed. At an early stage in the development of any individual patch there may be some erythema. The patches tend to be small and round or oval, but irregular bald patches may be formed by the confluence of many lesions. The hair in uninvolved scalp is normal, but if the process is active the hairs at the edges of each patch are very easily extracted.

The course is extremely variable. Most often there is slow development over many years of small round patches of alopecia that ultimately converge to produce larger irregular areas of hair loss. The hair in the uninvolved scalp is normal and the progression is sufficiently slow that even after 15–20 years patients may still be able to arrange their hair in such a way as to conceal the bald areas. The entire process can burn out spontaneously at

Table 63.3 Diagnostic criteria for pseudopelade of Brocq. (After Braun-Falco *et al*. [1].)

Clinical criteria
Irregularly defined and confluent patches of alopecia
Moderate atrophy (late stage)
Mild perifollicular erythema (early stage)
Female : male ratio = 3 : 1
Long course (more than 2 years)
Slow progression with spontaneous termination possible
Direct immunofluorescence
Negative (or only weak IgM on sun-exposed skin)
Histological criteria
Absence of marked inflammation
Absence of widespread scarring (best seen with elastin stain)
Absence of significant follicular plugging
Absence, or at least a decrease of sebaceous glands
Presence of normal epidermis (only occasional atrophy)
Fibrotic streams into the dermis

any stage, leaving behind only relatively small areas of alopecia.

The diagnostic criteria of Braun-Falco *et al*. [1] shown in Table 63.3, and based on the histological criteria of Pinkus [6], should be fulfilled before this specific diagnosis is made. Cases that do not fulfil these criteria should be diagnosed generically as scarring alopecia.

Treatment. The alopecia is irreversible and does not respond to topical or intralesional corticosteroids. No treatment is known to arrest progression. If the disfigurement is considerable and no active inflammatory changes are present, autografting from unaffected to scarred scalp may be considered [7], or surgical 'expansion' techniques in severe cases.

Follicular degeneration syndrome [1]

This condition begins as a single focus of cicatricial alopecia over the vertex scalp in black women that gradually spreads outwards in a centrifugal pattern, but remains unifocal. It was originally called hot comb alopecia, but many patients have no preceding history of hot comb usage. A possible relationship to other hair-straightening procedures is postulated, but not conclusively proven. The name 'central centrifugal alopecia' has also been proposed, and this focuses attention on the clinical appearance of the hair loss rather than the histological identification of premature degeneration of the inner root sheath, which is variable and not entirely specific [2].

Pathology. A superficial perivascular and perifollicular lymphocytic infiltrate is seen in active areas. There is no associated interface change. Sebaceous glands are lost early, but eccrine glands are spared. Premature disintegration of the inner root sheath epithelium has been emphasized, but is not always found. Hair follicle destruction is severe and widespread and leaves prominent concentric lamellar fibrosis. Release of hair fragments into the dermis results in granulomatous inflammation.

Clinical features. Most patients are middle-aged black females who chemically straighten their hair. The alopecia is slowly progressive and the symmetrical forward progression follows a pattern similar to female pattern hair loss.

Treatment. Minimal hair grooming is recommended, but many patients find this difficult. No treatment has been found to help. Many patients resort to wearing a suitable hair piece.

Folliculitis decalvans and tufted folliculitis [1]

Under the general term folliculitis decalvans we group the various syndromes in which clinically evident chronic folliculitis leads to progressive scarring. This is probably a heterogeneous group.

Aetiology. The cause of folliculitis decalvans is still uncertain. *Staphylococcus aureus* may be grown from the pustules. In the vast majority of people who develop a bacterial pustular folliculitis of the scalp it is transient, resolves with antibiotics and heals without scarring. In some, the folliculitis is more persistent, tends to recur in the same site after apparently successful treatment with antibiotics and produces a scarring alopecia. An abnormal host response to *Staph. aureus* is postulated, which may be the result of a defect in cell-mediated immunity.

Shitara *et al*. [2] reported severe folliculitis decalvans in two siblings who also had chronic candidiasis; defective cell-mediated immunity was demonstrated. Douwes *et al*. [3] reported simultaneous occurence in identical twins, with no identifiable immune abnormality.

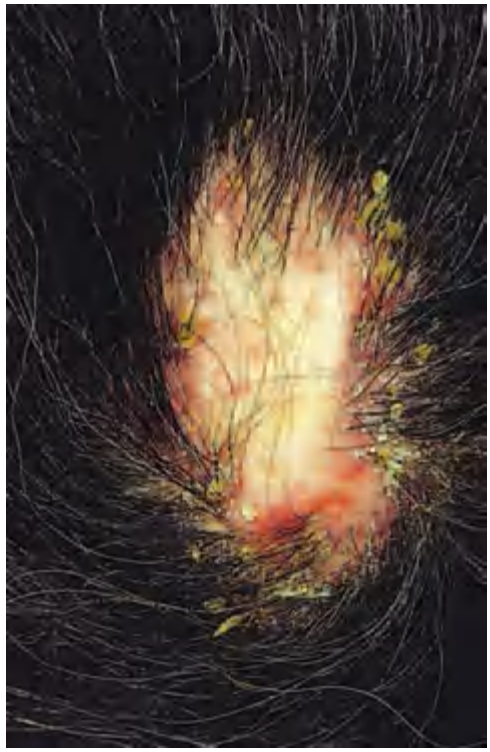

Fig. 63.43 Folliculitis decalvans showing active pustulation and scarring.

Pathology [1,4,5]. Histology reveals follicular abscesses, with a dense perifollicular polymorphonuclear infiltrate and scattered eosinophils and plasma cells. Foreign-body granulomas occur in response to follicular disruption, which is succeeded by scarring. Eventually all that remains of the follicle is extensive fibrosis.

Clinical features [1]. Men may be affected from adolescence onwards, whereas women tend not to develop this condition until their thirties. Following a pustular folliculitis of the scalp, usually one, but occasionally more, rounded patches of alopecia develop, each surrounded by crusting and a few follicular pustules. Successive crops of pustules appear and are followed by progressive destruction of the affected follicles (Fig. 63.43). In some cases the folliculitis spreads along the scalp margin in a coronal pattern, or along the edge of an AGA. The severity of the inflammatory changes fluctuates, but the course is prolonged.

Tufted folliculitis is a variant of folliculitis decalvans where circumscribed areas of scalp inflammation heal with scarring characterized by tufts of up to 15 hairs emerging from a single orifice (Fig. 63.44) [6–8]. The tufts consist of a central anagen hair surrounded by telogen hairs, each arising from independent follicles, converging towards a common dilated follicular infundibulum. Cases in which the tufts were comprised of only anagen hairs have also been described. Based on an animal model, it is suggested that erythema and scaling are the initial events and the tufting is a consequence of the emergence of hairs from beneath the free edge of the scales.

Fig. 63.44 Tufted folliculitis.

A scalp biopsy is required to confirm the diagnosis and swabs should be taken of any pustules. Investigation for an underlying defect in cell-mediated immunity is generally unrewarding, and only indicated when there is additional evidence of impaired immunity. As fungal kerion may mimic folliculitis decalvans, hairs should be plucked for fungal culture and a PAS stain should be performed on the scalp biopsy.

Treatment [1]. Essentially, treatment consists of attempts to eradicate *Staph. aureus* from the scalp. Prolonged courses of flucloxacillin induce remission, but relapse occurs when the antibiotics are stopped. For localized areas, topical clindamycin is useful. Tetracyclines are also commonly effective. Isotretinoin has been used to alter the follicular environment to make it less suitable for *Staph. aureus* colonization, but it may increase cutaneous carriage of this organism and make the condition worse. The only treatment shown to induce prolonged remission is rifampicin in a dosage of 300 mg twice daily. This should be given in combination with other antibiotics to prevent the emergence of resistant organisms. Drugs commonly used in combination include clindamycin 300 mg twice daily, fucidic acid 150 mg three times daily, ciprofloxacin, doxycycline and clarithromycin.

Tufting may be reduced by measures directed at reducing the scale, such as the use of tar shampoos and topical keratolytics.

Dissecting cellulitis of the scalp [1]

SYN. DISSECTING FOLLICULITIS; PERIFOLLICULITIS CAPITIS ABSCEDENS ET SUFFODIENS

This rare condition manifests with a perifolliculitis of the scalp, deep and superficial abscesses in the dermis, sinus tract formation and extensive scarring. It occurs predominantly in black males aged between 18 and 40 years. Familial cases are exceptional, as is childhood onset.

Aetiology. The aetiology of this inflammatory condition is unknown. Although staphylococci, streptococci and *Pseudomonas* may be cultured from various lesions, no specific causative organism has been isolated. Dissecting cellulitis associates with hidradenitis suppurativa and acne conglobata in the follicular occlusion triad [2]. Other reported associations include pilonidal sinus and spondyloarthropathy. The activity of the arthritis parallels the activity of the skin.

Clinical features. Painful, firm, skin-coloured nodules develop near the vertex of the scalp and later become softer and fluctuant (Fig. 63.45). Confluent nodules form tubular ridges with an irregular cerebriform pattern, on a red and oedematous background. Thin blood-stained pus exudes from crusted sinuses, and pressure on one region of the scalp may cause discharge of pus from a neighbouring intercommunicating ridge. Cervical adenitis is present in some cases, but is more remarkable for its absence in many others. Progressive scarring and permanent alopecia occur. Characteristically, hair is lost from the summits of these inflammatory lesions and retained in the valleys. The condition is chronic, with frequent acute exacerbations. Fatal squamous cell carcinoma has developed within the areas of scarring after many years [3].

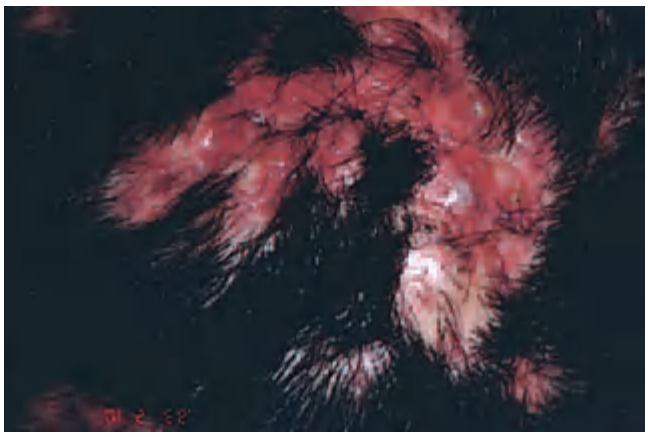

Fig. 63.45 Dissecting cellulitis of the scalp. (Courtesy of Dr D. Dyall-Smith and the *Australasian Journal of Dermatology* [5].)

Pathology [4]. Histology shows a perifolliculitis with a heavy infiltrate of lymphocytes, histiocytes and polymorphonuclear cells. Abscess formation results, and leads to destruction of the pilosebaceous follicles initially, and eventually the other cutaneous appendages. Keratin fragments induce a granulomatous reaction, with foreign-body giant cells, lymphoid and plasma cells. Special stains for bacteria, fungi and mycobacteria are negative.

Investigations. Culture from affected areas often grows bacterial organisms. Fungal cultures and a scalp biopsy for routine histology and direct immunofluorescence will exclude other causes of scarring alopecia.

Treatment. Although systemic antibiotics and topical or intralesional corticosteroids are sometimes helpful, relapses are frequent and the course is usually protracted. Isotretinoin in full dosage (1 mg/kg), in combination with prednisolone (1 mg/kg) and erythromycin 500 mg four times daily, may induce a rapid remission and significant hair regrowth in areas not yet irreversibly damaged [5]. Because the inflammation is predominantly perifollicular, a surprising amount of regrowth may occur. The antibiotics can be stopped after 4 weeks and the prednisolone gradually tailed off and replaced by topical steroids. The isotretinoin should be continued for at least 6 months, and reintroduced if the condition relapses. In recalcitrant cases, widespread excision and grafting may be considered, or alternatively in an older patient, X-ray epilation has been used with success [6]. Improvement has also been noted following laser-assisted hair removal [7].

Fig. 63.46 Linear morphoea (en coup de sabre). After having this lesion since adolescence this lady recently developed biopsy-proven lichen sclerosus of the vulva.

Circumscribed scleroderma and linear morphoea

Circumscribed scleroderma is rare in the scalp, but may occur there as single or multiple lesions. The hair is shed at an early stage to leave a cicatricial alopecia. The diagnosis must be confirmed histologically. Linear circumscribed morphoea in the frontal region—'en coup de sabre' morphoea (Fig. 63.46)—is slightly more common (see Chapter 56). It has been suggested that lesions may follow the lines of Blaschko [1]. Histological examination of both conditions shows chronic inflammation of the upper and mid-follicle, and prominent fibrosis [2]. Linear morphoea has been associated with hereditary deficiency of complement C2 [3].

Cicatricial pemphigoid

SYN. BENIGN MUCOSAL PEMPHIGOID

Cicatricial pemphigoid affects predominantly the elderly, and women more than men [1,2]. It is associated with autoantibodies to the basement-membrane-zone adhesion complex (see Chapter 41).

Bullae are formed at the dermal–epidermal junction. Direct immunocytochemical studies show that linear deposits of IgG, IgA, C3 and C4 may be found in the basement-membrane zone, but circulating basement-membrane-zone antibodies (IgG or IgA) are not always demonstrable [3,4].

Although the disease affects predominantly the ocular and/or genital mucous membrane, the skin is involved in 40–50% of cases, and skin lesions may precede the mucosal lesions by months or years [5]. The skin lesions repeatedly recur and leave scars. The favoured sites are the face and upper trunk, the scalp being involved in approximately 10% of cases [6]. Skin lesions, predominantly on the head and neck, are the major feature of the Brunsting–Perry variant.

Management is often dictated by the need to control mucosal lesions. If recurrent bullae in a localized area of skin are troublesome, excision and grafting may be successful [6]. Whether to prescribe oral corticosteroids or immunosuppressive drugs for skin lesions alone is controversial, but topical clobetasol propionate cream may inhibit the process to some degree.

Erosive pustular dermatosis of the scalp

This clinical entity particularly affects the elderly [1,2]. Its cause is unknown but Grattan *et al.* [3], in their study of 12 cases, suggested that local trauma and sun damage are important. Surgery, cryosurgery, skin grafting and radiation therapy may all precipitate this condition [4].

Pathology. Histological examination shows areas of epidermal erosion, a chronic inflammatory cell infiltration in the dermis consisting predominantly of lymphocytes and plasma cells, and sometimes small foci of foreign body giant cells where hair follicles have been destroyed.

Clinical features. This condition almost always occurs in association with AGA. Initially, a small area of scalp becomes red, crusted and irritable; crusting and superficial pustulation overlie a moist eroded surface (Fig. 63.47). As the condition extends, areas of activity coexist with areas of scarring. Squamous carcinoma has developed in the scars [5].

Differential diagnosis. Pyogenic and yeast infection is excluded by bacteriological examination and the lack of response to antibacterial or antifungal agents. Biopsy may be necessary to exclude pustular psoriasis, cicatricial

Fig. 63.47 Erosive pustular dermatosis of the scalp occurring on a sun-exposed bald scalp.

pemphigoid, 'irritated' solar keratosis or squamous cell carcinoma.

Treatment. The stronger topical corticosteroids (e.g. 0.05% clobetasol propionate) will suppress the inflammatory changes. Gradual reduction in the potency of topical steroid over a 6-month period may result in cure. Maintenance therapy with sun protection and intermittent moderate potency steroid can provide long-term relief. Ikeda *et al.* [6] suggested oral zinc sulphate and Boffa [7] suggested topical calcipotriol can be curative in some cases.

Necrobiosis lipoidica, granuloma annulare and sarcoidosis

Necrobiosis lipoidica occurs in 0.2–0.3% of cases of diabetes mellitus, and approximately 70% of patients with necrobiosis have diabetes. The diabetic cases begin in childhood or early adult life, and the non-diabetic cases rather later and usually in women.

The oval atrophic plaques classically occur on the shins but may be seen on other parts of the body including the scalp. The patches are glazed and yellowish, often with conspicuous telangiectases. Scarring may be dense. The clinical features in the scalp vary from large plaques of cicatricial alopecia to multiple small areas of scarring [1].

Fig. 63.48 Sarcoidosis of the scalp.

An atrophic form affecting predominantly the forehead and the scalp has been described [2,3]. In general, the differential diagnosis is from sarcoidosis and granuloma annulare [4–6].

Cutaneous sarcoidosis may produce plaques or nodules on the scalp as well as both cicatricial and non-cicatricial alopecia (Fig. 63.48) [7]. Affected areas may itch. There is a marked preponderance of females amongst reported cases. The histology is distinctive, with non-caseating granulomatous inflammation [5].

Fig. 63.49 Lichen sclerosus.

Lichen sclerosus et atrophicus

This disease affects females 10 times more often than males [1]. Lichen sclerosus of the scalp appears to be rare (Fig. 63.49). It may cause an extensive cicatricial alopecia that is relatively nondescript clinically, but which has all the characteristic features histologically. Associated lesions are usually found on the trunk and vulva [2,3].

Developmental defects and hereditary disorders

Scarring follicular keratosis

Numerous syndromes have been described and elaborately named, all of them characterized by keratosis pilaris associated with some degree of inflammatory change leading to destruction of the affected follicles [1].

Only detailed clinical and genetic studies can provide the essential facts to allow reliable differentiation of syndromes that some authorities regard as forms or degrees of a single state and others accept as distinct entities. For the time being, the reported cases can be conveniently classified in three groups; in addition, certain apparently well-defined entities can be recognized.

1 *Atrophoderma vermiculata* (acne vermiculata, folliculitis ulerythematosa reticulata). There is honeycomb atrophy of the cheeks. Scarring alopecia may occur, but rarely.

2 *Keratosis pilaris atrophicans faciei* (ulerythema oophryogenes). The process is more or less confined to the eyebrow region.

3 *Keratosis pilaris decalvans* (keratosis follicularis spinulosa decalvans, follicular ichthyosis). Keratosis pilaris of variable extent is associated with cicatricial alopecia [2].

All these conditions are assumed to be genetically determined, although many cases occur sporadically. Such genetic data as are available are considered under the individual forms.

The follicles are initially distended by horny plugs, the dermis is oedematous and there is some lymphocytic infiltration around follicles and vessels. Later, the follicles are destroyed. Small epithelial cysts may be numerous, particularly in keratosis pilaris atrophicans faciei.

Clinical features. Atrophoderma vermiculata usually begins in childhood. Follicular plugs, often in the preauricular regions, are gradually shed to leave reticulate atrophy. On the face, the extent of the process is variable. Exceptionally, cicatricial alopecia of the scalp may be associated [3].

Keratosis pilaris atrophicans faciei (ulerythema oophryogenes) is present from early infancy. Erythema and horny plugs begin in the outer halves of the eyebrows, which they eventually destroy, and then advance medially and to a variable extent on the cheeks. Involvement of the scalp has apparently not been reported in cases in which the eyebrows are predominantly involved. However, there are reports of cases to which this diagnosis has been applied, but which appear to be more rationally classified in one of the other categories, in which alopecia has occurred. Such cases emphasize the need for improved diagnostic criteria.

Keratosis pilaris decalvans is also such a variable syndrome that several genotypes must be considered. Keratosis pilaris begins in infancy or childhood, often on the face. Ultimately, it may be confined to the face or to face and limbs, or may be more or less universal. It is often succeeded by atrophy on the face, but rarely on the limbs or trunk. Cicatricial alopecia is noted from early childhood or later, and may be localized or extensive [4]. Familial cases without significant eyebrow involvement are reported [5].

Three members of one family developed keratosis pilaris of the face in early childhood [6] and then extensively on the back and limbs, and on the scalp, where horny papules replaced hairs. A similar syndrome was reported in a young man who had keratosis pilaris and severe cicatricial alopecia [7]. The occurrence of cases similar to those reported by MacLeod [6] in other siblings, born of normal parents, suggested recessive inheritance but the evidence was incomplete. The pattern of hair loss in the family reported by Ullmo [8] was in the distribution of the Marie–Unna type of congenital alopecia, apart from the presence of keratosis pilaris on the face.

What may be another distinct syndrome associates extremely severe keratosis pilaris—'closely woven bristles'

—with almost complete alopecia, reduced sweating and deafness [9].

Treatment. Only symptomatic measures are available. Retinoic acid deserves a trial. The status of oral retinoids remains controversial, although anecdotal response has been noted.

Porokeratosis of Mibelli

Porokeratosis of Mibelli commonly begins in childhood but may first appear at any age. It is most frequent on the limbs, particularly the hands and feet, the neck, the shoulders and the face, but may occur anywhere, including the scalp [1]. The initial lesion is a crateriform horny papule that gradually extends to form a circinate or irregular atrophic plaque with a raised horny margin, which may be surmounted by a furrow from which the lamina of horn projects. In the scalp there is loss of hair in the atrophic phase.

Incontinentia pigmenti

Cicatricial alopecia has been present in at least 25% of reported cases of incontinentia pigmenti; it appears in early infancy and ceases to extend after a variable period of up to 2 years, but the loss of hair is permanent. Other hair defects present in some cases have been hypoplasia of the eyebrows and eyelashes, and woolly hair naevus of the scalp [1].

Generalized follicular hamartoma

Cicatricial alopecia beginning in childhood was a feature of a syndrome described by Mehregan and Hardin [1]. Their patient was a woman aged 23 years. From infancy, she had widespread horny plugs over the trunk and limbs and small pits on the palms and soles. She later developed cicatricial alopecia, in which, from the age of 8 years, appeared follicular tumours. The tumours of the scalp were proliferating tricholemmal cysts. The lesions of palms and soles showed funnel-shaped dilatation of sweat ducts, which were plugged with parakeratotic material containing acid mucopolysaccharide. Ridley and Smith [2] described this entity with alopecia and myasthenia gravis.

Epidermolysis bullosa

The term epidermolysis bullosa is applied to a group of distinct, genetically determined disorders characterized by the formation of bullae of skin, and often also of mucous membranes, in response to trauma, or spontaneously (see Chapter 40). Only one of these diseases is accompanied by abnormalities of scalp or hair—recessive dystrophic epidermolysis bullosa. However, Gamborg Nielsen and Sjolund [1] described a new syndrome of localized epidermolysis bullosa simplex associated with hair, nail and teeth abnormalities. Alopecia may also occur in junctional epidermolysis bullosa.

Bullae form at the dermal–epidermal junction and fragments of dermis may adhere to the roof.

The inexorable blistering of skin and mucous membranes dominates the picture. The blisters are followed by atrophic scarring. This may give rise to more or less extensive cicatricial alopecia of the scalp [2,3]. Of 30 cases studied by Videl [4], three had cicatricial alopecia.

Cleft lip-palate, ectodermal dysplasia and syndactyly

This rare or rarely recognized syndrome is probably

hereditary, and determined by an autosomal recessive gene.

The constant features of the syndrome are mental retardation, cleft palate, genital hypoplasia, cicatricial alopecia, defective teeth and syndactyly [1].

REFERENCE

Polyostotic fibrous dysplasia

The progressive enlargement over a period of 10 years of a bald patch present since childhood was shown histologically to be caused by the replacement of the follicles by coils of fibrous tissue. The patient had polyostotic fibrous dysplasia [1].

Infections

[A.G. Messenger]

Tinea capitis

See Chapter 31.

Infestations

See Chapter 33.

Syphilis

Hair loss occurs in approximately 10% of cases of secondary syphilis and may be the presenting feature [1,2]. The hair loss typically has a 'moth-eaten' appearance but may be diffuse in nature [3]. Other features of secondary syphilis are present in most cases, particularly lymph node enlargement and hepatomegaly, but hair loss has been reported as the only sign of the disease [4]. Histological features include an increase in catagen and telogen forms, and a peribulbar lymphocytic infiltrate, similar to the changes seen in alopecia areata [3]. Additional features in syphilis include lymphocytic infiltration of the isthmus region, parabulbar lymphoid aggregates and the presence of plasma cells within the infiltrate.

The serpiginous nodulo-squamous syphilide of tertiary syphilis may affect the scalp and the syphilitic gumma is a cause of scarring alopecia.

Human immunodeficiency virus (see Chapter 26)

A variety of alterations in hair growth have been described in patients with HIV infection. Telogen effluvium is a common cause of hair loss [5]. Causes include chronic HIV-1 infection itself, secondary infections, nutritional deficiencies and drugs. Hair loss has been reported with several antiretroviral drugs, particularly indinavir [6], which may cause loss of hair on the body as well as the scalp. There are also reports of alopecia areata occurring in patients with HIV infection [7–9].

There are several reports of hypertrichosis of the eyelashes (eyelash trichomegaly) in HIV infection [9–11]. The cause of this striking and unusual feature is not known. It is usually associated with advanced disease and has been noted to regress with antiretroviral treatment [11].

Straightening of the hair is a common feature of HIV infection in black patients [12].

Various forms of folliculitis are seen in HIV infection, including acneiform eruptions, staphylococcal folliculitis and eosinophilic pustular folliculitis.

Leprosy

Loss of eyebrow and body hair may occur in lepromatous leprosy but the scalp is rarely involved.

Artefactual alopecia

[D.A.R. de Berker, pp. 63.61–63.65]

Cosmetic alopecia

The dictates of religion, custom and fashion have imposed an immense variety of physical stresses on human hair. Two types of hair loss occur as a result of cosmetic

Fig. 63.50 Traction alopecia from braiding.

practices: those characterized by structural damage to the hair shaft leading to excessive weathering and breakage, and those where hair follicles are injured by prolonged traction from hair styling. A third type, centrifugal cicatricial alopecia or follicular degeneration syndrome, which occurs in women of African extraction, has been ascribed to cosmetic procedures, but this is controversial.

Traction alopecia

Traction alopecia is brought about by hair styles that impose sustained pulling on the hair roots. The clinical features in the many variants of this syndrome include folliculitis, reduction in hair density with vellus hairs and sometimes broken hairs in the affected areas, and eventually scarring alopecia. Keratin cylinders ('hair casts') may surround many hairs just above the scalp surface [1]. The pattern of the hair loss is often distinctive and reflects the distribution of the traction.

Traction alopecia is seen most commonly in Afro-Caribbean hair styles where the hair is tightly braided. The hair loss commonly begins in the temporal regions and in front of and above the ears, but may involve other parts of the scalp margin, or even linear areas in other parts of the scalp (Fig. 63.50). If continued long term, permanent scarring alopecia may occur [2]. The use of rollers may cause alopecia in the frontal and temporal regions, as may 'ponytail' styles. Frontal and parietal traction alopecia has been reported in young Sikh boys as a result of twisting their uncut hair tightly on top of the head [3], and tight braiding and wooden combs produce traction alopecia in the Sudan; frontal loss is reported in Libyan women as a result of traction from a tight scarf [4].

Treatment. The diagnosis of traction alopecia is usually not difficult, provided the possibility is considered. The cause is not always recognized by the patient and may be received with suspicion. The patient, or parents of affected children, need to be educated to adopt hair styles that do not pull the hair tight [2].

Follicular degeneration syndrome

See p. 63.54.

Physical trauma

The diagnosis and treatment of the consequences of physical injuries of the scalp will seldom confront dermatologists, but they may be consulted as to the cause of an apparent physical injury (e.g. aplasia cutis may be falsely attributed to forceps injury at childbirth). The attachment of an electrode to the scalp for monitoring the fetal heartbeat during labour may occasionally cause some superficial damage, and this may be followed by a small scar. Aplasia cutis has sometimes been mistaken for such a lesion [1].

An unusual case of cicatricial alopecia in a boy aged 13 years was caused by injury to the scalp by an intravenous infusion given in infancy for gastroenteritis [2]. Exceptionally, self-inflicted injuries may involve the scalp and leave scars.

Halo scalp ring [3]

A type of alopecia, which may be temporary or permanent, is an area of scalp hair loss resulting from prolonged pressure on the vertex by the uterine cervix during or prior to delivery, resulting in a haemorrhagic form of caput succedaneum.

Scalp necrosis after surgical embolization

Adler *et al.* [4] described a case in which ischaemic necrosis of the occipital scalp occurred following embolization and surgery for a large convexity meningioma.

Women who had undergone prolonged pelvic operations in the Trendelenburg position developed, 12–26 days later, a vertical patch of alopecia, which was preceded by oedema, exudation and crusting. Pressure ischaemia during the operation was considered to be the cause of the alopecia [5]. In one large clinic, over a period of 3 years, 60 cases of occipital pressure alopecia were observed after open-heart surgery [6]. In 29 of these cases,

the hair loss was permanent. Temporary alopecia followed prolonged pressure on the scalp by a foam rubber ring used to prevent such an occurrence [7].

Chronic radiodermatitis [1,2]

Roentgen discovered X-rays in 1895. X-ray epilation of the face for hirsutism was frequently employed during the first two decades of the 20th century and, although Schultz [3] condemned this treatment, it continued to be so widely used that Cipollaro and Einhorn [4] entitled their paper: 'The use of X-rays for the treatment of hypertrichosis is dangerous'.

X-ray epilation for the treatment of scalp ringworm was introduced in Paris in 1904. The discovery of griseofulvin in 1958 gradually made X-ray epilation unnecessary, but it has been estimated that between 1904 and 1959 some 300 000 children throughout the world were treated with X-rays for ringworm of the scalp. Correct dosage did not cause toxicity; however, technical errors were frequent, from inadequate and poorly calibrated apparatus. The treatment produced complete epilation in approximately 3 weeks and regrowth after 2 months. The follow-up of 2043 patients treated in childhood showed a higher incidence of cancer in the patients than in a control group [1]. Radiodermatitis of the scalp may occur also as an unavoidable consequence of skin damage during the treatment of both internal malignant disease and malignant disease of the skin.

The use of X-rays for epilation depends on the high susceptibility of anagen hairs to radiation. Epilating and subepilating doses produced dystrophic changes in human hairs as early as the fourth day after exposure [5]. Chronic radiodermatitis may follow acute radiodermatitis, but may develop only slowly as degenerative changes induced by sun exposure and ageing become superimposed. In chronic radiodermatitis, the epidermis is generally atrophic, with loss of hair follicles and sebaceous glands, but there are also irregular areas of acanthosis. Degenerative changes and nuclear abnormalities are frequent in the epidermis. Dermal collagen stains irregularly. Superficial small vessels are telangiectatic, but deeper vessels are partially or completely occluded by fibrosis.

Clinical features. The development of a basal cell carcinoma in middle age or later in an area of the scalp should lead the dermatologist to enquire about X-ray epilation for ringworm in childhood [6]. In other cases, the patient complains of hair loss, which is apparently accentuated in certain areas, and these areas are found to show both AGA and reduction of follicle population as a result of the earlier radiation.

Chronic radiodermatitis produced by radiation therapy of a malignant tumour of the scalp presents a circumscribed area of cicatricial alopecia. Radiation necrosis may simulate a recurrence of carcinoma, but the edges of the necrotic ulcer are not raised. The diagnosis should be confirmed by a biopsy. Superficial X-ray of Grenz ray type does not penetrate deeply enough to damage scalp follicles. Malignant tumours arising in radiodermatitis should be excised [7].

Trichotillomania (see also Chapter 61)

First described by Hallopeau in 1889 [1], trichotillomania is a psychiatric disorder with dermatological expression, in which there is a compulsive habit of pulling out the hair. It is probably a symptom of several different psychopathologies [2].

Pathology. The histological changes vary according to the severity and duration of the hair plucking. Numerous empty canals are the most consistent feature. Some follicles are severely damaged; there are clefts in the hair matrix, the follicular epithelium is separated from the connective tissue sheath, and there are intraepithelial and perifollicular haemorrhages and intrafollicular pigment casts (Fig. 63.51) [3]. Injured follicles may form only soft twisted hairs—a process that has been described as a separate entity under the name of trichomalacia [4]. Many follicles are in catagen, with very few or no follicles in

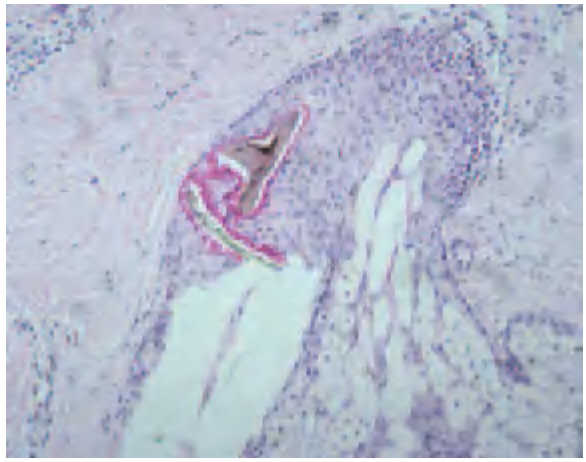

Fig. 63.51 Histology of trichotillomania showing fragmentation of the hair shaft.

Table 63.4 DSM-IV criteria for trichotillomania.

Recurrent pulling out of one's hair resulting in noticeable hair loss
An increasing sense of tension immediately before pulling out the hair or when attempting to resist the behaviour
Pleasure, gratification or relief when pulling out the hair
The disturbance is not better accounted for by another mental disorder and is not due to a general medical condition (e.g. a dermatological condition)
The disturbance causes clinically significant distress or impairment in social, occupational or other important areas of functioning

telogen. Some dilated follicular infundibula contain horny plugs [5].

Aetiology and psychopathology. Trichotillomania occurs in two main forms. In infants and young children it is usually a habit akin to thumb-sucking and nail biting. It seems slightly more common in boys and usually resolves spontaneously or with minimal treatment. Parents who have not noticed hair-pulling behaviour in their offspring may deny the diagnosis. In older children and adults trichotillomania is usually a chronic psychiatric problem, although periods of remission occur in some patients. This form occurs predominantly in females, with women outnumbering men by up to 7 : 1, although this figure may be skewed by a greater likelihood of women presenting for medical advice [2]. The American Psychiatric Association classifies trichotillomania as an impulse control disorder. Their diagnostic criteria are given in the fourth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV), and are listed in Table 63.4, although not all patients with trichotillomania fit these criteria.

Trichotillomania shares some features of obsessive–compulsive disorder (OCD), but some authorities consider it may be the result of a number of psychopathologies including OCD, personality disorders, body dysmorphobic disorders, mental retardation and psychosis. There is an extensive psychiatric literature on trichotillomania, but this may be biased because psychiatric help is likely to be sought only in those patients who accept that it is a self-inflicted problem. This is not true of all patients presenting to dermatologists.

Fig. 63.52 Trichotillomania. Characteristic 'tonsure' pattern with scalp margin hair spared.

Clinical features. In young children, the hair-pulling tic develops gradually and unconsciously. Hair is plucked most frequently from one frontoparietal region. This results in a patch of hair loss, often in a bizarre or angular pattern, in which the hairs are twisted and broken at various distances from the clinically normal scalp. Older patients present with an area of scalp on which the hair has been reduced to coarse stubble uniformly 2.5–3 mm long. The plucked area may be asymmetrical or cover the entire scalp apart from the margin (Fig. 63.52). It is unusual for hair to be lost completely within the affected area (in contrast with alopecia areata). The scalp skin appears normal. Over time the extent of hair loss can vary, and hair growth may recover temporarily.

Hair in sites other than the scalp can also be affected, such as eyelashes, eyebrows and beard. Exceptionally, the patient may pluck hair also, or only, from other regions of the body, such as the mons pubis and perianal region.

A hairball (trichobezoar) is a rare accompaniment of trichotillomania in those who also eat the plucked hair (trichophagia) [6,7].

Differential diagnosis. The minor form in young children can be confused with ringworm or with alopecia areata. In ringworm, the texture of the infected hairs is abnormal and the scalp surface may be scaly. Alopecia areata may be difficult to exclude with certainty at the first examination, but the course of the condition usually establishes the correct diagnosis. Unlike alopecia areata, it is unusual for hair to be lost completely in trichotillomania and, in contrast with exclamation mark hairs, the broken hairs of trichotillomania are firmly anchored in the scalp. Where doubt remains a skin biopsy will usually establish the correct diagnosis. However, there are reports of the co-existence of alopecia areata and trichotillomania [8]. In rare cases, genetic disorders characterized by increased hair fragility, such as monilethrix, may resemble trichotillomania and should be excluded by hair microscopy.

Treatment. The establishment of a relationship between the physician and the patient, or with the parents of an affected child, is an important step in management of trichotillomania. A confident diagnosis is essential, but this is not always easy and may require observation over time and sometimes a scalp biopsy. The habit tic in young children is often self-limiting, but input from a paediatric psychologist can be very helpful. Trichotillomania in adolescents and adults is a different proposition, and can be an intractable problem [9]. Patients with insight should be referred to a psychiatrist or clinical psychologist. A number of psychotherapeutic approaches have been used, particularly behaviour therapy aimed at habit reversal, but none is uniformly successful. Various drugs have been reported to be helpful, including clomipramine [10] and neuroleptic agents [11], but relapse rates are high. Promising results have also been claimed for the selective serotonin reuptake inhibitor fluoxetine [12], but this was not confirmed in controlled trials [13,14]. Behavioural therapy appears more effective than either clomipramine [15] or fluoxetine [16]. Some patients are helped by contact with fellow patients, and there are several patient support groups and Internet websites devoted to trichotillomania. Patients who fail to admit the self-inflicted nature of the hair loss present particular difficulties, as they are unlikely to accept psychiatric referral and, like dermatitis artefacta, a confrontational approach will probably be unsuccessful. Management should be aimed at helping the patient recognize the cause for themselves. This can be a long and slow process requiring skill and empathy on the part of the physician.

Scaling disorders of the scalp

[A.G. Messenger, pp. 63.65–63.67]

Scaling of the scalp is a feature of a number of clinical disorders including dandruff (pityriasis capitis), seborrhoeic dermatitis, psoriasis and pityriasis amiantacea. These disorders show overlapping clinical and histological features and, when confined to the scalp, it can be difficult to distinguish between them. Scalp scaling is also seen in other inflammatory dermatoses such as atopic dermatitis, tinea capitis, discoid lupus erythematosus and cutaneous T-cell lymphoma.

Pityriasis capitis

Pityriasis capitis, or dandruff, and seborrhoeic dermatitis confined to the scalp are generally regarded as the same entity, with dandruff representing the mild non-inflammatory end of a spectrum of scalp scaling. Its peak incidence and severity are reached at the age of approximately 20 years, and it becomes less frequent after 50 years of age. At age 20 years, some 50% of white people are affected to some degree. Although previously thought to be uncommon in children, an epidemiological study from Australia found that approximately 40% of children under the age of 6 years showed at least mild pityriasis capitis, and 10% of neonates had seborrhoeic dermatitis of the scalp [1].

Aetiology [2]. It is reasonably well established that pityriasis capitis and seborrhoeic dermatitis are related, in some way, to the presence on the skin of lipophilic yeasts of the genus *Malassezia*, previously known as *Pityrosporum*. This idea, which evolved in the 19th century when these organisms were first identified [3–5], is based largely on the clinical observations of improvement with antifungal treatment. For a time during the 1960s and 1970s the microbial hypothesis was disputed [6], but it became re-established with the advent of azole antifungal agents [7–9]. Treatment of patients with seborrhoeic dermatitis with azole antifungal agents such as ketoconazole is associated with improvement of the rash, a reduction in colonization of the skin by *Malassezia*, and relapse as the skin is recolonized following treatment [10]. Scalp skin affected by dandruff or seborrhoeic dermatitis tends to be more heavily colonized by *Malassezia* species than normal scalp [11] although, in seborrhoeic dermatitis, the colonization rates are highly variable and there is no clear relationship between the number of organisms present on the skin and disease activity [12]. As *Malassezia* is present on normal skin there must be other factors involved that lead to scalp scaling. Possible explanations have included a direct inflammatory effect of toxins released by the organisms and an altered immune response to *Malassezia* [2].

Clinical features. Small, white or grey scales accumulate on the surface of the scalp in localized, more or less segmental patches or more diffusely. After removal with an effective shampoo, the scales form again within 4–7 days. The condition first becomes a cosmetic problem during the second and third decades, but there are long- and short-term variations in its severity, without obvious cause. There are also variations in the ease with which the scales become detached and drift unaesthetically among the hair shafts or fall on the collar and shoulders. Although pityriasis usually clears spontaneously during the fifth or sixth decade, it may persist in old age. Pityriasis merges, almost imperceptibly, into seborrhoeic dermatitis where signs of inflammation and itching are also present, and other skin sites may be involved. Pruritus is not a feature of simple pityriasis.

Diagnosis. Asymptomatic scalp scaling in children also occurs in pediculosis and in tinea capitis. The latter is typically associated with broken hair shafts and patchy hair loss, but these features may be absent in carriers of anthropophilic dermatophyte infections. Pediculosis should also be considered in adults with scalp scaling. Other than in the neonatal period, seborrhoeic dermatitis is uncommon in children, and psoriasis should be considered in the presence of significant scalp inflammation. Differentiation between seborrhoeic dermatitis and scalp psoriasis can be difficult at any age. Psoriasis is suggested by more demarcated plaques, extension of lesions beyond the hairline and the silvery character of the scaling. Occasionally, atopic dermatitis is confined to the scalp, when pruritus is usually a major feature. Profuse adherent silvery scale should suggest pityriasis amiantacea.

Treatment. Pityriasis in its milder forms is a physiological process. The object of treatment is to control it at the lowest possible cost and inconvenience to the patient, appreciating that any procedure found to be effective will need to be repeated at regular intervals.

Shampoos containing the anti-yeast agents ketoconazole or zinc pyrithione are effective in most cases of pityriasis capitis. One controlled trial reported an excellent response in 88% of subjects using ketoconazole [13]. Another study showed a 71% reduction in the dandruff score after 4 weeks of treatment with ketoconazole shampoo and a 67% reduction in subjects using a shampoo containing zinc pyrithione [14]. The scaling will return if treatment is discontinued, but the frequency of relapse can be reduced by prophylactic treatment (e.g. once weekly treatment with ketoconazole shampoo [13]). Shampoos containing selenium sulphide or tar have also been widely used to treat pityriasis capitis. Topical steroids may be used in patients with seborrhoeic dermatitis who do not respond to a shampoo. Salicylic acid-containing preparations (e.g. sulphur and salicylic acid cream) can be helpful for heavy scaling.

Pityriasis amiantacea

Pityriasis amiantacea is an inflammatory scaling reaction of the scalp, often without evident cause. One Scandinavian follow-up study reported that psoriasis occurred in 15% of patients with pityriasis amiantacea [1]. Another study failed to show an association with psoriasis but suggested that seborrhoeic dermatitis was more common [2]. In Knight's study of 71 patients, two had associated psoriasis and nine had eczema [3]; he pointed out that pityriasis amiantacea may occur at any age, but the average age was 25 years (range 5–40 years).

Pathology. Biopsies from 18 patients were examined by Knight [3]. The most consistent findings were spongiosis, parakeratosis, migration of lymphocytes into the epidermis and a variable degree of acanthosis. The essential features responsible for the asbestos-like scaling are diffuse hyperkeratosis and parakeratosis together with follicular keratosis, which surrounds each hair with a sheath of horn.

Clinical features. Masses of adherent silvery scales, overlapping like the tiles on a roof, adhere to the scalp and are attached in layers to the shafts of the hairs, which they surround (Fig. 63.53). The underlying scalp is usually reddened. The disease may be confined to discrete areas of the scalp, or may be very extensive, either involving a large area diffusely or affecting a number of small patches. The majority of patients notice some hair loss in areas of severe scaling. The hair regrows when the scaling is effectively treated, although scarring alopecia has been reported following pityriasis amiantacea [4].

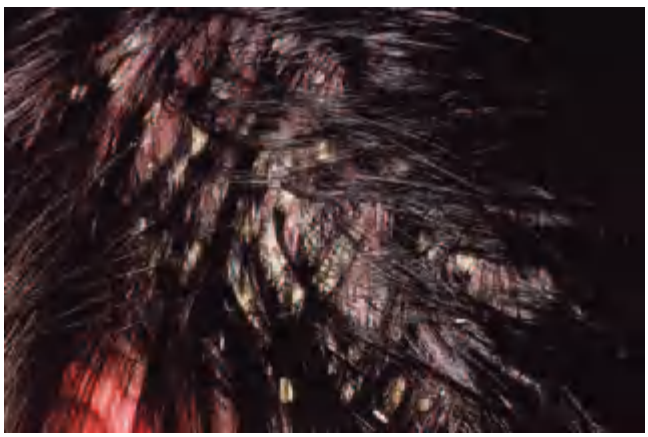

Fig. 63.53 Pityriasis amiantacea.

Diagnosis. The distinctive clinical appearance usually makes the diagnosis easy, but the identification of the underlying disease may not be straightforward; indeed, none may be established.

Treatment. Generous applications of an oil-based product are needed to remove the scales. Tar or salicylic acid ointments are commonly used. The preparation is left on the scalp for several hours and then washed out. The scales may be gently removed using a metal-toothed comb. Once the scaling is controlled an antidandruff or tar-based shampoo may help to maintain remission, but most patients will need to re-treat with an ointment from time to time. Potent topical corticosteroid lotions are beneficial in some cases, but are not effective in removing thick scales.

Thickened scalp disorders

[D.A.R. de Berker, pp. 63.67–63.69]

Cutis verticis gyrata

The term cutis verticis gyrata (CVG) describes a morphological syndrome in which there is hypertrophy and folding of the skin of the scalp to present a gyrate or cerebriform appearance. Polan and Butterworth [1] established the classification of CVG, dividing it into primary and secondary forms. The classification was later modified by Garden and Robinson [2] who subdivided the primary form into primary essential CVG, in which there are no associated features, and primary non-essential CVG, which is associated with a wide range of mental, cerebral and ophthalmological abnormalities.

Primary CVG. The aetiology of primary CVG is not known. Most cases appear to be sporadic although familial forms

have been reported in the context of complex syndromes [3,4]. The skin changes typically develop after puberty and usually before 30 years of age. It is more common in men, with a male : female ratio of 5 : 1 or 6 : 1. There is a strong association with mental retardation. Akesson [5] found 47 cases (3.4%) of CVG in institutionalized mentally retarded subjects in Sweden, and CVG was observed in 22 out of 494 (4.5%) patients in an Italian psychiatric institution [6]. Cytogenetic analyses in the latter study showed chromosome fragile sites in nine subjects (chromosomes 9, 12 and X).

Secondary CVG. This has been described with a wide range of underlying causes. Congenital melanocytic naevi appear to be the most common but other naevoid abnormalities, such as naevus lipomatosus and connective tissue naevi, and acquired lesions such as neurofibroma, may also cause CVG [7–9]. CVG has been described in association with a variety of endocrine and genetic disorders, including acromegaly [10,11], myxoedema [12], insulin resistance [13] and Turner's syndrome [14,15]. The age of onset is more variable than in primary CVG and, in the naevoid forms, it may be present at birth.

Pachydermoperiostosis. This genetically determined syndrome also occurs mainly in men and has often been confused with CVG. It differs from it in several particulars. The scalp is folded but the skin of the face is affected, as is that of the hands and feet. The cutaneous changes, which are accompanied by thickening of the phalanges and of the long bones of the limbs, progress for 10–15 years, then become static.

Pathology. The essential abnormality appears to be overgrowth of the scalp in relation to the underlying skull. In primary CVG, the histology appears normal in most cases. The histopathology in the secondary form depends on the nature of the underlying pathology.

Clinical features. CVG typically affects the vertex and occipital scalp but it may involve the entire scalp. The folds are usually arranged in an antero-posterior direction but may be transverse over the occiput. Hair density may be reduced over the convexities of the folds.

Treatment. Investigations are aimed at identifying underlying causes. These may include neurological, endocrine, ophthalmological and cytogenetic studies. In early-onset CVG, a biopsy is advisable to identify those cases caused by a structural lesion, such as a melanocytic naevus. In the majority of cases treatment is symptomatic. Patients should be educated in scalp hygiene to avoid accumulation of skin debris and secretions in the furrows. Surgical correction can be helpful in selected cases, and may be indicated in cerebriform naevi.

Lumpy scalp syndrome [1]

The inheritance of this syndrome is determined by an autosomal dominant gene of variable expressivity. Raw areas are present in the scalp at birth. They heal to leave irregular nodules of connective tissue that, on histological examination, are not keloidal in structure. The pinnae are deformed; the tragus, antitragus and lobule are small or rudimentary. The nipples are rudimentary or absent, and only areolae are present.

Lipoedematous alopecia [1,2]

Lipoedematous alopecia is a rare condition of unknown aetiology. It is characterized by a thick boggy scalp with varying degrees of hair loss. This syndrome has been recognized mainly in black women. There is slowly progressive diffuse alopecia and obvious thickening of the scalp, with associated pruritus [3]. There are no associated medical or physiological conditions. The fundamental pathological finding consists of an approximate doubling

in scalp thickness resulting from expansion of the subcutaneous fat layer in the absence of adipose tissue hypertrophy or hyperplasia. There is associated atrophy and fibrous replacement of many hair follicles. Light and electron microscopy suggests that the increase in scalp thickness is caused by localized oedema, with disruption and degeneration of adipose tissue. Mucin is not seen [4].

Congenital alopecia and hypotrichosis

[R.D. Sinclair, pp. 63.69–63.72]

Total or partial absence of hair of developmental origin occurs in a bewildering variety of clinical forms, either as an apparently isolated defect or in association with a wide range of other anomalies. A logical classification must be based on detailed histological and genetic investigations and these, unfortunately, are seldom carried out. Provisionally, a purely clinical classification is useful to enable the clinician at least to understand the clearly defined types [1].

Total alopecia

SYN. ATRICHIA CONGENITA

As an isolated abnormality [1,2]

Aetiology. Total alopecia as an apparently isolated defect is usually determined by an autosomal recessive gene. Some pedigrees have been traced back to the early 19th century [1]. Dominant or irregular dominant inheritance has occurred in some families [3,4]. The two genotypes seem to be phenotypically indistinguishable, but detailed investigation would probably reveal differences. The term 'total' is relative, but if any hairs are present they are extremely few. Many isolated cases and families reported under the diagnosis of congenital alopecia are found on review of the original reports to be unquestionably examples of other syndromes; many were hidrotic ectodermal dysplasia.

Pathology. The hair follicles are absent in adult life, even when the fetal hair coat has been normal. Sebaceous glands are smaller than normal. When a few stray hairs have survived, the structure of the shaft appears to be normal.

Clinical features [4,5]. The scalp hair is often normal at birth but is shed between the first and sixth months, after which no further growth occurs. In some cases the scalp has been totally hairless at birth and has remained so [5]. Eyebrows, eyelashes and body hair may also be absent [6], but more often there are a few straggling pubic and axillary hairs and scanty eyebrows and eyelashes. Teeth and nails are normal, and general health, intelligence and life expectancy are unimpaired.

With associated defects

Total or almost total alopecia is unusual in hereditary syndromes.

Papular atrichia [7]. This rare autosomal recessive syndrome is associated with mutations in the zinc finger domain of the hairless gene [8]. Patients are born with hair that falls out and is not replaced. They are completely devoid of eyebrows, eyelashes, and axillary and pubic hair. Histological studies show the presence of the infundibular portion of the hair follicles, but the middle and lower portions of the follicle are replaced by small keratinizing epithelial cysts. No hair shafts are formed. At any age between 1 and 10 years, numerous small horny papules appear, first on the face, neck and scalp, and then gradually over the greater part of the limbs and trunk. Histologically, the papules are thick-walled keratin cysts [7]. Whitish hypopigmented streaks can be found on the scalp. Nails, teeth, sweating, growth and development are normal.

The underlying disorder in papular atrichia appears to be that towards the end of the first anagen phase the hair bulb, proximal inner root sheath and outer root sheath all undergo premature and massive apoptosis and disintegrate into separate cell clusters that lose contact with the dermal papilla. As a result the dermal papilla fibroblasts fail to migrate upward, and break up into clusters of shrunken cells stranded in the reticular dermis as dermal cyst precursors, and the follicle loses the ability to cycle [9].

The genetics are complex. Apart from cases of pseudodominant inheritance [10], there is phenotypic and genetic heterogeneity in inherited atrichias caused by mutations in the *hr* gene, suggesting different roles for the regions mutated in atrichia with papular lesions and in other forms of congenital atrichia during hair development [11]. Furthermore, mutations in a number of genes such as the vitamin D receptor [12], ornithine decarboxylase [13] and RXR-α genes result in a similar phenotype.

Progeria [14]. Scalp and body hair is totally deficient in this exceedingly rare syndrome, which is caused by mutation in the lamin A gene.

Hidrotic ectodermal dysplasia [15]. Total or almost total alopecia is associated with palmoplantar keratoderma and thickened discolored nails. Any hairs that are present are structurally normal but are often finer than the average. Mutations in the *GJB6* gene encoding the gap junction protein connexin 30 have been shown to cause this disorder.

Moynahan's syndrome [16]. This autosomal recessive syndrome, reported in male siblings, is associated with mental retardation, epilepsy and total baldness of the scalp; the hair may regrow in childhood between 2 and 4 years of age.

Baraitser's syndrome [17]. This autosomal recessive syndrome presents as almost total alopecia following the loss of some downy scalp hair present at birth.

Three cases are reported in an inbred family [9]; all had almost total alopecia of all sites, including eyebrows and lashes. There were occasional isolated hairs. Mental and physical retardation were associated.

Hypotrichosis [1,2]

Aetiology and pathology. Congenital hypotrichosis of sufficient degree to cause social embarrassment is not uncommon, and is probably determined by an autosomal dominant gene. There are a number of distinct syndromes, but the two most common are hypotrichosis simplex [3] and hereditary hypotrichosis simplex of the scalp [4]. Both conditions are autosomal dominant.

Hypotrichosis simplex maps to 18p11.32-p11.23 [5] and is characterized by reduced hair growth on the scalp and body, although eyelashes, eyebrows and male beards are normal. In contrast, hypotrichosis simplex of the scalp only [6] is associated with mutations in the *CDSN* gene located on 6p21.3. *CDSN* encodes a protein called corneodesmosin that is exclusively expressed in cornified squamous epithelia.

Hypotrichosis is also a relatively common feature of many hereditary syndromes, usually in association with other ectodermal defects. In the majority, the hair is not only sparse but is structurally abnormal. Where hypotrichosis is the most prominent manifestation and the structural defect is distinctive and well characterized, it has given its name to the syndrome, as in monilethrix and pili torti. In other syndromes, the scanty scalp hair is a minor and sometimes inconstant manifestation, and the shaft defect is usually less specific, although often gross. The follicles are sparse and are reduced in size, and the hair shafts are brittle and deficient in pigment. The nature of the disturbance in keratinization is not known.

Clinical features [7]. When hypotrichosis occurs as an isolated abnormality, the scalp hair at birth is normal in quantity and quality, but is shed during the first 6 months and never adequately replaced. It is sparse, fine, dry and brittle, and seldom exceeds 10 cm in length. The eyebrows, eyelashes and vellus may be absent, sparse or normal. In exceptional cases, improvement or recovery has taken place at puberty, but the condition is usually permanent.

In some families, the hair is normal until the age of 5 years or later, when growth becomes retarded and the scalp is progressively denuded so that baldness is almost total by the age of 25 years [4].

There are many hereditary syndromes of which hypotrichosis is a constant or frequent feature. In the majority, the hair is not only sparse but fine and brittle, and is often hypopigmented. The hair shafts are often defective, but may show no consistent well-characterized structural abnormality. As the hypotrichosis is not the most prominent feature of these syndromes, they are described more fully in other chapters.

There are also other syndromes, as yet incompletely investigated, in which hypotrichosis is associated with other defects.

Hypohidrotic ectodermal dysplasia [8]. Affected males show hypotrichosis, abnormal teeth and absent sweat glands. The hair is fine and silky but thin and short. Both X-linked and autosomal dominant forms exist, with the X-linked condition being caused by mutations in the ectodysplasin gene and the autosomal dominant form because of mutations in the downless gene that encodes a member of the TNF receptor superfamily, which is an ectodysplasin receptor. Mutations in either the ectodysplasin gene or its receptor disrupt ectodysplasin-mediated cell–cell signalling, which regulates the morphogenesis of ectodermal appendages.

Hypotrichosis resulting from short anagen [9]. This autosomal dominant condition is characterized by hair that is fine and short from birth. While the growth rate is normal, shortening of the duration of the anagen phase limits hair length to a few centimetres.

Hypotrichosis with keratosis pilaris [10]. The hair is apparently normal at birth, but after the birth coat has been shed, between the second and sixth months, it fails to grow satisfactorily and remains sparse, short, brittle and poorly pigmented. Eyebrows and eyelashes may be normal or sparse. Keratosis pilaris is present on the occipital region and neck, and sometimes on the trunk and limbs. Nails, teeth and general physical development are normal. The hairs show no beading or other distinctive abnormality.

Hypotrichosis with keratosis pilaris and lentiginosis [10]. Seven females in three generations in a family of three males and 13 females developed hypotrichosis at or just after puberty, which progressed until the menopause. Axillary and pubic hair was completely lost. There was keratosis pilaris of the scalp and axillae, brittleness and longitudinal striation of the nails, and centrofacial lentiginosis.

Eyelid cysts, hypodontia and hypotrichosis. See [11].

Hypomelia, hypotrichosis, facial haemangioma syndrome [12]. This 'pseudothalidomide' syndrome, which is probably determined by an autosomal recessive gene, associates gross reduction defects of the limbs, a mid-facial capillary naevus and sparse silver–blonde hair.

Hypotrichosis, Marie–Unna type [13–15]. In this rare but very distinctive syndrome the hair in affected individuals may be normal, sparse or absent at birth. If present, it remains fine and sparse until during the second or third year when it becomes coarse and twisted. The coarse wiry unruly hair may resemble a poor quality wig.

Unna described two patterns of alopecia. In the more severe form, the child's hair is always sparse and is progressively lost, so that alopecia is advanced by puberty. In the other, milder form, the hair is initially thick and the hair loss only commences in the second or third decade. At puberty, progressive loss begins over the parietal scalp bilaterally and progresses from anterior to posterior. Ultimately, the hair loss joins up centrally over the vertex to resemble Hamilton stage VIII androgenetic alopecia. There is usually also a subtle simultaneous loss from around the scalp margins.

The eyelashes, eyebrows and body hair are typically absent from birth, and after puberty any axillary or pubic hair that develops is also sparse. General physical and mental development is normal. Scanning electron microscopy shows that the hair shafts are coarse, irregularly twisted and fluted [13].

Although a distinct gene close to the hairless locus on chromosome 8p underlies hereditary Marie–Unna hypotrichosis, it has not yet been identified [16]. Other disorders clinically very similar to Marie–Unna hypotrichosis, but genetically distinct, are now recognized and indicate that more than one form of progressive patterned alopecia with wiry hair exists [17].

Hypotrichosis in disorders of amino acid metabolism. In many disorders with amino aciduria, the hair is hypopigmented and is often also fine, friable and sometimes sparse. Fine sparse hair has been reported in phenylketonuria, arginosuccinic aciduria and hyperlysinaemia.

A number of case reports associate hypotrichosis with a variety of ectodermal defects. Some such cases may represent partial forms of recognized syndromes but it is probable that many additional distinct syndromes remain to be identified and characterized.

Differential diagnosis. Microscopy of plucked hairs will exclude the more distinctive structural defects (pili torti, monilethrix and pili annulati). Other ectodermal defects should be carefully sought and relatives should be examined.

Circumscribed alopecia of congenital origin [1,2]

The differential diagnosis of circumscribed alopecia of congenital origin presents little difficulty if a reliable history is available. Without it, alopecia areata and the acquired cicatricial alopecias must be considered.

The most common forms are naevoid. Epidermal naevi are usually devoid of hair and present as warty or smooth but slightly indurated plaques. A zone of non-cicatricial alopecia sometimes develops around melanocytic naevi.

Aplasia of all layers of the skin gives rise to a congenital defect, usually a circular or rectilinear area of scarring, somewhat depressed below the scalp surface and commonly on the vertex.

Irregular areas of cicatricial alopecia not preceded by clinically apparent inflammatory changes produce the syndrome known as pseudopelade. Pseudopelade may develop during early infancy in association with certain hereditary syndromes (e.g. incontinentia pigmenti and Conradi's syndrome).

Circumscribed non-cicatricial alopecia is uncommon. It is the result of hypoplasia or aplasia of a group of follicles. The scalp is clinically normal and histologically shows no change other than a reduced number of follicles. Any follicles present are usually small and of vellus rather than terminal type. The first hair coat is normal and the patches develop between the third and sixth months, although if they are small and not completely bald they may not be noticed by the parents until considerably later.

Several clinical forms occur [1,2]. In *vertical alopecia*, a small and often irregular patch of alopecia is present on the vertex at birth. It has been confused with aplasia cutis, but the skin is normal apart from the absence of appendages. In *sutural alopecia*, which is one component of the Hallermann–Streiff syndrome, multiple patches overlie the cranial sutures. *Triangular alopecia* [3–6] was first recognized by Sabouraud. In the usual form, a triangular area overlying the frontotemporal suture just inside the anterior hairline, and with its base directed forwards, is completely bald or covered by sparse vellus hairs. Rarely, similar triangular patches have occurred on the nape of the neck.

Single or multiple small patches of total alopecia or hypotrichosis may occasionally occur in other sites, but are often inconspicuous.

Abnormalities of hair shaft

[D.A.R. de Berker, pp. 63.72–63.120]

Structural defects of the hair shaft may be sufficient in degree to cause significant cosmetic disability, or they may render the hair abnormally susceptible to injury by minor degrees of trauma (excessive weathering). Hair microscopy can be a useful part of clinical assessment in some situations [1], including a range of hereditary or acquired metabolic disorders, where the hair shaft can sometimes provide clues to the diagnosis [2].

Price [3] classified anomalies of the shaft into those that are associated with increased fragility, and those that are not. This distinction is useful because only the former present clinically as patchy or diffuse alopecia. Price's classification will be followed throughout the present section. Whiting [4] and Rogers [5] have reviewed the structural abnormalities.

Fig. 63.55 Monilethrix. Nape of the neck showing follicular keratoses and short broken hairs.

Structural defects with increased fragility

Monilethrix (beading of hair)

Smith [1] initially called this condition 'a rare nodose condition of the hair'. Radcliffe Crocker subsequently suggested the term monilethrix. Nevertheless, some early reports, and even some more recent ones, confuse monilethrix with other shaft defects (e.g. trichorrhexis nodosa) when 'weathering' is severe.

Aetiology. Autosomal dominant transmission has been demonstrated in numerous large pedigrees [2–4]. The alleged occurrence of normal carriers of the dominant gene has not been proven, as a parent with only 5% of abnormal follicles is easily passed as normal [5]. Several pedigrees have suggested an autosomal recessive trait [6], but this is probably a result of the difficulty in making the diagnosis in a parent where the manifestations are subtle. Monilethrix can be a heterogeneous condition [7]. The abnormality is attributable to mutations in the genes coding for the human hair keratins hHb1 and hHb6. There is no clear correlation between the severity of the phenotype and the mutation responsible [8].

Pathology. The hair shaft is beaded and breaks easily (Fig. 63.54). Elliptical nodes 0.7–1 mm apart, are separated by narrower internodes with a form resembling the body and neck of a skittle. The widths of the nodes and the distances between them vary between the hairs of an individual and between members of the same family. The nodes and some of the internodes show a normal imbricated scale pattern, but most internodes show longitudinal ridging [9,10].

Histologically, the follicle shows wide and narrow zones corresponding to the nodes and internodes [11], but the general structure of the follicle is otherwise normal. Salamon and Schneyder [3] and Gummer *et al.* [12] noted that changes were visible in the zone of keratinization; the cell membranes of the deeper hair shaft cuticular cells are thrown into folds, particularly at the narrower internodes where breakage occurs.

Attempts have been made to investigate the mechanism of node formation and to relate it to the diurnal rate of hair growth. Klingmuller [13] claimed to have found a 48-h cycle in two patients. Baker [14] studied four cases in which he found that a complete nodal complex was formed in 24 h. Comaish [9] found no daily rhythm and no simple time cycle. Lubach and Traintos [15] showed no regular rhythm of node formation.

Intermittent administration of an antimitotic agent can give rise to zones of constriction alternating with zones of normal diameter [16].

Studies with the electron microscope [17] have shown that increased susceptibility of the hair shaft to the effects of trauma—premature weathering—is an important factor in the failure of the hair to attain a normal length.

Clinical features. Monilethrix shows considerable variation in age of onset, severity and course [18].

The hair may be obviously abnormal at birth but is most commonly normal, and is progressively replaced by abnormal hair during the first months of life; in other cases, normal hair is succeeded by horny follicular papules from the summit of which emerge fragile beaded hairs. The follicular keratoses and the abnormal hairs are most frequent on the nape and occiput but may involve the entire scalp. In a typical case, the short stubble of brittle hairs and rough horny plugs give a distinctive appearance (Fig. 63.55). In some cases, the eyebrows and eyelashes, pubic and axillary hair and general body hair may be affected.

In many patients, the condition persists with little change throughout life [4]. Spontaneous improvement or complete recovery has occurred [1] and has been reported during pregnancy [19]. Griseofulvin also has temporarily restored normal hair growth [20].

Associated defects. Some investigators thought the association with oligophrenia and with nail and tooth defects was significant [3]. It has been proposed that such associations may be a feature of the recessive phenotype, as oligophrenia and poor physical development were noted also in two siblings with monilethrix [21]. Association with juvenile cataract has been reported [22].

Reports of abnormalities of amino acid metabolism are conflicting. Argininosuccinic aciduria has been reported [23], but a technical error was subsequently detected [24]. No abnormality in the urinary amino acid pattern was found in the autosomal dominant type [19] or in an isolated case [25]. An apparent excess of aspartic acid and arginine in the urine of an affected mother and daughter was described by Marques Llagaria *et al.* [26].

Treatment. None is available, but Tamayo [27] has suggested that oral retinoids can induce some hair regrowth. This may result from a therapeutic effect on the keratosis pilaris, which lessens in combination with a reduction of shaft beading and modest increase in overall hair length [28]. Although improvement has been attributed to the hormone changes of menarche in one report [29], male and female cases may both improve at puberty. Iron supplementation has been reported to be of value in the presence of iron deficiency [30]. Reduction of hairdressing trauma may be followed by some improvement, by lessening the 'weathering' from chemical and physical insults.

Pseudomonilethrix

It is not uncommon to see patients who complain that their hair is of poor quality or brittle. Microscopy of the hair to exclude the classical shaft defects is a routine procedure. Bentley-Phillips and Bayles [1] described a condition which they termed 'pseudomonilethrix' in South Africans of European or Indian descent. The status of the diagnosis is uncertain; some of the shaft deformities may be artefactual.

The patients present with alopecia starting in childhood. The family history suggests inheritance is determined by an autosomal dominant gene. The defect renders the hair so fragile that it readily breaks with the trauma of brushing, combing or other hairdressing procedures.

On microscopy, one, or occasionally two, of three abnormalities can be seen:

1 Pseudomonilethrix—irregular nodes, which on electron microscopy prove to be the protruding edges of depressions in the shaft

2 Irregular twists of 25–200° without flattening of the shaft

3 Breaks with brush-like ends in an apparently normal shaft.

There is no keratosis pilaris. Most authorities now believe that pseudomonilethrix microscopic changes are

Fig. 63.56 Hair lacquer can cause fusiform bulges along the hair shaft.

artefactual. They can be produced in normal hairs by trauma from tweezers or forceps, or compressing overlapping hairs between two glass slides; the indentation in one shaft caused by another overlying hair exactly mimics the appearance of pseudomonilethrix [2]. Hair lacquer and gel can also cause beading visible under the light microscope (Fig. 63.56) [3].

Pili torti (twisting of hair)

The first definite description of pili torti was given by Schutz [1], although earlier authors had referred to the condition. Ormsby and Mitchell [2] twice presented the same patient to the Chicago Dermatological Society; on the first occasion the diagnosis was 'atrophia pilorum'; monilethrix. In discussion, attention was drawn to the fact that the hairs were twisted and not beaded. Galewsky [3] suggested the term 'pili torti', which was also adopted by Ronchese [4] in the USA.

In pili torti, the hairs are flattened and at irregular intervals completely rotated through 180° around their long axis (Fig. 63.57). True pili torti of Menkes' syndrome and the isolated expression of the abnormality in an otherwise unaffected person, demonstrate the same distinct twisting (Figs 63.58 & 63.59). Scanning electron microscopy has made it clear that twisted hairs occur in many distinct forms, and that the twisting may be associated with a number of other shaft defects. Occasional twists of varying angle should not be taken to be this distinctive genetically 'fixed' abnormality of pili torti—many dystrophies and distortions of the follicular zone of keratinization will vary the hair shaft 'bore', sometimes showing less than 180° irregular twists.

Fig. 63.57 Pili torti. Light micrograph showing 180° twists.

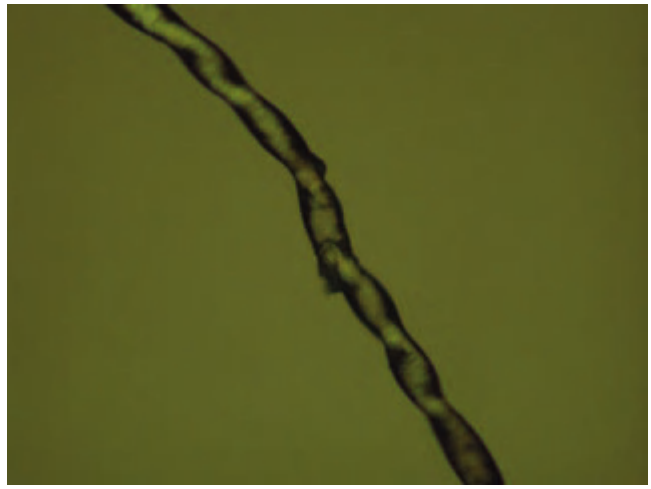

Fig. 63.58 Pili torti in a 6-month-old boy with Menkes' disease.

Syndromes in which twisted hair is a feature

Menkes' syndrome. Light-coloured twisted hair is a manifestation of a hereditary defect of intestinal copper transport; the inheritance is of sex-linked recessive type. Accumulation of copper in the neonatal period leads to brain damage, mental retardation and fitting. The latter

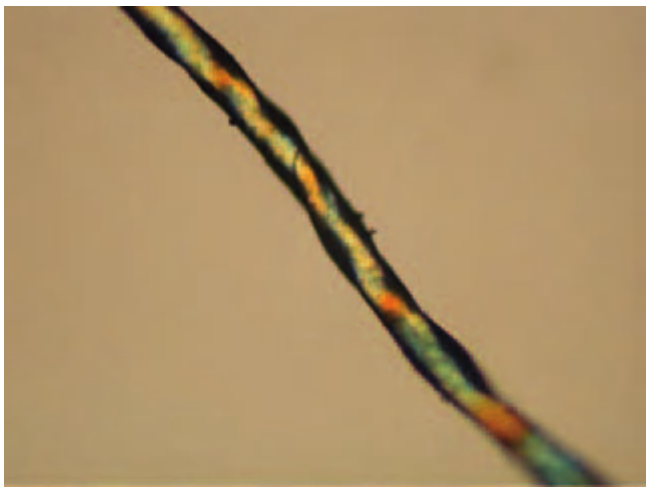

Fig. 63.59 Pili torti in a 27-year-old woman with no personal or family history of associated disorders.

may be the presenting complaint, with the diagnosis made later on hair microscopy. The twisting of the hair microscopically is generally exactly the same as in pili torti [5,6]. The disorder is caused by a mutation in the gene encoding Cu^{2+} transporting ATPase, α-polypeptide. The occipital horn syndrome is caused by mutation in the same gene.

Björnstad's syndrome (see below). Twisted hair with sensorineural deafness; probable autosomal dominant inheritance.

Crandall's syndrome. Twisted hair and deafness are associated with hypogonadism; probable sex-linked recessive inheritance. This may be a variant of Björnstad's syndrome.

Bazex syndrome. Twisted hair, with basal carcinomas of the face and follicular atrophoderma. Although this condition has come to be associated with the term pili torti, it illustrates how features of hair microscopy can be termed with low precision. The hair changes are probably more a form of irregular twisting than the tight distinctive changes seen with pili torti [7]. Vabres *et al.* [8] found evidence for X-linkage and regional assignment to Xq24–q27.

Hypohidrotic ectodermal dysplasia. Twisted hairs associated with characteristic facies and dental defects. The hairs are twisted irregularly and are not true pili torti.

Pseudomonilethrix. Twisted hair is associated, in the individual or the family, with apparently beaded hairs of autosomal dominant inheritance. However, the twists are irregular and the beads may be part of trauma sustained by the hair when plucked.

When patients with these syndromes are excluded, only pili torti remains, but there is evidence that it does not constitute a homogeneous entity: the hairs show considerable variation from patient to patient in their ability to withstand breaking and pulling; the hairs in some patients weather badly, but in others they do not [9].

Pollitt *et al.* [10] reported siblings with mental retardation, pili torti and trichorrhexis nodosa; their hair keratin was deficient in cysteine. However, dystrophic pili torti may occur with a normal cysteine content [11]. Reduction in cysteine implies the diagnosis of trichothiodystrophy, where the hairs are flattened and single twists are common—again illustrating the care needed to make a precise morphological diagnosis of pili torti rather than referring to isolated or heterogeneous twists by this term.

Aetiology. In those cases in which classic pili torti of early onset appears to have occurred as an isolated defect, inheritance has usually been determined by an autosomal dominant gene [12]. There are many reports of apparently sporadic cases [13]. However, there are also cases in which the siblings of consanguineous parents have been affected and in which recessive inheritance must be suspected [14].

Local inflammatory processes that distort the follicles can result in distorted and twisted hairs, such as may be found around the edges of patches of cicatricial alopecia [15]. Acquired pili torti-type changes may be produced by retinoids [16], but the hair is more 'kinked' than twisted. Non-scarring acquired pili torti has also been recorded in anorexia nervosa [17].

Pathology. The earlier reports emphasized that the affected hairs were flattened and twisted through 180° around their long axis at irregular intervals along the shaft. The load-extension curve (breaking stress analysis) resembles that of the wool of merino sheep; the hairs breaking more easily than normal. Histologically, the only abnormality is some curvature of the hair follicles. With the scanning electron microscope, the cuticle of the hair shaft appears normal [18], although severe weathering changes are not uncommon.

Clinical features. The hair is usually normal at birth, but is gradually replaced by abnormal hair, which becomes clinically evident as early as the third month, or not until the second or third year. There is a wide variation from case to case in the fragility of the hair, and hence in the clinical picture. Affected hairs are brittle and may break off at a length of 5 cm or less, or grow longer in areas of the scalp less subject to trauma. There may therefore be only a short coarse stubble over the whole scalp or there may be circumscribed baldness, irregularly patchy or occipital. Affected hairs have a spangled appearance in reflected light. The cosmetic appearance of isolated pili torti can improve greatly with transition from childhood to early adulthood [19].

The diagnosis should be suspected if the hair is brittle and dry. The typical spangled appearance in reflected light is present only if the hair is at least moderately severely affected, yet is not so brittle that it breaks to leave only a sparse stubble. Microscopic examination of several hairs must be made to confirm the diagnosis.

Other ectodermal defects may be associated with pili torti. Keratosis pilaris is the most recently reported, but nail dystrophies, dental abnormalities, corneal opacities and mental retardation have all been described [20]. The syndrome described as corkscrew hair [21] is microscopically separate, with an intrinsic spiral both in the axis of the hair and around the axis.

Björnstad's syndrome [1,2]

SYN. CRANDALL'S SYNDROME

In this syndrome, pili torti is associated with sensorineural hearing loss. The loss of hair usually begins in infancy but in one case it was not noticed until the age of 8 years [3]. There is a correlation between the severity of the hair defect and the degree of hearing loss. On microscopy, the hair shafts show longitudinal ridging and irregular twisting. Pedigrees have suggested both dominant and recessive inheritance [4,5]. The disease gene maps to chromosome 2q34–q36 [5].

Two brothers were investigated after they had reached puberty and were found to have secondary hypogonadism [6] with deficiency of luteinizing and of growth hormones.

Netherton's syndrome (bamboo hair) [1–4]

Netherton [5] observed bamboo-like nodes in the fragile hairs of a girl with 'erythematous scaly dermatitis'. It has gradually become apparent that ichthyosis linearis circumflexa (ILC) and 'bamboo hairs' (trichorrhexis invaginata) (Fig. 63.60) are two features of a single syndrome [6]. Most cases of Netherton's syndrome have had ILC but some have ichthyosis vulgaris [7] or both conditions, or ichthyosiform erythroderma. Features of ILC may be seen in variants of psoriasis. It is controversial as to whether it occurs as an isolated disease in the absence of Netherton's

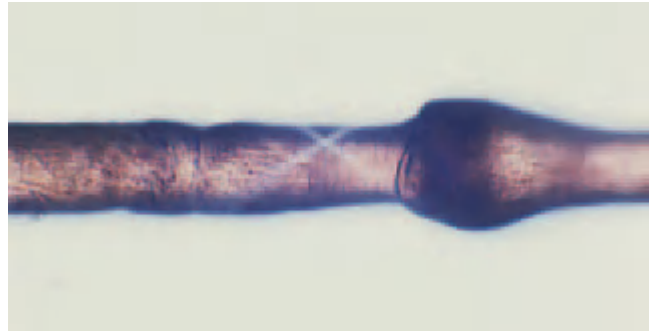

Fig. 63.60 Light microscopy revealing a trichorrhexis invaginata node likened to bamboo.

syndrome, or whether it is the fluctuating prevalence of the hair shaft changes that leads to difficulty in detecting both characteristics at the same time in some patients.

ILC is thus an almost constant feature of the syndrome, with hair shaft defects of various types and degrees of severity. Some authorities [8] question the variability of the syndrome.

The inheritance of Netherton's syndrome appears to be determined by an autosomal recessive gene of variable expressivity. Girls are affected more than boys. The underlying defect has been localized to a gene on chromosome 5q32, known as SPINK5, an acronym for serum protease inhibitor. The gene product is termed LEKTI (lympho-epithelial kazal-type-related inhibitor), as the gene is expressed in several lympho-epithelial tissues [9,10]. The protein has antitrypsin activities, but the mechanistic significance of this is not clear [11]. Examination of the SPINK5 gene in 13 families revealed 11 mutations, nine of which were associated with RNA instability. This is consistent with the low levels of SPINK5 gene product in those with the disease, where relevant RNA has decayed [12]. Immunohistochemical techniques are under development to allow tissue diagnosis of Netherton's syndrome on the basis of absence of LEKTI immunostaining. Identification of the gene has allowed prenatal diagnosis [13].

Pathology. As Netherton's syndrome results in fragile hair, samples should be cut at the scalp surface thus reducing the chances that the hair will break at the point of diagnostic interest, making diagnosis more difficult. Light microscopy is the best tool for detecting features of Netherton's syndrome in hair. However, an individual may have multiple hairs with characteristic changes in one sample and then no features in another sample taken some months later. Because of this it is important that samples of at least 100 hairs are carefully examined on several occasions before a definite negative is asserted. Alternatively, finding a single trichorrhexis invaginata node in a single hair is a conclusive positive (Figs 63.61 & 63.62).

To assess such large numbers of hairs it is necessary to use the light microscope, as electron microscopy will only allow assessment of small lengths of a small number of hairs. Detail of the surface features is enhanced using partially crossed polarizing filters, and the cortical anatomy of the hair is revealed if the hair is prepared on a slide in histological mounting medium. Scanning electron microscopy of the hair shafts shows focal defects that produce the development of torsion nodules, invaginated nodules (trichorrhexis invaginata) and trichorrhexis nodosa [14,15].

Where diagnosis is difficult, sampling the eyebrows may provide confirmation [16]. The proximal remnant of an invaginate node may resemble a golf tee and can allow diagnosis where classic nodes are absent [4].

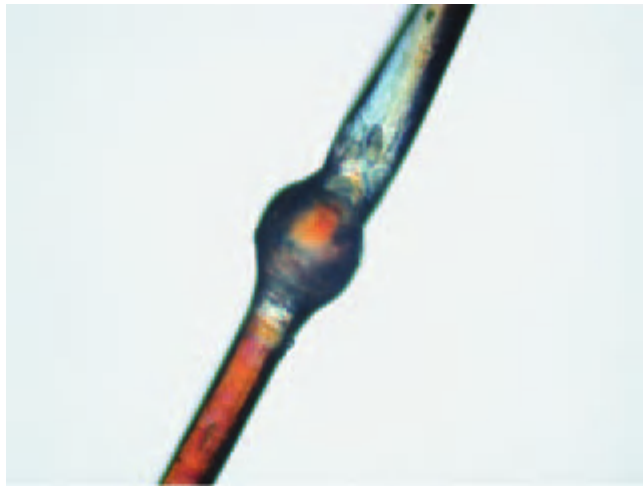

Fig. 63.61 Netherton's syndrome with an invaginate node showing partial twisting of the hair at the upper pole.

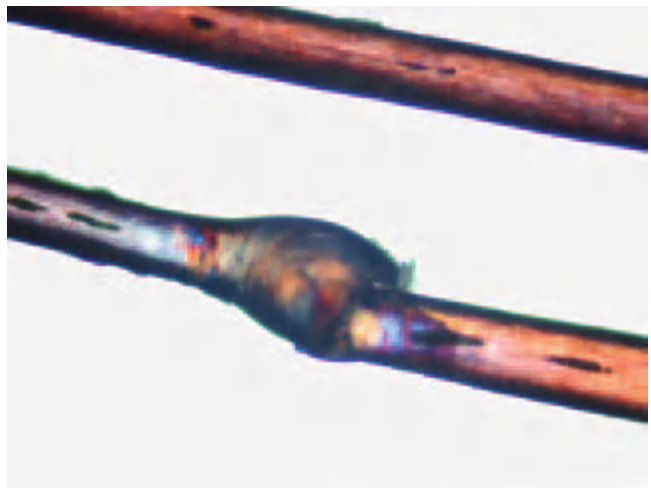

Fig. 63.62 Netherton's syndrome with the invaginate node acting as a point of weakness in the hair shaft.

Clinical features [17]. The patient may present primarily either with cutaneous changes or complaining of sparse and fragile hairs. Generalized scaling and erythema are present from birth or early infancy, but the degree, extent and persistence of the erythema are very variable. In some cases, the erythema may be slight and transient. In many it has the characteristics of atopic eczema accompanied by an elevated IgE. On the trunk and limbs, the fine dry scales are associated with a polycyclic and serpiginous eruption whose horny margin slowly changes its pattern.

The hair defects may be detected only if deliberately sought, but in most cases are readily apparent clinically [17]. The hair is short, dry, lustreless and brittle, and the eyebrows and lashes are sparse or absent. Jones *et al.* [18] described two cases in which neonatal hypernatraemia occurred. The severity of the phenotype does not show strict correlation with the mutation, and members of the

same kindred may share a mutation but have different degrees of disease [19].

Treatment. There is no specific effective skin treatment. Copious emollient use is standard. In spite of features shared with atopic eczema, there is a disappointing response of the skin to topical steroid, and persistence with this therapy can lead to systemic side effects. Topical tacrolimus 0.1% ointment has been used. Although the therapeutic response was reasonable, monitoring of blood levels revealed them to be at or above levels considered safe in organ transplant patients [20]. This raises the question as to whether it would represent a useful systemic therapy. Nagata [21] described some response to photochemotherapy. Oral retinoids, even at low dosage [17], do not produce significant benefit and can result in deterioration. Hair management entails avoiding chemical and physical trauma.

Trichorrhexis nodosa

Trichorrhexis is best regarded as a distinctive response of the hair shaft to injury [1]. If the degree or frequency of the injury is sufficient, it can be induced in normal hair [2], and this is probably the most common scenario. The cuticular cells become disrupted, allowing the cortical cells to splay out to form nodes [3]. If, however, the hair is abnormally fragile, trichorrhexis may follow relatively trivial injury. The trauma of hairdressing procedures has often been incriminated [4]. Scratching may produce identical changes in pubic hairs [4]; and the severity of experimentally induced trichorrhexis nodosa is related to the degree of trauma in patients with or without pre-existing trichorrhexis. The cumulative effect of shampooing, brushing, sea bathing and sunlight has led to seasonal summer recurrences [5].

Congenital and hereditary defects of the hair shaft resulting in fragility can predispose to trichorrhexis nodosa.

Trichorrhexis nodosa is a feature of the rare metabolic defect argininosuccinic aciduria, in which it is associated with mental retardation [6]; there is a deficiency of the enzyme argininosuccinase. Some 20 patients have been reported [7,8]. The hair tends to be dry, brittle and lustreless and may show trichorrhexis nodosa, but it does not occur in all patients with this metabolic disorder.

Trichorrhexis nodosa may occur in certain families as an apparently isolated defect of the hair; node formation and fracture are induced by minimal trauma and develop during the early months of life. Wolff *et al.* [9] described as 'trichorrhexis congenita' the presence from birth of trichorrhexis nodosa confined to the scalp, with normal teeth and nails.

In a case of generalized trichorrhexis nodosa in a male adult [10], electron histochemical study showed evidence of a disorder in the formation of α-keratin chains within the globular matrix of the hair cortex with respect to cysteine.

Pathology. In simple trichorrhexis nodosa, the shaft may appear normal with the light or electron microscope, except at the nodes; or the shaft, apart from the proximal 1 cm, may show signs of abnormal wear and tear [3]. At the nodes, the cuticle bulges and is split by longitudinal fissures (Fig. 63.63). If fracture occurs transversely through a node (trichoclasis), the end of the hair resembles a small paintbrush.

Clinical features. In trichorrhexis nodosa complicating a congenital defect of the hair shaft, the hair breaks so easily

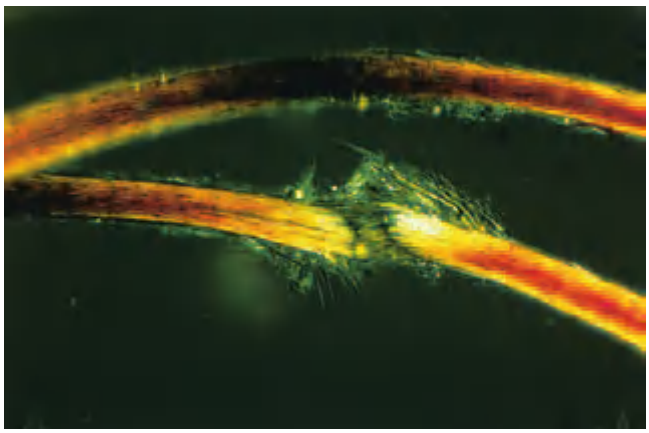

Fig. 63.63 Trichorrhexis nodosa. Polarized light examination demonstrates the splayed cortical fibres radiating from the transverse fracture in a trichorrhexis node.

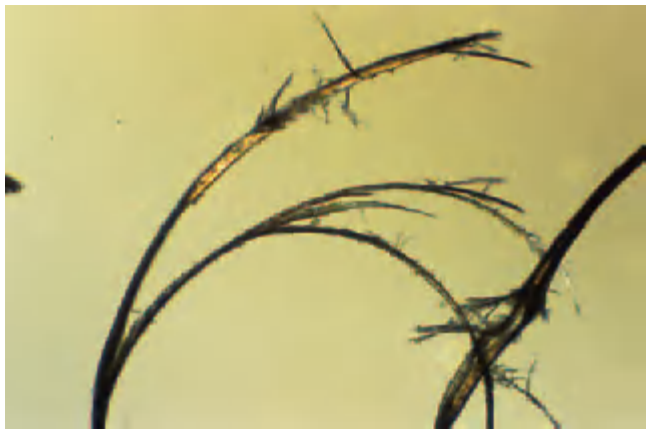

Fig. 63.64 Proximal trichorrhexis nodes and dramatic split ends (trichoptilosis) are visible in hair from an Afro-Caribbean woman.

that large or small portions of the scalp show only broken stumps and alopecia may be gross. However, the common situation is where trauma plays a major part and predisposition has a relatively minor role. In this setting there are three principal clinical presentations [11].

1 Distal trichorrhexis nodosa occurs in all races. Often it is discovered incidentally, and only a few whitish nodules are seen near the ends of scattered hairs. If many hairs are affected, the patient may complain that the hair is dry, dull or brittle. The longer the hair, the more likely it is to occur.

2 There is a generalized variant seen in Afro-Caribbean women called proximal trichorrhexis nodosa. The scalp hair is universally short and brittle and demonstrates severe weathering on light microscopic examination (Fig. 63.64). There may be an association with the follicular degeneration syndrome where there is a central scarring alopecia in the absence of an overt inflammatory process [12].

3 The third clinical form was well described by Sabouraud [13] but it appears now to be rare. In a localized area of scalp, moustache or beard, some hairs are broken and others show from one to five or six nodules [14].

Diagnosis. The congenital forms must be differentiated from other shaft defects. The distal acquired form may simulate dandruff or even pediculosis. In all cases, diagnosis depends on careful microscopy. Excessive physical and chemical (cosmetic) trauma must be avoided, apart from shampooing.

Trichothiodystrophy

The term trichothiodystrophy (TTD) was coined [1,2] to describe brittle hair with an abnormally low sulphur content [3]. The term covers a range of phenotypes, with low sulphur fragile hair representing the central defining criterion [4–10]. TTD can be classified according to the constellation of features that accompany the hair changes [4].

Using current criteria, approximately 50% of those with TTD are photosensitive. In this group, there is phenotypic and genetic crossover with xeroderma pigmentosum (XP). Of the different complementation groups within XP, most of the photosensitive TTDs share features with XP complementation group D, some with XP complementation group B and a small group represent an isolated photosensitive category, termed TTD-A. The common genetic defect in XPD and photosensitive TTD is within the ERCC2 (excision repair cross-complementation 2) gene on chromosome 19q as defined by *in vitro* complementation studies. Mutations of the ERCC3 gene on chromosome 2q

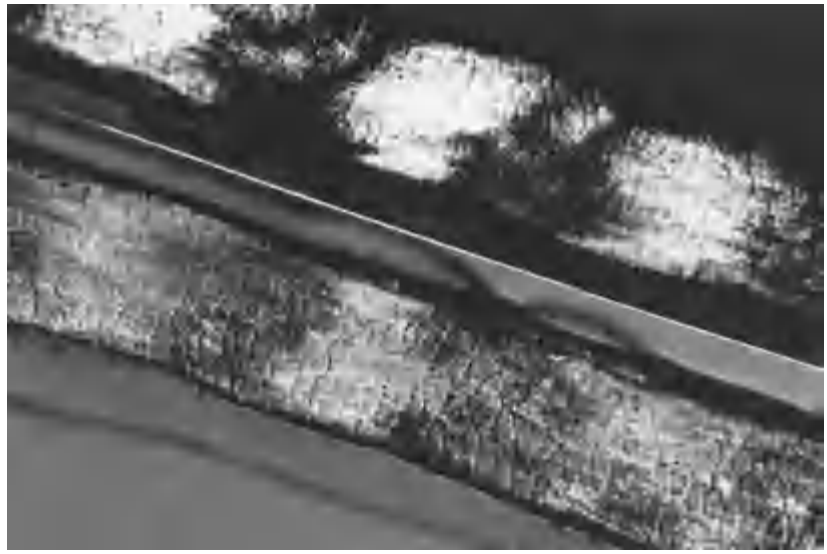

Fig. 63.65 Trichothiodystrophy. Alternating bright and dark zones in the polarizing microscope. (Courtesy of D. Van Neste, Brussels.)

have a corresponding role in XPB. These genes code for a transcription factor TFIIH, which has a dual function. First it acts as a helicase, which unravels the double helix of segments of photodamaged DNA as part of nucleotide excision and repair (NER). Secondly, it acts to enable transcription of segments of DNA to produce RNA and gene expression. A range of mutations in this gene can lead to changes in function of TFIIH. Where defects in NER occur, there is cumulative photodamage to the DNA, which is clinically expressed as photoageing and dysplasia. In XP, this ultimately predisposes to skin cancer, but not in TTD. Equally, the genetic basis for TTD can result in neuroectodermal changes that are not part of XP. A further mystery is that the genetic defect in Cockayne's syndrome arises within the same gene and affects the same transcription factor, but results in a different phenotype [5].

Currently, the genetic basis of the non-photosensitive forms of TTD has not been established.

Pathology. The hair is brittle and weathers badly [6]. With trauma it may fracture with a clean transverse break (trichoschisis) or may form nodes somewhat resembling trichorrhexis nodosa but without conspicuous release of individual spindle cells [1,2]. The hairs are flattened and can be twisted into various appearances—rather like a ribbon or shoe lace. Details of these changes are clarified by scanning electron microscopy. The shaft is irregular, with ridging and fluting, and the cuticular scales are patchily absent. Using crossed polarizing filters with a light microscope the hairs show alternating bright and dark zones (Fig. 63.65). This feature alone is not diagnostic of TTD and may occur in a range of genetic and acquired disorders where the longitudinal organization of cortical fibres within the hair is thrown into a sine wave pattern through loss of rigidity. As a sign, it may arise at different stages in infancy. In one instance it has been used prognostically when identified in a fetal eyebrow biopsy obtained *in utero* [7]. Other cases illustrate that the sign may fail to develop until a few months of age [8].

Using transmission electron microscopy, Gummer and Dawber [9] showed a decrease in high-sulphur protein staining in the hair shaft and a reduction of this protein in the exocuticular part of the cuticle cells. Gillespie and Marshall [10] demonstrated a quantitative reduction in high sulphur proteins in the hair shaft. A large proportion of these are termed keratin-associated proteins (KAPs), of which there are at least 11 classes. KAPs 1–5 are highest in cysteine and are the likely targets of a condition where this amino acid is deficient.

Clinical features. There is a wide range of phenotypic characteristics, depending on the variant of TTD (Table 63.5). The hair is sparse, short and brittle, but the degree of alopecia varies considerably. There may be lamellar ichthyosis. The nails may be dystrophic. Mental and physical development may be normal but one or both may be slightly, moderately or severely retarded. The central feature of altered hair remains the basis of diagnosis, but the mechanism linking the associated features requires further elucidation.

Marinesco–Sjögren syndrome

This rare syndrome, of autosomal recessive inheritance, has as its principal features cerebellar ataxia, dysarthria, retarded physical and mental development, and congenital cataracts [1]. The teeth are abnormally formed and the lateral incisors may be absent. The nails are flat, thin and fragile.

The hair is sparse, fine, light in colour, short and brittle. On microscopy, transverse fractures (trichoschisis) can be seen at the sites of impending breaks. In polarized light the hair is irregularly birefringent. Scalp biopsy shows normal anagen follicles, but with incomplete keratinization of the internal root sheath [2]. The combination of neurological and physical retardation with fragile hair is reminiscent of non-photosensitive trichothiodystrophy, although there are no skin changes in Marinesco–Sjögren syndrome.

Structural defects without increased fragility

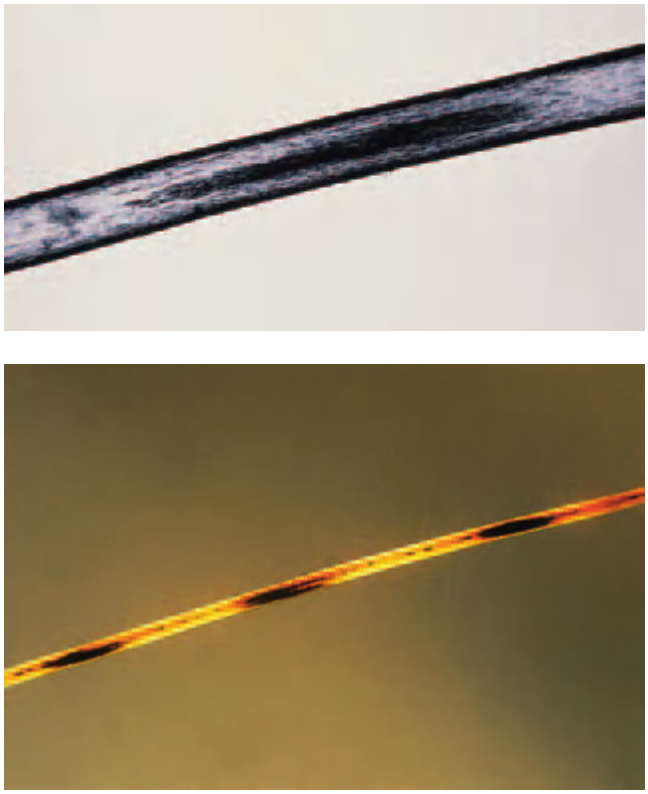
Pili annulati (ringed hair) [1,2]

Aetiology. This abnormality is characterized by hair showing alternate light and dark bands along its length, but which is otherwise normal. The inheritance of ringed hair has been shown in many extensive pedigrees to be determined by an autosomal dominant gene [3,4]. One pedigree was compatible with autosomal recessive inheritance [5]; sporadic cases have been described [6]. Blue naevus and ringed hair were associated in some members of a family, but the two conditions segregated [3].

Pathology and pathogenesis [7]. With the light microscope the abnormal dark bands alternating with normal light bands are reversed. The bright appearance of the abnormal bands in reflected light is caused by air spaces in the cortex (Fig. 63.66) [8]. Detection of the cortical defect is made easier if the hair is mounted in histological mounting medium because this enhances transmission of light through the hair.

The rate of growth has been measured in one case [3] and found to be 0.16 mm/day, which is less than half the average normal rate, but in our experience this is not a consistent finding. Breaking stress analysis showed no significant abnormality in ringed hair, but fractures were always in the normal bands. More recent studies have revealed protrusion of cortical fibres through the cuticle where there are cortical defects. Although this illustrates that the pathology can result in structural weakness, it only rarely leads to a clinical complaint of fragility [9].

Electron microscopic studies [10] showed that the clusters of air-filled cavities, randomly distributed throughout the cortex in the abnormal bands, lie partly within cortical cells and between macrofibrils, or in the case of larger cavities appear to replace cortical cells. Hairs from the family described by Dawber [3] showed an abnormal surface cuticle, which appeared 'cobble-stoned' on scanning electron microscopy. Electron histochemical methods confirmed this finding: cuticle cells are thrown into folds [11]. The pathogenesis of ringed hair remains uncertain. The abnormal alternating bands appear to be produced at random and not cyclically in relation to specific periods of growth [3].



(a)

(b)

Fig. 63.66 (a) Pili annulati. Hair shaft by transmitted light showing an abnormal dark band (central part) caused by multiple cortical air spaces. This corresponds to a bright region as seen by reflected light. (b) The abnormality is intermittent, causing the beaded or ringed appearance.

Clinical features. Pili annulati is normally diagnosed as a coincidental finding or as part of pursuance of the unusual, but quite attractive, spangled appearance. The condition has been reported in association with alopecia areata on several occasions. It is uncertain whether this represents a genuine association or if medical scrutiny reveals the otherwise subtle diagnosis [12]. If many hairs are affected and fragility is great, then short hair may attract attention in early life and the 'banded' and sandy appearance of the shafts in reflected light can be readily detected. The axillary hair is occasionally affected [13].

The diagnosis is readily established on microscopy of affected hair. A defect in which partially twisted shafts have an elliptical cross-section has been named pseudo-pili annulati because such hair may give an impression of alternating light and dark bands [14].

Prognosis and treatment. The prognosis is good in the sense that severity of the defect does not increase with age.

Woolly hair

History and nomenclature. Woolly hair is more or less tightly coiled hair occurring over the entire scalp or part of it. In those of African origin, woolly hair is the norm and is dominantly inherited. Tight coiling, knots and fractures are common [1]. The investigation by Hutchinson *et al*. [2] was important in delineating the clinical types.

The types may be classified as follows:

1 *Dominant woolly hair*. Some families have woolly hair inherited as an autosomal dominant trait.

2 *Recessive woolly hair*. Early genetic evidence is inconclusive but the condition has occurred in siblings whose parents were normal. Autosomal recessive inheritance is probable. Kindreds manifesting woolly hair as part of two different syndromes with heart disease have demonstrated an autosomal recessive inheritance [3].

3 *Acquired woolly hair*. This is usually circumscribed, occurs from adolescence onwards, and is also termed acquired progressive kinking of hair.

4 *Woolly hair naevus*. This is a circumscribed developmental defect, present at or near birth.

In a further uncommon variant, there are woolly hairs interspersed with otherwise normal hair [4].

Hair microscopy in all the woolly hair disorders reveals non-specific features that are consistent with a woolly, stiff hair phenotype. This usually arises in association with grooves, partial twists, irregularity of bore and sometimes features of trauma. When a hair shaft has an irregular shape and is stiffer, it is more prone to damage. The changes are often subtle, and are better appreciated on assessment of at least 20 and preferably 50 hairs or more. Isolated reports describing hair morphology often fall

into the trap of describing individual hairs rather than the population of hairs as a whole. This mistake can be compounded by using scanning electron microscopy for the main assessment rather than as a supplementary tool. Although electron microscopy is excellent for revealing great detail in a small number of hairs, it is very poor at showing the characteristics of a population of hairs, which is the usual determinant of a phenotype.

Dominant woolly hair

In some pedigrees, the shaft diameter in affected individuals is reduced; the hair is fragile and may show trichorrhexis nodosa. Excessively curly hair is evident at birth or in early infancy; it has sometimes been described as negroid in appearance. Anderson [5] considered that the hair, although tightly coiled, was not negroid. The degree of variation in severity within a family is inconstant [1]. The hair shaft may be twisted [6]. In some cases the hair is brittle and breaks readily.

On the island of Naxos in Greece, a dominantly inherited condition has been identified, which now bears the name of the island. Naxos disease is characterized by woolly hair, palmoplantar keratoderma and a right ventricular cardiomyopathy that causes arrhythmia, heart failure and sudden death. The gene responsible for the disorder has been mapped to 17q21, which is the plakoglobin gene. Plakoglobin is an important constituent of desmosomes and adherens junction. Its loss in heart muscle leads to tissue replacement with fibrofatty material. The role in hair morphology is less clear [7]. A recent Dutch kindred were reported as having woolly hair as part of an ectodermal dysplasia, with dominant inheritance [8]. However, it should be noted that there are problems with terminology in hair science and genetics, and there is a type of hair change sometimes seen in ectodermal dysplasia that can be described as 'wiry' rather than 'woolly'.

In some cases of loose anagen syndrome, there may be associated woolly hair [9].

Recessive woolly hair

The hair is reported as brittle and on scanning electron microscopy shows signs of cuticular wear and tear [2]. In three cases [2], fine, tightly curled, poorly pigmented hair was present from birth; in two of them the hair never achieved a length of more than 2 or 3 cm. Eyebrows and body hair were sparse.

Two different variants of recessively inherited woolly hair have been defined in association with palmoplantar keratoderma and mutations causing defects in desmoplakin. One variant was associated with cardiomyopathy [10] and the other not [11].

Acquired woolly hair

There are a range of acquired patterns of woolly hair which have different and confusing names. They divide into those that develop as part of ageing and those that are attributable to trauma or drugs. The appearances may be indistinguishable when the drug is simply eliciting or catalysing an underlying process. Whisker hair describes the appearance seen in some cases, mainly males, from adolescence onwards. An irregular band of coarse, whisker-like hair extends around the edge of the scalp from above the ears towards the occipital region [12]. The hair shaft features are indistinguishable from acquired progressive kinking of hair [13], although the pattern and history may be different when drugs are implicated. Retinoids are most commonly cited [14,15]. In all these conditions the patient gradually becomes aware that the hair is changing in texture in one or more areas. On examination, the hair of the scalp is wiry, kinky, unruly, dry and lustreless. There are no sharply defined boundaries between normal and abnormal hair, although the appearance may be most marked in the frontal margins. In some of the cases described, the acquired kinking preceded hair loss, whether drug-induced or as part of the development of AGA [1].

Woolly hair naevus [16,17]

The hair in a circumscribed area of the scalp is woolly or curly and contrasts in colour and coarseness with the surrounding hair. The affected hair is usually finer at the outset, which also makes it more vulnerable to trauma. In time the contrasts may reverse, with hair in the naevoid patch becoming darker and coarser than the surrounding hair. The size of the affected area usually increases only proportionately with general growth. The abnormal hair is usually paler than that of the rest of the scalp [18]. In over half of the reported cases, a pigmented or epidermal naevus has been present, but not always at the same site. A woolly hair naevus has been reported in association with ocular defects [19], and with precocious puberty [20]. In the latter case the naevus was not limited to the scalp.

Uncombable hair syndrome

SYN. SPUN-GLASS HAIR; CHEVEUX INCOIFFABLES; PILI TRIANGULI ET CANALICULI

Aetiology [1]. This is a combination of a striking clinical presentation and distinctive hair shaft defect first described by Dupré *et al*. [2]. Since then, many more cases have been reported, some of them under the name of 'spun-glass hair'. Others have preferred the term pili trianguli et canaliculi, with emphasis on the triangular cross-section and longitudinal groove that is commonly found on microscopy. The mode of inheritance is probably autosomal dominant [3].

Pathology. Light microscopy reveals the features in a hair shaft that makes it rigid: the triangular cross-section (Fig. 63.67) and longitudinal grooving (Fig. 63.68). Twisting can also be present and contributes to stiffness to a minor degree. The first two features are best sought using partially crossed polarizing filters with air-mounted hair. If a histological mountant is used, the surface contours of the hair are not seen. On histological (horizontal sections) examination of the scalp hair, cross-sectional characteristics are more easily seen but preparation is time consuming. Scanning electron microscopy can be helpful on selected hairs (Fig. 63.69) [4–6]. The term 'pili trianguli et canaliculi' has been proposed for these defects. The pili canaliculi are present in all cases, pili trianguli in the majority and pili torti in a few [6]. Van Neste *et al*. [7] have suggested that the misshapen dermal papilla alters the shape of the internal root sheath, which hardens (before the hair within) in a triangular cross-sectional shape; the hair then hardens into a shape complementing the root sheath. The defect resembles the 'straight hair naevus' of which it may be a diffuse form.

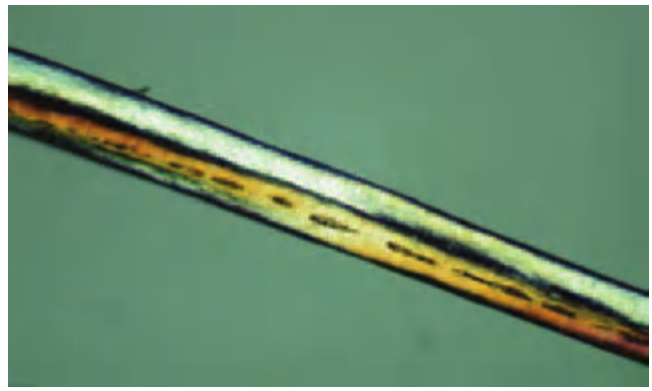

Fig. 63.67 Triangular cross-section of the hair contributes to stiffness.

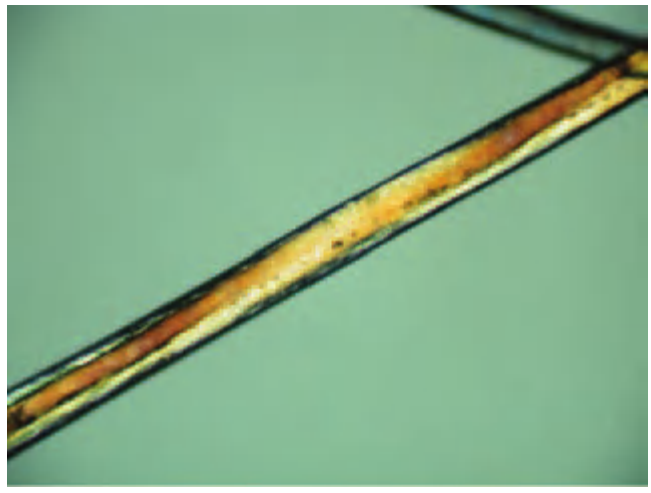

Fig. 63.68 Light microscopy reveals grooving when using partially crossed polarizing filters.

Clinical features [4,5]. The abnormality may first become obvious from 3 months to 12 years of age. The hair is normal in quantity and sometimes also in length, but its wild disorderly appearance totally resists all efforts to control it with brush or comb. In some cases, these efforts lead to the hair breaking, but increased fragility is not a constant feature [8]. The hair is often a rather distinctive silvery blonde colour. The eyebrows and eyelashes are normal. The appearance becomes less marked with time [9].

Fig. 63.69 Uncombable hair syndrome. Scanning electron micrograph showing essentially triangular cross-section and canalicular depression or gutter along one side.

The clinical appearance is usually distinctive. With light microscopy the diagnosis is dependent upon the experience of the microscopist as the three-dimensional aspect of the shaft changes can be difficult to establish. No treatment is known, although oral biotin therapy has been suggested [10].

Straight-hair naevus

In the straight-hair naevus, the hairs in a circumscribed area of a negroid scalp are straight, and are round in cross-section. The abnormal hair may be associated with an epidermal naevus [1,2]. With the scanning electron microscope, the cuticular scales may appear small and their pattern disorganized.

It has been suggested that this is a localized form of cheveux incoiffables.

Loose anagen hair syndrome [1]

This condition features anagen hairs that are loosely anchored and easily pulled from the scalp [2–4]. The majority of cases are fair-haired children, aged 2–9 years, mostly girls. There is usually a pattern of autosomal dominant inheritance. They typically have slightly unruly hair, which is of uneven length and patchy in quality. Variants of this include those with stiff, uncombable hair and those in whom shedding is the primary complaint. All three phenotypes may coexist within the same family [5]. The children may present with patchy alopecia, leading to a misdiagnosis of alopecia areata, but which, in fact, represents modest hair pulling. The child is well, and there are no other ectodermal abnormalities.

Hair is usually easily and painlessly plucked with the hair-pull test, although this is not a constant or specific finding [6]. Microscopy of plucked hair may show ruffling of the cuticle adjacent to the anagen bulb, giving the appearance of a 'floppy sock'. The hair shaft may have twists and grooves, and be angular in cross-section. The root sheath is absent or there may be a small everted remnant.

The hair becomes more normal with age, although the pull test may still yield abnormally large numbers of hairs into adulthood [7].

There have been isolated reports of loose anagen syndrome associated with hypohidrotic ectodermal dysplasia [8] and ocular coloboma [9].

Histological examination shows premature keratinization of the inner root sheath layers of Huxley and Henle. Trichograms show 98–100% anagen hairs. Keratin 6irs is an inner root sheath keratin proposed as a protein that might control manifestations of the disorder [10]. In one report, mutations in the gene coding for such a keratin supported this possibility [11].

Some authorities have had good results with 5% topical minoxidil [11], although it is not commonly employed and is not of clear value.

Other abnormalities of the shaft

Trichoclasis

Trichoclasis is the common 'greenstick' fracture of the hair shaft. Transverse fractures of the shaft occur, partly splinted by intact cuticle. Cuticle, cortex and sulphur content are normal. This sign may be seen in a variety of congenital and acquired 'fragile' hair states.

In the condition termed trichorrhexis blastysis [1], with unusual facies, failure to thrive, unexplained diarrhoea and abnormal hairs, the scanning electron micrographs showed features resembling trichoclasis.

REFERENCE

1 Stankler L, Lloyd D, Pollitt RJ *et al*. Unexplained diarrhoea and failure to thrive in two siblings with unusual hair. *Arch Dis Child* 1982; **57**: 212–4.

Trichoptilosis

History and nomenclature. The term trichoptilosis describes longitudinal splitting of the hair shaft from the tip. The patient often refers to the condition as 'split ends'.

Aetiology. Trichoptilosis is the most common macroscopic response of the hair shaft to the cumulative effects of chemical and physical trauma. It can readily be produced experimentally by vigorous brushing of normal hair, and it occurs in the nodes of pili torti. It is one component of the 'weathering' process particularly seen in long hair in normal individuals and in any congenital 'brittle hair' syndrome.

Pathology. The distal end of the hair shaft is split longitudinally into two or several divisions. Other microscopic evidence of hair damage may be present. The split surface often lacks cuticle, and the split commences from the distal tip, thus distinguishing the problem from pili bifurcati or multigemini. The latter are abnormalities of hair genesis, rather than the results of hair damage.

Clinical features. Trichoptilosis is often an incidental finding in a person who complains that their hair is dry and brittle. Trichorrhexis nodosa and trichoclasis are often also present. Central trichoptilosis, a longitudinal split in the hair shaft without involvement of the tip, sometimes occurs [1]. Such a finding would be in the context of general hair damage and other more classic forms of trichoptilosis, which would distinguish it from pili bifurcati.

Treatment. Careful explanation is necessary to encourage the patient to avoid further hair trauma, because otherwise the condition will inevitably recur. Short hair and frequent trimming usually solve the problem.

Circle hairs [1,2]

Circle and spiral hairs occur in middle-aged men on the back, abdomen and thighs as small dark circles next to hair follicles. They are an unusual form of ingrown hair lying in a coiled track just below the stratum corneum, and can be easily extracted. Keratin follicular plugging is not associated (cf. scurvy, which may demonstrate keratosis pilaris with rolled and 'corkscrew' hairs).

Trichomalacia

Miescher [1] described as trichomalacia a patchy alopecia in which some follicles are plugged and contain soft deformed swollen hairs. The changes have been attributed to the repeated trauma resulting from a hair-pulling tic [2,3], and subsequent histological studies in trichotillomania confirm this opinion.

Pathology. Above the bulb, the cells of the hair shaft appear to be disconnected and the hair is shapeless or partially disintegrated. High in the follicle, the shaft is thin and may be coiled. Whiting [4] described biopsy specimens as showing partially avulsed hair roots that are deformed and twisted. Clefting occurs between matrix

cells and between hair bulb and outer connective tissue sheath. There is no inflammatory reaction; these changes are said to be pathognomonic of trichotillomania. One study of 26 patients with trichotillomania recorded trichomalacia in horizontal sections of 57% [5].

Trichoschisis [1]

Trichoschisis is a clean transverse fracture across the hair shaft through cuticle and cortex; the fracture is associated with localized absence (loss) of cuticular cells. It is said to be a characteristic microscopic finding of trichothiodystrophy. It probably represents a clean fracture through hair with decreased high-sulphur matrix protein content and, in particular, a similar decrease in the exocuticle and A layer of cuticular cells. It may be prominent in the sulphur deficiency syndromes but it should not be considered as specific or pathognomonic.

Pohl–Pinkus constriction [1]

In some individuals, a zone of decreased shaft diameter coincides in time with a surgical operation, an illness or the administration of folic acid antagonists or other drugs that inhibit mitosis; it was first described by Pohl in 1894—he later changed his name to Pinkus. The proportion of affected hairs is variable and it seems probable that hairs in early anagen are most susceptible to a period of hypoproteinaemia or disturbed protein synthesis. This phenomenon was present in 21 of 100 hospitalized patients [2]; whether the illness or operation had been associated with pyrexia was not a relevant factor.

These constrictions in the hair shaft have been considered to be analogous to the transverse furrows in the nails (Beau's lines), which also coincide with episodes of ill health. Longer narrowings, resembling monilethrix, may occur with 'bolus' doses of cytotoxic drugs that do not lead to anagen effluvium.

Tapered hairs

Tapered hairs are those with a distal end that resembles the tip of a javelin. Most commonly, tapered hair is seen in any condition where there are many hairs regrowing after an effluvium, or where anagen is short. Regrowth after telogen effluvium, alopecia areata and trichotillomania may result in hairs with tapered ends. At body sites where the hairs are always short, such as the eyelashes, they are tapered. When scalp hair has a short anagen, such as in hypotrichosis simplex [1], the ends are also tapered. This is also the case in the newborn, as the duration of anagen has only been a few months from commencement *in utero*. As a feature on microscopy, tapered hairs are a useful sign that short hair is caused by the length of anagen rather than intrinsic hair shaft fragility.

REFERENCE

1 de Berker D. Congenital hypotrichosis. *Int J Dermatol* 1999; **38** (Suppl. 1): 25–33.

Bayonet hairs

Bayonet hairs are characterized by a 2–3 mm spindle-shaped hyperpigmented expansion of the hair cortex just proximal to a tapered tip, and may be associated with hyperkeratinization of the upper third of the follicle.

Trichonodosis

Michelson [1] first proposed the term noduli laqueati, and noted that naturally curly hair was most frequently affected. The term trichonodosis was popularized later by Kren [2], who found the condition in 35 out of 64 consecutively examined patients with skin disease.

Aetiology. The knotting of the hair shafts is induced by trauma. Short curly hair of relatively flat diameter is most readily affected [3]. Knots were seen most frequently in hair from people of African origin [4] and in short curly hair in white people; none was seen in long straight hair.

Some knotting is caused by braids and cosmetic manipulation. These knots are of a different form and scale to the inadvertent knotting brought about by hair type and random trauma. However, it is capable of inducing marked changes in the cuticle, which in turn results in a lower threshold for hair fracture.

Pathology. The only abnormalities are secondary to the knotting and are localized to that part of the shaft that forms the knot [3]. With the scanning electron microscope, the cuticle shows longitudinal fissuring and fractures, and cuticle scales are lost.

Clinical features [3]. Trichonodosis is usually an incidental finding, because it is inconspicuous and must be deliberately sought. One or few hairs are affected. The trauma of brushing or combing may cause the shaft to break at the site of the knot.

Trichostasis spinulosa

This is probably a normal age-related phenomenon—easily overlooked—in which successive telogen hairs are retained in predominantly sebaceous follicles [1]. When it was specifically sought, 51 cases were seen in 1 month in Madras [2].

Aetiology. Ladany [3] thought trichostasis was no more than a variant of the comedo, and pointed out that 85% of comedones contain from one to 10 or more vellus hairs. Trichostasis is found most commonly in the middle-aged or elderly and is said by most authors to occur particularly on the nose and face [3]. Other sites were perhaps not always examined, for others have found it to be not uncommon on the trunk, limbs [4] and interscapular area [5].

Pathology. The affected follicles contain up to 50 vellus hairs embedded in a keratinous plug. A mild perifolliculitis is often present. The condition must be differentiated from the 'multiple hairs' of Flemming—Giovannini in which up to seven hairs grow from a composite papilla with a common outer root sheath [6]. Follicles may contain *Malassezia* yeasts and *Propionibacterium acnes* [5].

Clinical features [7]. Those reported to be affected have ranged in age from 17 to over 60 years. The lesions, which closely resemble comedones, may occur predominantly on the nose, forehead and cheeks, or the face may be spared and the nape, back, shoulders, upper arms and chest may be affected. The lesions vary greatly in number. On inspection with a hand lens, the 'comedones' seem to be unusually prominent and in some cases a tuft of hairs may be seen projecting through the horny plug.

Treatment. Keratolytic preparations have often been recommended but we have found them of little value. The most effective treatment is topical retinoic acid [8], which should be used as in the treatment of acne. Depilatory wax has also been successfully employed [7], and specialized cleaning pads have been advocated [9].

Pili multigemini

SYN. PILI BIFURCATI

The term pili multigemini [1] describes an uncommon developmental defect of hair follicles as a result of which multiple matrices and papillae form hairs that emerge through a single pilosebaceous canal. The incidence of multigeminate hairs in the general population is unknown. Numerous follicles showing this defect have been seen in a patient with cleidocranial dysostosis [2].

Pathology. From two to eight matrices and papillae, each with its internal root sheath, form hairs that are often flattened, ovoid or triangular in configuration and may be grooved. In the follicular canal, contiguous hairs may adhere, bifurcate and then re-adhere.

Clinical features. Multigeminate follicles occur mainly on the face, especially along the lines of the jaw. Tufts of hair may be seen emerging from a few or many follicles. Their discovery is often a matter of chance, but the patient may complain of recurrent inflammatory nodules, leaving scars.

Treatment. If the hairs are plucked, they regrow [2]. A single report of ablation after three treatments with a ruby laser may indicate that this is a therapeutic option [3].

Hair casts

Hair casts (peripilar keratin casts) are firm yellowish white accretions ensheathing, but not attached to, scalp hairs. They freely move up and down the affected shafts [1]. Such casts are often found in scaly and seborrhoeic disorders of the scalp, and in children with hairstyles requiring traction [2].

Pathology. In cross-section, casts are composed of a central layer of retained internal root sheath and an outer thick keratinous layer. Scalp histology shows the follicular openings packed with parakeratotic squames, which break off at intervals to form hair casts.

Casts are found quite commonly in scaly, mainly parakeratotic conditions of the scalp such as psoriasis and pityriasis amiantacea [3]. Cases have been described in association with traction hairstyles [2,4,5] and hair sprays [6].

Clinical features. Hair casts (Fig. 63.70) may occur as an isolated abnormality unrelated to any overt scalp disease and may mimic pediculosis capitis [7]—hence the designation 'pseudonits' [8,9]. Girls and young women are most commonly affected; hundreds of casts may develop within a few days. No cause is known, but sex-linked inheritance has been suggested [1]. It is possible that this type may represent an unusual manifestation of psoriasis.

If patients with scaly parakeratotic diseases of the scalp complain of persistent dandruff that resists apparently adequate treatment, this is likely to be caused by multiple hair casts.

Diagnosis. In the absence of associated scalp disease, casts may be mistaken for pediculosis capitis, trichorrhexis nodosa or hair knots [10]. Of these nodal shaft abnormalities, only hair casts are freely movable along the hair.

Treatment. Any causative scalp disease must be treated. Keratolytic preparations and shampoos that readily improve scalp scaling frequently fail to remove casts; prolonged brushing and combing is necessary to slide casts off the affected hairs [3,11].

Weathering of the hair shaft [1,2]

All hair fibres undergo some degree of cuticular and secondary cortical breakdown from root to tip before being shed during the telogen or early anagen phase of the hair cycle. The term 'weathering' of hair has been limited by some authorities to structural changes in the hair shaft resulting from cosmetic procedures; indeed, both *in vivo* and *in vitro* studies carried out by cosmetic scientists have shown the type of damage that factors such as combing, brushing, bleaching and permanent waving can cause [3,4]. However, in considering the degeneration of hair fibres, cosmetic and other influences such as natural friction, wetting and UV radiation are so interwoven that it is more useful in practice to define weathering as the degeneration of hair from root to tip because of a variety of environmental and cosmetic factors. Scalp hair, having a long anagen phase and being subject to more frictional damage and cosmetic treatment, shows more deep cuticular and cortical degeneration than fibres from other sites.

Weathering of scalp hair has been studied in greater detail than hair from other sites. At the root end, surface cuticle cells are closely apposed to deeper layers. Within a few centimetres of the scalp, the free margin of these cells lifts up and breaks irregularly [5]. Increasing scale loss leads to surface areas denuded of cuticle. Many fibres show complete loss of overlapping scales well proximal to the tip (Fig. 63.71). This is particularly common on long hair shafts, which frequently have a frayed tip. Proximal to terminal fraying, longitudinal fissures may be present between exposed cortical cells. Hairs subjected to considerable friction damage may show transverse fissures and some nodes of the type seen in trichorrhexis nodosa [6,7]. Hair that has been bleached or permanently waved may show shaft distortion. The most severe changes are mostly

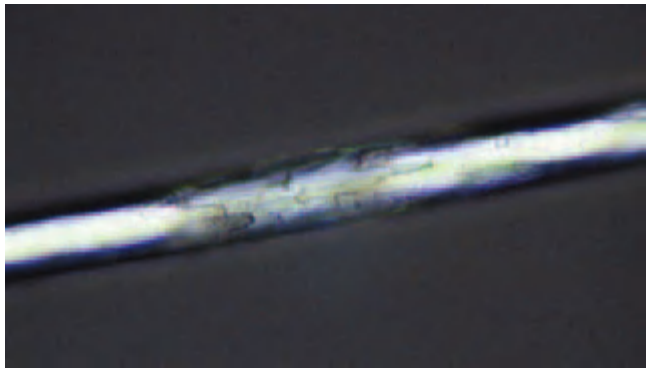

Fig. 63.71 Focal loss of cuticle in a weathered hair.

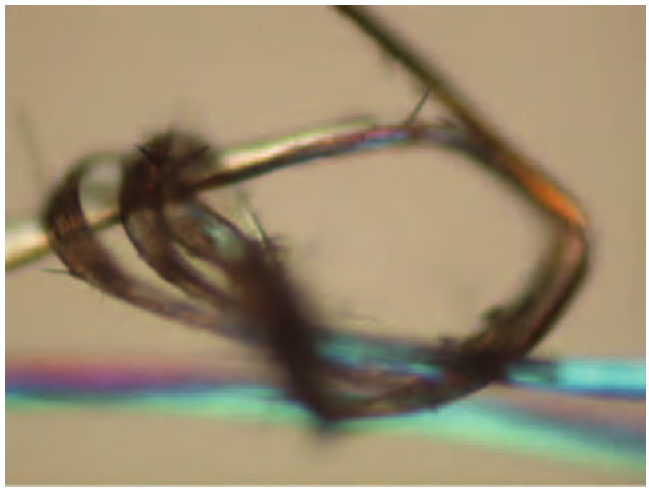

Fig. 63.72 Knotting of single and multiple hairs contributes to hair shaft trauma.

seen near the distal part of the hair shaft in normal scalp hair.

Hair knotting (Fig. 63.72) and braids (Fig. 63.73) are a significant source of hair shaft trauma, with loss of cuticle and damage to cortical fibres.

Trichorrhexis nodosa is the most severe form of weathering. Many of the changes seen in normal hair towards the tip are visible more proximally in congenitally weakened hair [8,9] and in trichorrhexis nodosa caused by overuse of cosmetic treatments [10].

In some hair structural abnormalities such as monilethrix and pili torti, specific weathering patterns may be seen.

Bubble hair

Brown [1] reported an unusual case of an acquired, localized, reversible hair shaft defect with intrinsic 'bubbles' within hairs, thought to be caused by repeated cosmetic trauma. Subsequent reports [2,3] have demonstrated that the bubbles are a sign of thermal injury, particularly of damp hair [3]. This may be because of poor thermostat control of a hair dryer, but most of us suffer bubble hairs by singeing over the cooker (Fig. 63.74).

Excessive growth of hair [1–3]

Growth of hair that in any given site is coarser, longer or more profuse than is normal for the age, sex and race of the individual is regarded as excessive. The terms hirsutism and hypertrichosis are often confused and applied

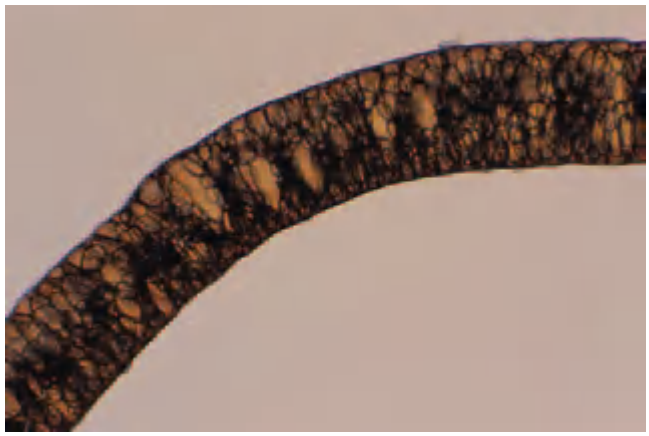

Fig. 63.74 Appearance of normal scalp hair after exposure to naked flame. Bubbles form within the cortex.

Fig. 63.75 Congenital hypertrichosis lanuginosa. (Courtesy of Dr Partridge, Leamington, UK.)

interchangeably and indiscriminately to excessive hair growth of any type in any distribution. On phylogenetic grounds, and on the basis of its specific androgenic induction, the growth in the female of coarse terminal hair in the adult male pattern should be differentiated clearly from the numerous other forms of excessive hair growth of widely varying aetiology. The term hirsutism will be restricted to androgen-dependent hair patterns of typically terminal hair and the term hypertrichosis will be applied to other patterns of excessive hair growth, typically vellus. In some areas it is difficult to make the distinction, such as in the excess facial hair in porphyria cutanea tarda. This is typically referred to as hypertrichosis, but the point can be argued.

There is much confusion in the literature concerning generalized congenital hypertrichosis because of a plethora of names such as apeman, bearman, dogman, manlion and wildman [4].

Hypertrichosis

The terminology used in describing different patterns of hypertrichosis is inconsistent as reports have given synonymous terms to clinically different forms of the problem. Baumeister *et al.* [1] sought to unravel the matter. Hypertrichosis usually conforms to the classification of localized or generalized of congenital or acquired pattern, where congenital is loosely interpreted as that seen in early infancy.

Congenital generalized hypertrichosis

Hypertrichosis lanuginosa

In congenital hypertrichosis, the fetal pelage is not replaced by vellus and terminal hair but persists, grows excessively and is constantly renewed throughout life. In the acquired form, the previously normal follicles of all types revert at any age to the production of hair with lanugo characteristics [1].

Aetiology. Traditionally, cases of congenital hypertrichosis have been classified into two groups—'dog faced' and 'simian'—but a survey [2] suggests that there may be only a single genotype, with considerable interfamily variation in the phenotype. With one exception [3], all published pedigrees suggest autosomal dominant inheritance.

Clinical features [2,4–7]. The child is usually noticed to be excessively hairy at birth (Fig. 63.75). The hair gradually lengthens until by early childhood the entire skin, apart from the palms and soles, is covered by silky hair, which may be 10 cm or more long. Long eyelashes and thick eyebrows are conspicuous features. Some affected individuals are normal at birth and sometimes for the first few years of life, before the universal replacement of other hair types by lanugo. Once established, the hypertrichosis is permanent, but some diminution of hairiness of trunk and limbs may be noted in later childhood. At puberty, axillary, pubic and beard hairs retain their downy character. Hypodontia or anodontia and deformities of the external ear are apparently associated in some families, but the physical and mental development of most patients has

been normal. In a Mexican family, hypertrichosis was associated with an osteochondral dysplasia [8].

The status of the apparently recessive form is still more uncertain. Three children of a normal mother were densely hairy at birth and died within a week. Neonatal shaving was of cosmetic benefit in one rare case [6].

Treatment of children with long-pulsed ruby laser can result in a useful reduction of hair, although the benefits tend to wane over 6–12 months. Morley reported a 63% reduction in hair counts at 6 months [9].

Universal hypertrichosis

Not all people with congenital universal hypertrichosis will represent the same entity. If it is possible to make the distinction between lanugo and vellus hair, those with vellus hair may be classified as a form of universal hypertrichosis known as the Ambras syndrome, in which there are dysmorphic features. There is a debate concerning the distinction between Ambras syndrome and other forms of generalized hypertrichosis. Baumeister [10] argues that the uniformity of facial growth and the hypertrichosis of the external ear help set Ambras syndrome apart from other extreme forms of universal hypertrichosis where facial hair is not uniformly distributed and the ear hair growth is less marked. Although those outside the diagnosis of Ambras syndrome may have other associated features, such as gingival hyperplasia [11], there are some areas of overlap with respect to rearrangements on chromosome 8 [12,13].

There are also individuals who might be classified as demonstrating universal hypertrichosis, but with less extreme manifestations and without associated or dysmorphic features. The hair pattern is normal but in any site the hairs are larger and coarser than usual. The eyebrows may be double. Inheritance is determined by an autosomal dominant gene. The features begin to merge into what is considered the normal spectrum.

Congenital generalized hypertrichosis associated with other syndromes

Hurler's syndrome and other mucopolysaccharidoses (see Chapter 12). Hypertrichosis is usually present from early infancy or early childhood on the face, trunk and limbs and may be a conspicuous feature. The eyebrows are often bushy and confluent. In abortive forms, the hair growth may first appear after puberty and be more limited in extent.

Congenital macrogingivae (see Chapter 66) [1]. Exuberant overgrowth of the gingivae as an isolated congenital defect is not uncommon. The association with profuse hypertrichosis of trunk, limbs and lower face has been reported on several occasions. Some patients have markedly acromegaloid features [2] or thyroid disease [3].

Cornelia de Lange syndrome (see Chapter 12). These mildly microcephalic, mentally defective children have a low hairline and profuse overgrowth of the eyebrows. The forehead is covered with long fine hair. Hypertrichosis is usually also conspicuous on the lower back, and may be generalized.

Winchester syndrome. This rare hereditary disorder is characterized by dwarfism, joint destruction and corneal opacities. The skin in many parts of the body becomes thickened, hyperpigmented and hypertrichotic [4,5].

Berardinelli's syndrome [6]. From early life, growth and maturation are accelerated and there is lipodystrophy with muscular hypertrophy. Enlargement of the liver and hyperlipidaemia are other constant features. The skin is coarse and often hypertrichotic.

Trisomy 18 (see Chapter 12). Generalized hypertrichosis of variable degree is present in these patients.

Hypertrichosis has been reported in the rare hereditary globoid leukodystrophy, Krabbe's disease. Most patients die in infancy [4].

Teratogenic syndromes

Fetal alcohol syndrome [7]. Mental and physical retardation affects the infants of many mothers with chronic

alcoholism. The cutaneous changes include hypertrichosis and capillary haemangiomatosis.

Congenital localized hypertrichosis

Naevoid hypertrichosis

The growth of hair abnormal for the site and the age of the patient in its length, shaft diameter and colour may occur as a circumscribed developmental defect, either isolated or associated with other naevoid abnormalities [1], such as duplication of the thumb [2].

Melanocytic naevi (see Chapter 38) may be accompanied by a vigorous growth of coarse hair. The hair may be present from infancy or may develop at puberty. Less often, circumscribed hypertrichosis may occur as the only clinical abnormality. Histologically, the epidermis is acanthotic and the follicles are large, but there is no excess of melanocytes.

Hypertrichosis is a characteristic feature of Becker's naevus (see Chapter 15). The coarse hairs develop in the same body regions as the pigmentation, usually the thoracic or pelvic girdle, but pigmentation and hypertrichosis are not coextensive. It has been suggested that this naevus is a functional one, being androgen dependent; acne may also occur in the same site [3]. It has also rarely been reported in association with limb asymmetry and other ipsilateral anatomical abnormalities [4].

True linear hypertrichotic naevi are rare and hair growth may not be sustained [5].

A tuft of hair in the lumbosacral region, the so-called faun-tail naevus, is often associated with diastematomyelia (Fig. 63.76).

Fig. 63.76 Lumbosacral hypertrichosis ('faun tail'), here associated with diastematomyelia.

Acquired generalized hypertrichosis

Acquired hypertrichosis lanuginosa associated with malignancy

Aetiology. In its most dramatic severe form, this syndrome is rare. It usually accompanies a serious and often fatal illness. Fine downy hair grows over a large area of the body, replacing normal hair and primary and secondary vellus. Approximately 60 cases have been reported and all except two (in which there was no follow-up) were suffering from malignant disease of the gastrointestinal tract, bronchus, breast, gall bladder, uterus, bladder or other organs [1–5]. One patient with lymphatic leukaemia had acquired ichthyosis as well as hypertrichosis, and one had a lymphoma. The hypertrichosis may precede the diagnosis of a neoplasm by several years [6].

Pathology. In one case [7] the lanugo follicles lay almost parallel to the surface, and were apparently derived from mantle follicles.

Clinical features [8–10]. In the milder forms ('malignant down' [7]), hair is confined to the face, where it attracts attention by its appearance on the nose and eyelids and other sites that normally are clinically hairless. As the growth of hair continues, it may ultimately involve the entire body, apart from the palms and soles. Existing terminal hair of scalp, beard and pubes may not be replaced, and may contrast in colour and texture with the very fine white or blonde lanugo. Such hair may grow abundantly, even on the previously bald scalp. The hair may grow exceedingly rapidly, up to 2.5 cm/week, and may be more than 10 cm long.

Non-malignant acquired generalized hypertrichosis

There is a range of non-malignant systemic diseases in which hypertrichosis may develop. Generally, the hair is coarser and less profuse than the lanugo hair associated with systemic malignancy. However, at any single point early in the process, the distinction may not always be obvious.

Endocrine disturbances

Hypothyroidism [1]. A profuse growth of hair on the back and the extensor aspects of the limbs develops in some children with hypothyroidism.

Hyperthyroidism. Coarse hair often grows over the plaques of pretibial myxoedema as it may over other forms of inflammation on the anterior shin.

Possible diencephalic or pituitary mechanisms. Severe generalized hypertrichosis has been reported in young children after encephalitis [2] and after mumps followed by the sudden onset of obesity [3]. A diencephalic disturbance is postulated. Generalized hypertrichosis occurred in a girl after traumatic shock [4] and remitted in 6 months. There are many reports of hypertrichosis after head injuries, especially in children. The hair growth is first noticed 4–12 weeks after the injury (which seems to be of no consistent type) and appears as fine silky hair on the forehead, cheeks, back, arms and legs, and may be asymmetrical. It is sometimes shed after a few months, but may persist.

Other conditions

Malnutrition [5]. Gross malnutrition, which may be primary or occur in coeliac disease or other malabsorption states or in severe infections, may cause profuse generalized hypertrichosis in children.

Anorexia nervosa [6]. An increased growth of fine downy hair on the face, trunk and arms, sometimes of severe degree, has been reported in 20–77% of adult cases [7,8], and is also seen in children [9]. The prevalence of hypertrichosis in bulimia is reported to be half of that in anorexia, and both are associated with approximately 60% prevalence of scalp alopecia [7].

Acrodynia [5]. Some increased growth of hair on the limbs is common. In severe cases, the hypertrichosis is very conspicuous on the face, trunk and limbs. One child was described as monkey-like.

Dermatomyositis [10]. Excessive hair growth has been noted mainly in children and principally on the forearms, legs and temples, but it may be more extensive.

Epidermolysis bullosa. Gross hypertrichosis of the face and limbs has occurred in association with epidermolysis bullosa of the dystrophic type, although this is rare (see Chapter 40).

Hypertrichosis is seen affecting the extensor surface of the arm (Fig. 63.77) in a sporadic or familial form in children, resolving in adolescence. Although associations with

Fig. 63.77 Hypertrichosis of the elbows in a child.

other disorders have been sought, it appears as a largely isolated finding [11].

Iatrogenic hypertrichosis

In iatrogenic hypertrichosis, there is a uniform increased growth of fine hair over extensive areas of the trunk, hands and face, unrelated to androgen-dependent hair growth.

The mode of action of the offending drugs on hair follicles is not known; the same mechanism is not involved in all cases. Cortisone, diphenylhydantoin and penicillamine are all known to affect connective tissue, but in different ways. Psoralens presumably induce hypertrichosis in predisposed subjects by accentuating the tendency of sunlight to induce this temporary change. The stimulation of hair growth on sun-exposed sites by benoxaprofen may have a similar mechanism. Existing vellus hairs increase in length and less so in diameter. The hairs are seldom more than 3 cm in length and are considerably finer than terminal hair.

Diphenylhydantoin induces hypertrichosis after 2–3 months. It affects the extensor aspects of the limbs, then the face and trunk, and clears within a year of cessation of therapy [1].

Diazoxide produces hypertrichosis in all of those treated but it seems to be a cosmetic problem in only half [2,3]; in adults, the anagen phase may last longer [4]. There are no associated changes in the sebaceous glands [2].

Minoxidil commonly induces hypertrichosis [5]. It is apparent after a few weeks' therapy [6].

Hypertrichosis of some degree develops in 60% of patients treated with ciclosporin [7–9]. Keratosis pilaris may precede the appearance of thick pigmented hair on the face, trunk and limbs. Changes in other parts of the pilosebaceous unit occur: keratosis pilaris (21%), sebaceous hyperplasia (10%) and acne (15%) [8].

Benoxaprofen induced a fine downy growth of hair on the face and exposed extremities after only a few weeks [10].

Streptomycin caused hypertrichosis in 22 of 27 children who had received 1 g/day for miliary tuberculous meningitis [11,12].

Prolonged administration of cortisone may induce hypertrichosis, most marked on the forehead, the temples and the sides of the cheeks, but also on the back and the extensor aspects of the limbs.

Penicillamine appears to cause lengthening and coarsening of hair on the trunk and limbs.

Psoralens, used in the treatment of vitiligo and psoriasis, may induce temporary hypertrichosis of light-exposed skin [13].

Latanoprost eye drops used for glaucoma may cause hypertrichosis of eyelashes and increased vellus hair on the eyelid skin [14]. This prostaglandin receptor agonist is the subject of current research in the sphere of hair regrowth products [15].

Acquired localized hypertrichosis

Cutting or shaving the hair influences neither its rate of growth nor the calibre of the hair shaft. However, repeated or long-continued inflammatory changes involving the dermis, whether or not clinically evident scarring is produced, may result in the growth of long and coarse hair at

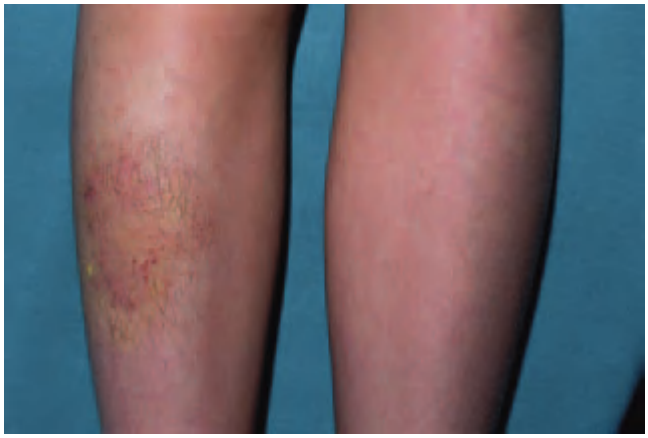

Fig. 63.78 Circumscribed hypertrichosis in an area of steroid-treated lichen simplex.

the site. The cause of the hair growth is usually obvious but may be overlooked when the trauma is occupational; for example, circumscribed patches of hypertrichosis on the left shoulder in people frequently carrying heavy sacks [1] or religious items during holy week in Spain [2]. A patch of hypertrichosis on one forearm has been reported in those with mental retardation who have acquired the habit of chewing the site [3]. Sometimes, hypertrichosis develops at the site of an accidental wound or a vaccination scar [4]. It has developed on the back of the hand and fingers 3 months after the excision of warts [5]. It has been reported also in an irregular pattern on the legs in chronic venous insufficiency [6], around the edges of a burn [7] and at the site of multiple clusters of excoriated insect bites [8]. Hypertrichosis of this type may occur near inflamed joints and has been reported particularly in association with gonococcal arthritis [9] and in the skin overlying chronic osteomyelitis of the tibia [10]. Very exceptionally, inflammatory dermatoses, especially in children, may induce a temporary overgrowth of hair; for example after eczema (Fig. 63.78) [11] and varicella [12]. A linear pattern of hypertrichosis on the leg has been described after recurrent thrombophlebitis that persisted for a year [13]. Hypertrichosis may occur in the indurated skin in melorheostotic scleroderma [14]. The damaged skin in epidermolysis bullosa may also become hypertrichotic [15]. Children have developed itching eczema and local hypertrichosis at the site of injection of diphtheria–tetanus vaccine adsorbed on aluminium chloride [16].

Hypertrichosis of one leg or forearm after a prolonged period of occlusion by plaster of Paris is a phenomenon well known to orthopaedic surgeons. It is seen in association with 55% of cases of reflex sympathetic dystrophy and may be accompanied by Beau's lines [17]. It occurs mainly in children. The hypertrichosis is likely to result from prolongation of anagen. It is not clear whether this is caused by local vascular changes, as occurs with hypertrichosis associated with areas of skin inflammation.

Porphyria (see Chapter 57). Hypertrichosis of exposed skin is a common feature of the very rare erythropoietic porphyria; appearing first on the forehead, it later extends to the cheeks and chin and, to a lesser degree, to other exposed areas. It is also present in many cases of the much more common erythropoietic protoporphyria [18].

In porphyria cutanea tarda, hypertrichosis is an inconstant finding, but may accompany the pigmentation, plethora, blistering and scleroderma-like changes on exposed skin, and is marked in some children with the disease [19]. Darkening of scalp hair in a subject with white hair at the onset of porphyria cutanea tarda has been reported [20], and hypertrichosis has been reported as the presenting complaint in one subject in whom porphyria cutanea tarda was the underlying cause [21]. In black people, hypertrichosis and pigmentation may be present without blistering [22].

The most extreme degree of hypertrichosis is seen in children with hepatic porphyria induced by hexachlorobenzene or other chemicals. Hypertrichosis is frequent in porphyria variegata. The temples, forehead and cheeks are covered with downy hair. There is also increased pigmentation.

Some forms of localized hypertrichosis are caused by the local application or effect of drugs and are discussed in the section on iatrogenic causes of hypertrichosis (see p. 63.96).

Hirsutism

Perception of hirsutism is by definition subjective, and women present with a wide variation in severity [1]. Both the severity of the hirsutism and the degree of its acceptance are dependent on racial, cultural and social factors. Even the criteria for the definition of hirsutism used by physicians vary widely [2–6]. In order to resolve this issue, different groups have evolved different grading schemes for body hair growth. The scheme employed in the study by Ferriman and Gallwey [3], which has become the standard grading system, defined hirsutism purely on quantitative grounds. Hirsutism is graded as numerical scores beyond an upper limit of twice the standard deviation from the mean. Scoring can be on a global basis assessing 8–11 body sites, or it can be based on a single site. Others have examined women complaining of hirsutism and compared them with controls; they have demonstrated that there is a considerable overlap in the grades of hirsutism between the two groups [4,6]. Hair on the face, chest or upper back is a good discriminating factor between hirsute women and controls with similar hair growth scores. In clinical practice, it has often been suggested that 'real' hirsutism is simply that which the woman in question thinks is excessive.

Facial and body hair is less commonly seen on oriental people [7], black people and native Americans than on white people [8]. Even among white people there are differences; hair growth is heavier on those of Mediterranean than those of Nordic ancestry [9]. The pattern of hair growth in hirsutism within different racial groups is identical [3–6]. However, different criteria have made the determination of the comparative incidence and severity within these groups difficult to assess. Only one study of a random population stated how many women considered themselves to be hirsute. McKnight [5] examined 400 unselected students, 60% of whom were Welsh: 9% were considered by both the women and investigator to be hirsute and 4% were considered to be disfigured by their facial hair growth. This investigation also included studies of hair growth in women who were not complaining of hirsutism. It is important to the definition of hirsutism that a sizeable proportion of normal women have some terminal hairs on their face, breasts or lower abdomen.

Lorenzo [10] studied 90 hirsute women and found an increased incidence of hirsutism in their female relatives compared with control populations. McKnight [5] reported that 14% of hirsute Welsh women gave a positive family history. This tendency to familial clustering in hirsutism might be anticipated, as some of the underlying disorders that result in hyperandrogenism have a familial basis. For example, congenital adrenal hyperplasia is autosomal recessive and linked to MHC [11], and a very strong family relationship has been reported in the polycystic ovary syndrome (PCOS) [12].

In hirsutism, one role of society is to determine the threshold level for normality and this is now determined by the media. Women receive a barrage of advertisements for cosmetics that are based on the premise that only a woman with a hairless body can be normal, healthy and attractive. To some extent, men are falling victim to the same media aesthetic, with the advent of laser techniques capable of removing hair from large areas.

There have been few studies on the psychological status of hirsute women. Meyer and Zerssen [13] concluded on the basis of a small sample of patients studied within a psychoanalytic framework that many suffered reactive psychological problems. A small controlled study [14] revealed increased levels of anxiety. In contrast, Callan *et al*. [15] were unable to detect significant differences in comparison with normal.

Another approach to the psychological aspect of hirsutism has been to implicate 'stress' as an aetiological factor. Segre [16] states, in his monograph on the hirsute female, that: 'Lack of peace of mind appears at the core of the problem. We believe it to be both a cause and result of hirsutism.' This view has been endorsed [17]. The onset of hirsutism in four of 10 hirsute women was noted to coincide with a period of emotional stress [18]. Bush and Mahesh [19] reported stress-induced hirsutism in a young woman whose unstressed twin was not hirsute. Objective before and after data on this observation are difficult to identify.

Endocrine factors and hirsutism [1]

Hirsutism attracts a wide range of endocrine investigations, which differ according to the presentation and the specialty background of the clinician. However, the assumption that hirsutism is wholly related to androgens can be challenged on an individual and general level. The increasing awareness of insulin metabolism and hirsutism has highlighted this and, on an individual level, it is very clear that many women with unwanted hair have no endocrinological disturbance.

There have been several attempts to correlate hair growth in women with plasma androgen levels but these reports have yielded conflicting results. Reingold and Rosenfield [2] noted a considerable variability between hair growth scores and free testosterone, but no significant relationship. Ruutiainen *et al.* [3] have calculated a complex formula for multiple plasma androgen levels:

Testosterone/SHBG + androstenedione/100 + dehydroepiandrosterone sulphate/100.

This correlates with hair growth only in women with idiopathic hirsutism. In a further study, the same group [4] found a relationship between hair growth and salivary testosterone levels, but in this study no selection of patients was required. A different ratio has been determined for female baldness [5]:

3α-androstanediol glucuronide/SHBG.

Both equations demonstrate the significance of SHBG as a factor modifying the effects of circulating androgen.

The first sign of androgen production in women occurs 2–3 years before the menarche and is caused by adrenal secretion [6]. The major androgens secreted by the adrenal are androstenedione, dehydroepiandrosterone (DHA) and DHA sulphate (DHAS). Their control during postpubertal life is unknown, but it is thought that androstenedione and DHA may be controlled by adrenocorticotrophic hormone (ACTH), as their serum levels mirror those of cortisol [7,8].

Ovarian androgen production begins under the influence of the pubertal secretion of luteinizing hormone (LH) and takes place in the theca cells. The predominant androgen secreted by the ovaries is androstenedione during the reproductive years, and testosterone after the menopause. Androgen secretion continues throughout the menstrual cycle but peaks at the middle of an ovulatory cycle [9]. Androstenedione secretion is greater from the ovary containing the dominant follicle [10].

In normal women, the majority of testosterone production (50–70%) is derived from peripheral conversion of androstenedione in skin and other extrasplanchnic sites [11–13]. The remaining proportion is secreted directly by the adrenals and ovaries. The relative proportion estimated from each gland varies between reported studies: 5–20% from the ovary and 0–30% from the adrenal [13,14]. DHA is the source of less than 10% of circulating androstenedione and 1% of circulating testosterone [15,16].

Androgen transport proteins

In non-pregnant women, the majority of circulating androgens are bound to a high-affinity β-globulin, SHBG. A further 20–25% is transported loosely bound to albumin, and approximately 1% circulates freely. The free steroid is believed to be active, and the binding protein is therefore of paramount importance. The affinity of the androgens for SHBG is proportional to their biological activity.

The function of SHBG is unknown. It is probable that its main role is to buffer acute changes in unbound androgen levels and to protect androgens from degradation. Burke and Anderson [17] suggested that it also acts as a biological amplifier. High oestrogen levels increase SHBG and therefore reduce available androgen; high androgen levels reduce SHBG and increase available free androgen.

Androgen pathophysiology in hirsutism [1,2]

The growth of normal secondary sexual hair is a response of the hair follicles to androgens. Abnormal degrees of hair growth are therefore often seen in endocrine disorders characterized by hyperandrogenism. However, not all women with greater amounts of secondary sexual hair will have abnormal androgens. Many will lie within the range of normal for their age and ethnic origin—albeit possibly at an extreme of the spectrum. For those objectively classified as hirsute, many will have underlying PCOS. Most of the others will have no detectable hormonal abnormality and are usually classified as having 'idiopathic' hirsutism. This subgroup is gradually becoming smaller as diagnostic techniques for PCOS become more refined.

Polycystic ovary syndrome [3–5]. The perception of PCOS has changed dramatically since it was first described by Stein and Leventhal in 1935 [6]. They defined a syndrome consisting of obesity, amenorrhoea, hirsutism and infertility associated with enlarged polycystic ovaries. This diagnosis is complicated by the fact that it is defined by the appearance of organs that are difficult to visualize. This has led to the use of multiple diagnostic formulations based on clinical and biochemical abnormalities. A more fundamental issue has been raised by modern imaging techniques, which have revealed the presence of polycystic ovaries in normal women [7] or mildly polycystic ovaries in hirsute women with normal menses [8]. The latter finding has led to the inclusion of women who were previously labelled as having idiopathic hirsutism under the diagnosis of PCOS. An estimated one-third of women in the UK have polycystic ovaries—defined as 10 or more follicles/ovary detected on ultrasound [9]. One-third of these women will suffer from PCOS, which is now formally defined in the UK as the presence of polycystic ovaries in the presence of one or more of hirsutism, male pattern baldness, acne, oligomenorrhoea or amenorrhoea, obesity, or raised serum concentrations of testosterone and/or luteinizing hormone [10]. The pattern of these features will depend upon the presenting complaint, be it dermatological, endocrinological or gynaecological. Using ultrasound visualization of polycystic ovaries as the diagnostic criterion in those presenting to a gynaecologist, Conway *et al.* [11] found the following clinical features in a series of 556 patients: hirsutism (61%), acne (24%), alopecia (8%), acanthosis nigricans (2%), obesity (35%), menorrhagia (1%), oligomenorrhoea (45%), amenorrhoea (26%) and infertility (over 29%). However, those patients who present to a dermatologist will almost invariably have acne and/or hirsutism.

Laboratory investigations in PCOS usually reveal an elevated level of LH, often with an increased LH : follicle-stimulating hormone (FSH) ratio, and testosterone, androstenedione and oestradiol levels are also often raised [12], although these tests are neither wholly sensitive nor specific. The demonstration by ultrasound examination of multiple peripheral ovarian cysts around a dense central core will depend on the expertise of the operator [13].

Ideas concerning the pathogenesis of PCOS have been as controversial as the diagnosis, and different authorities embrace beliefs that it is primarily caused by an ovarian abnormality, inappropriate gonodotrophin secretion, a disorder of the adrenal glands or increased peripheral aromatase activity resulting in hyperoestrogenaemia [14]. Whether the increased androgen is of adrenal or ovarian origin remains unclear [15]. However, in addition to the presence of elevated testosterone, commonly in the range of 2.6–4.8 nmol/L [4], 50% or more of patients will have hyperinsulinaemia of varying degrees [16]. This appears to be the case for both the classically obese and the non-obese PCOS patient [17]. Insulin acts to inhibit production of SHBG and stimulates ovarian testosterone production. Both effects amplify androgenic features in PCOS. Excess insulin production is related to the feedback loop of peripheral insulin resistance which increases in PCOS. This is characteristic of type 2 diabetes mellitus, which is a disease more common in PCOS. Consistent with this association, PCOS patients are also at higher risk of dyslipidaemias and coronary artery disease [18]. Altered glucose tolerance, hyperinsulinaemia and hirsutism are all exacerbated by obesity, and the relationship between diabetes and hyperandrogenism in women, or 'diabetes of bearded women', has been recognized for many years [19].

Such features are not invariably part of PCOS. Hyperinsulinaemia may be an autonomous process causing acanthosis nigricans (AN), which acts as a cutaneous marker for the insulin resistance (IR). The combination of AN and IR occurs in 5% of women with hyperandrogenism (HA) [20] and in 7% of women presenting with

hirsutism [21]. Women with HAIR-AN have marked features of virilism: muscular physique, acne, alopecia and hidradenitis suppurativa [21]. The cause of hyperinsulinaemia is not always apparent, but its effects can be partly reversed by troglitazone [22], and its significance is illustrated by the evolution of HAIR-AN syndrome with an insulin-secreting tumour, cured by partial pancreatectomy [23].

Leptin is a protein secreted by adipocytes that increases energy expenditure and decreases appetite [24]. In genetically obese *ob*/*ob* mice, leptin is functionally deficient and the mice develop obesity, insulin resistance, diabetes and infertility. In recent years, there has been much interest in determining the role of this protein in PCOS. High serum levels appear primarily related to obesity rather than the diagnosis of PCOS alone [25] and there is evidence that its fluctuations are synchronized with those of luteinizing hormone [26]. However, although there is some correlation between polymorphisms of the leptin gene and insulin regulation, no mutation specific to PCOS has yet been identified [27]. Although family studies of PCOS suggest an autosomal dominant inheritance, no single gene has been defined. Linkage has been found to the follistatin gene on 5q (follistatin is a peptide with the ability to inhibit release of FSH). PCOS is also strongly associated with polymorphisms of the gene for cytochrome P-450, CYP, on chromosome 15q [28], and a susceptibility gene for PCOS located on chromosome 19p13.3, in the insulin receptor gene region, has been demonstrated [29].

SAHA syndrome. The term SAHA syndrome is used by some to describe the constellation of features that arise with cutaneous virilization [30]. The acronym stands for *s*eborrhoea, *a*cne, *h*irsutism and *a*ndrogenetic alopecia. The term does not suggest any specific aetiology; all the causes of hirsutism need to be considered and investigated where clinically indicated. As with all women with hirsutism, androgen receptor sensitivity can be implicated where there are no apparent endocrine abnormalities. The four features exist together in only 20% of women embraced by this diagnosis, but the concept is favoured by some as a clinical label encompassing the range of problems associated with the diagnosis of hirsutism.

Ovarian tumours. Hirsutism is an almost universal feature in virilizing ovarian tumours; however, functioning tumours that cause virilization represent approximately 1% of ovarian tumours [31]. Amenorrhoea or oligomenorrhoea develop in all premenopausal patients, and alopecia, clitoromegaly, deepening of the voice and a male habitus develop in approximately half of the patients [32,33]. The majority of patients with virilizing ovarian tumours have raised plasma testosterone levels [31,33]. As a rule, these levels exceed double the upper limit of normal and combine with the more extreme and evolving clinical picture to distinguish these women from those with PCOS.

Hirsutism in pregnancy. Hirsutism has only rarely been reported to develop during pregnancy; it may be caused by the development of PCOS or a virilizing tumour. PCOS has been reported to present with virilization during the first or third trimester and may regress postpartum [34]. Androgens freely cross the placenta and virilization of a female fetus may occur [35]. The range of tumours occurring during pregnancy has been reviewed by Novak *et al.* [36].

Congenital adrenal hyperplasia. Cholesterol is metabolized in the adrenal cortex, via a complex pathway, into aldosterone, cortisol, androgens and oestrogens. A defect in cortisol synthesis results in redistribution of the precursors to other pathways, which results in overproduction of the other hormones. In approximately 95% of cases, 21-hydroxylation is impaired [37] so that 17-hydroxyprogesterone (17-OHP) is not converted to 11-deoxycortisol. Because of defective cortisol synthesis, ACTH levels increase, resulting in overproduction and accumulation of cortisol precursors, particularly 17-OHP. This causes excessive production of androgens, resulting in virilization.

Congenital adrenal hyperplasia (CAH) is divided into four categories:

1 Salt-losing, which presents in infancy with dehydration
2 Simple virilizing, in which children present with precocious puberty and short stature
3 Non-classic, attenuated or acquired, and it is this variant that is likely to present to the dermatologist with degrees of hirsutism in otherwise well women
4 Cryptic.

The diagnosis of non-classic late-onset CAH (LO-CAH) cannot be made clinically, and dynamic endocrine investigations are required to differentiate between it, PCOS and idiopathic hirsutism. These women may have only mild degrees of hirsutism, normal physique, normal menses and no metabolic sequelae to the changes in cortisol pathways; however, approximately 80% will have polycystic ovaries [38].

21-Hydroxylase deficiency is the most common defect found with (more than 90%) LO-CAH. As many as 3–6% of women presenting with hirsutism may be affected with this form. It is an allelic variant of the classic childhood salt-wasting type. It is associated with a mutation of the gene controlling cytochrome P-450, CYP 21 on chromosome 6 [39]. Among a group of 56 women with LO-CAH, a range of mutations was found. Some put the woman at risk of progeny with classic salt-losing CAH if the father is heterozygous for the same mutation. This raises the significance of detailed analysis of this pathway in such women and the genotypic basis in the woman and male partner [40]. 3β- and 11β-hydroxylase deficiencies are less

common forms of CAH and are consequently less frequently found in hirsute women [41]. This is not a diagnosis made in men, although we must presume that they are equally affected and that it is not of any metabolic significance. Where men are heterozygous for mutations relevant to the salt-losing variant, the genotype of the mother will be relevant.

Acquired adrenocortical disease. Adrenal carcinomas usually present with abdominal swelling or pain; however, 10% of both adenomas and carcinomas may present with isolated virilization [42]. The combination of virilization and Cushing's syndrome strongly suggests the presence of a carcinoma. The testosterone level is usually markedly raised in the latter.

Patients with Cushing's syndrome are said to have both hypertrichosis, a generalized diffuse growth of fine hair resulting from hypercortisolaemia, and androgen-induced coarse hair in the usual male pattern [43].

Gonadal dysgenesis. Moltz *et al*. [44] described six patients with 46XY gonadal dysgenesis. All had unambiguously female genitalia but male skeletal characteristics: wide-span broad shoulders and chest; two were hirsute, two had temporal recession and three had deep voices. Rosen *et al*. [45] reported a further 30 patients with gonadal dysgenesis, of whom three (with Y chromosome material) presented with slowly progressive hirsutism and secondary amenorrhoea.

Hyperprolactinaemia. The exact relationship between prolactin and hirsutism is not clear. The incidence of hirsutism in the amenorrhoea–galactorrhoea syndrome has been reported as 22–60% [46]. This may be caused by a direct effect of prolactin on adrenal androgen production or to PCOS, with which it is frequently associated; prolactin has also been reported to attenuate cutaneous 5α-reductase activity both *in vivo* and *in vitro* [47].

Idiopathic hirsutism (Fig. 63.79). Idiopathic hirsutism is the diagnostic label given to those hirsute women in whom no overt underlying endocrine disorder can be detected. There are a number of subtle dynamic alterations in the androgen metabolism of some hirsute women compared with non-hirsute women: daily testosterone production can be increased 3.5–5-fold; the majority of androgen is secreted as testosterone (hirsute 75%, versus normal less than 40%) rather than as androstenedione [48]; increased androgens in hirsute women are associated with lower levels of SHBG, which binds less testosterone and increases its free level [49]. More free testosterone is therefore available for peripheral metabolism and clearance; these two factors disguise the increased rates of testosterone production.

Normal values for total testosterone are found in 25–60% of hirsute women and in 80% of those with regular menstrual cycles [50]. This may be a result of the effect of SHBG or to the wide fluctuations in plasma testosterone seen in hirsute women, or it may reflect the role of androgen receptor sensitivity. The finding of a small elevation of testosterone is not a holy grail, and the tendency to repeat the test many times in the setting of hirsutism is only warranted in progressive or extreme cases where a neoplasm is suspected. Although many women classified as having idiopathic hirsutism may have subtle PCOS, others may be completely normal.

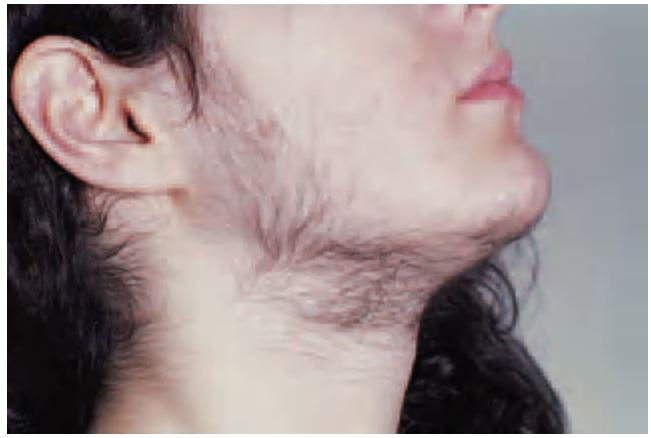

Fig. 63.79 Facial hirsutism: in this case not associated with any systemic disease or detectable biochemical endocrine abnormality.

Diagnostic approach to the hirsute woman

Most hirsute women have noted excess hair since puberty; some will give a shorter history but it will be in the order of years. It is important to obtain information from the history regarding patterns of hirsutism, alopecia, other features of cutaneous virilism and evidence for PCOS, in particular irregular menses or infertility. A family history of childhood dehydration or precocious puberty in a brother might be a feature of CAH. A drug history may point to an ingested source of androgens (e.g. glucocorticoid or anabolic steroids) and those used to enhance athletic performance. The progestogenic components of many contraceptive preparations are relatively androgenic and this is often cited as a cause of hirsutism, but it has not been a major factor in our experience.

The cutaneous examination should include the pattern and severity of hair growth and the associated presence of acne, androgenetic alopecia and acanthosis nigricans. Systemic virilization is very rare, and likely to indicate significant pathology such as a testosterone-secreting tumour. Features include a deepening voice, increased muscle bulk and loss of the smooth skin contours, hypertension, striae distensae and clitoromegaly. Clitoromegaly is probably the most important physical sign of systemic virilization. These changes are set apart from cutaneous virilism, and if evolving over a short period (e.g. 12–18 months) they warrant detailed investigation.

The extent to which it is necessary for hirsute women without suspicious signs or history to be investigated is debatable. The main reason cited for investigation of most hirsute women is the inability to differentiate between idiopathic hirsutism, PCOS and LO-CAH on clinical grounds. Not all dermatologists consider it necessary to pursue a diagnosis of PCOS and its ramifications in a woman with normal menses who is not attempting to conceive. Equally, the value of pursuing a diagnosis of LO-CAH is doubtful when there is no clinical metabolic problem, and the therapeutic tools available at present are

too clumsy to warrant such diagnostic sensitivity [1,2]. However, it remains an overriding priority to exclude a virilizing tumour if this is suggested by the history and examination.

If it is necessary to undertake investigations, these should be directed by the presenting complaint and diagnostic objectives. In addition to clinical assessment, abnormal menses represent a trigger for investigation. The best screening test for an androgen-secreting tumour is plasma total testosterone. Mild elevations will usually occur in individuals with PCOS, and those in whom the level is more than twice the upper limit of normal require further investigation to exclude a neoplasm. However, if confirmation of a diagnosis of PCOS is required, estimation of plasma LH and FSH and pelvic ultrasound are indicated. In addition, the metabolic aspects of PCOS warrant a fasting glucose and lipid profile. Some authorities would suggest a full glucose tolerance test in those with established PCOS.

Prolactin levels, and assessment of adrenal and thyroid status would normally be undertaken if there were clinical clues suggesting abnormality of these systems. Pursuance of the diagnosis of LO-CAH is controversial. There is no record of women with this disorder being at risk of any significant salt-losing process. However, there may be reduced fertility [3] and if the woman is heterozygous for a mutation that predisposes to the salt-losing variant, her progeny may be at risk if their father is heterozygous for the same mutation [4]. This last point raises the question of whether the diagnosis should be sought more rigorously. Although it may not alter clinical management of the hirsutism, it may be of significance to the reproductive plans of the woman. At present, defining whether the woman is heterozygous for a mutation of the CYP 21 gene that can lead to the salt-losing variant of CAH in offspring is limited to gene analysis. The phenotype and endocrine investigations are not sufficiently sensitive to distinguish between heterozygosity for a range of CAH mutations of differing significance. The standard screening test for such mutations is estimation of the basal plasma 17-hydroxyprogesterone level.

Treatment [1–4]

For most women, medical consultation concerning excess hair is on two levels. First it is necessary to determine whether the pattern is pathological and related to a definable aetiology. For some, weight loss will contribute to a reduction of insulin resistance, hyperinsulinaemia and hyperandrogenism. Often, medical intervention is not needed. However, the next level concerns whether there is a medical avenue for providing help, even with the acknowledgement that treatment is not for a disease, but in order to achieve a cosmetic norm.

Cosmetic measures

Where a woman has failed to make full use of physical methods of hair removal it is helpful if the dermatologist is familiar with what is available [4] or can direct her to a reliable beautician or other expert in cosmetic care for advice. The easiest measure is to bleach the hair with hydrogen peroxide. This produces a yellow hue because of the native colour of keratin. Hair plucking is widely performed, but the act of plucking not only removes the hair shaft but also stimulates the root into the anagen phase and there is only a brief delay while the shaft grows through the epidermis. Shaving avoids this problem by removing all the hairs but is followed by growth only of the hairs that were previously in anagen.

Depilatory creams contain thioglycolates that dissolve sulphur bonds within keratin molecules, making the hair gelatinous. They are irritant and require care in terms of strength of preparation and duration of exposure. It is often the case that the patient has used a depilatory cream once and given up because she became sore or it did not work. Results can be improved by employing the cream much in the same way that one might use dithranol when treating psoriasis, using small test areas to gain experience.

Waxing is performed by the application of a sheet of soft wax to the skin and, as soon as it has hardened with the hair shafts embedded, it is abruptly peeled off, removing all the shafts. This is a painful method and is often complicated by folliculitis. Certain natural sugars, long used in parts of the Middle East, are becoming popular in place of waxes as they appear to depilate as effectively, but with less trauma. Both methods require the hair to be long enough for the wax, resin or sugar to gain sufficient purchase on the hair shaft.

Electrolysis is a more permanent method of hair removal [4]. A fine electrical wire is introduced down the hair shaft to the papilla, which is destroyed by an electrical current. Laser thermolytic hair removal is now widely used. Although its long-term efficacy is not yet known [5], laser-assisted hair removal has been in use for sufficient time to allow a reasonable estimate of its efficacy and safety. Most practitioners will select patients for dark hair and light skin. This maximizes the absorption of laser energy by the hair and minimizes absorption by the skin. Nevertheless, it is still possible for soreness and crusting to occur following treatment. In darker skin this can be

associated with post-inflammatory pigmentary changes. Treatments are usually administered as part of a course of at least three visits separated by several weeks. This reflects the biology of the follicle, which is most responsive to abalation when in anagen. The gap between treatments allows those hairs initially in telogen to move into anagen. Sommer *et al.* [6] compared the hair counts 36 weeks after four treatments to the face with a normal pulse ruby laser with the effects of a single pulse. Hair counts were reduced by 61% and 41%, respectively. As well as laser techniques, there are alternatives to the use of lasers. Broad-band intense pulsed light represents a cheaper technology with less restriction on the licensing of those who use it. There are no good comparative studies of laser and pulsed light, but results from open trials of the latter suggest it is useful [7]. In a study of pulsed light therapy of hirsutism, 76% hair clearance was reported following a mean of 3.7 treatments [8].

Drug therapy [9]

Because hirsutism is a condition mediated by androgens, attempts have been made to reduce the growth of hair with antiandrogens. The complete spectrum of therapeutic agents evaluated in the treatment of hirsutism is described in the following text. However, it is our practice to use cyproterone acetate in combination with ethinylestradiol as first-line therapy for women whose hirsutism is so severe as to warrant systemic therapy. Spironolactone is the next alternative [1]. The oral contraceptive can be useful to avoid conception during therapy with antiandrogens. At the same time, it will increase the amount of SHBG and reduce free androgen. A progestogen in the oral contraceptive, such as norethisterone, is best avoided in favour of one of the synthetic progestogens to avoid any potential intrinsic androgenic effect.

It is important that hirsute women are carefully assessed prior to initiating therapy for the following reasons. First, the effect on hair growth takes several months to become apparent and only partial improvement may be expected. Secondly, antiandrogens feminize a male fetus and it is essential that the women do not become pregnant during therapy. Thirdly, these drugs only have a suppressive, and not curative, effect that wears off a few months after cessation of therapy [10]. Consequently, it may be necessary to take therapy indefinitely if improvement occurs. Finally, the long-term safety of these drugs is unknown and tumours in laboratory animals have been reported with several of the following agents.

Cyproterone acetate [11,12]. Cyproterone acetate (CPA) is a synthetic progestogen that acts as both an antiandrogen and an inhibitor of gonadotrophin secretion. It reduces androgen production, increases the metabolic clearance of testosterone and binds to the androgen receptor; in addition, long-term therapy is associated with a reduction in the activity of cutaneous 5α-reductase. Although CPA is a potent progestogen it does not reliably inhibit ovulation. It is usually administered with cyclical oestrogens in order to maintain regular menstruation and to prevent conception in view of the risk of feminizing a male fetus.

Several regimens have been advocated. Low-dose therapy (Dianette; Schering AG) is an oral contraceptive containing 35 μg ethinylestradiol and 2 mg CPA, taken daily for 21 in every 28 days. However, many of the dose-ranging and efficacy studies have been performed using the preparation that contained 50 μg ethinylestradiol; this may be relevant, as only the higher dose of oestrogen increases SHBG. Current dosage recommendations for CPA usually advise that 50 mg or 100 mg CPA should be administered for 10 days/cycle (e.g. day 1–10 or 5–15). However, there have now been many dose-ranging studies that suggest that there is no dose effect. Objective studies comparing Dianette with and without extra CPA found no difference in the reduction of overall hirsutism grades, although the rate of onset of benefit was faster with the additional cyproterone [13].

Side effects of CPA include weight gain, fatigue, loss of libido, breast tenderness, nausea, headaches and depression. All these side effects are more frequent with higher dosage. As with all medication for a cosmetic problem, safety can be a concern for those needing long-term treatment. Contraindications to its use are the same as for the contraceptive pill and include cigarette smoking, age, obesity and hypertension. Venous thromboembolism is the adverse effect of greatest medical significance. A case–controlled study indicated that risk of this was four times greater in women taking an oral contraceptive containing CPA as the progestogen in comparison with those containing levonorgestrel [14].

One retrospective study of 188 women taking CPA 50–100 mg/day, described side effects in 23%. Nine per cent of the total group stopped therapy on account of these effects, but it is difficult to discern whether the problems were a result of the CPA or ethinylestradiol that many also took. Most of the problems were related to mood, weight or menstrual disturbance. Within the group, 24 had been treated for 5 years or more, nine for 10 years or more and two for 15 years [15].

Spironolactone [16,17]. Spironolactone is a popular and relatively safe treatment for hirsutism. Formal proof of its efficacy is not to the highest standards, although a Cochrane review concluded that it was of some value [18]. The discovery of its benefit in hirsutism was serendipitous—a 19-year-old hirsute woman with PCOS was treated with spironolactone (200 mg/day) for concurrent hypertension and she noted after 3 months the need to shave less frequently.

Spironolactone has several antiandrogenic pharmacological properties. It reduces the bioavailability of testosterone by interfering with its production and increases its

metabolic clearance. It binds to the androgen receptor and, like CPA, long-term therapy is associated with a reduction in cutaneous 5α-reductase activity [19]. Different regimens of spironolactone have been studied, varying between 50 and 200 mg taken either daily or cyclically (daily for 3 weeks in every 4). Within this dosage range, the one chosen will depend on the severity of the hirsutism. A 3 out of 4 week cycle will result in a withdrawal bleed in the fourth week which is similar to that seen with the oral contraceptive. However, spironolactone cannot be relied on as a contraceptive and care must be taken to avoid conception while on the drug.

Spritzer *et al.* [20] compared the relative benefits of a combination of CPA 50 mg/day and ethinylestradiol 35 µg/day with spironolactone 200 mg/day over 12 months. Both groups were stratified for those with PCOS and idiopathic hirsutism. In both groups, those with idiopathic hirsutism did equally well. However, those with PCOS did significantly better with the CPA/ethinylestradiol combination. Where spironolactone is used in combination with ethinylestradiol 35 µg and CPA 2 mg, there may be some modest advantage [21].

When compared with finasteride 5 mg, spironolactone 100 mg produced a significantly greater improvement during a 9-month trial [22]. Spironolactone may feminize a male fetus. Long-term high-dose spironolactone has been shown to produce tumours in rodents. Some clinicians feel that this finding makes long-term use inappropriate in healthy young patients with hirsutism.

5α-Reductase inhibitors. 5α-Reductase inhibitors are a potential systemic therapy for hirsutism. Finasteride inhibits the type 2 isoenzyme of 5α-reductase and has been assessed in small placebo-controlled trials, with some benefit after 6 months' therapy. In open trials, maximal benefit was seen in idiopathic hirsutism after 12 months [23]. Controlled comparative trials suggest that flutamide [24] and spironolactone [22] are more effective. Topical finasteride has been trialled with mixed results [25]. Other similar systemic and topical 5α-reductase inhibitors are likely to be available in the near future. This group of drugs feminizes a male fetus, which is a drawback in the therapy of women of child-bearing potential and has precluded a drug licence for the treatment of hirsutism.

Corticosteroids. Corticosteroids have a logical place in the treatment of LO-CAH. However, any benefits that they may have in this setting need to be balanced against their well-described side effects. Although their use is justified on the basis of physiological replacement, it is likely that pharmacological regimens will far exceed this, with consequent problems. Spritzer *et al.* [26] demonstrated the superiority of ethinylestradiol 35 µg with CPA 2 mg over hydrocortisone in treatment of hirsutism associated with LO-CAH [26].

Metformin. Metformin is a biguanide originally used in the treatment of type 2 diabetes mellitus. It has found a place in the treatment of hirsutism associated with hyperinsulinaemia and insulin resistance. In this setting, it can reduce levels of insulin, increase insulin sensitivity and, particularly when associated with a low-calorie diet, result in weight loss [27]. In many, this constellation of problems will be part of PCOS, and metformin has also been shown to assist in normalization of menstruation and improvement in lipid profiles [28]. These broader metabolic effects can make it a useful therapy where hirsutism is not the only problem, although its use in PCOS requires further assessment [29,30].

Eflornithine. Eflornithine was originally used orally in the treatment of hyperactivity in childhood. It is an inhibitor of ornithine decarboxylase and is able to delay the initiation of anagen [31]. Consequently, it can help to keep hair in telogen. Limited studies show some reduction in hirsutism when used as a cream on women's faces [32].

Medroxyprogesterone acetate. Medroxyprogesterone acetate (MPA) is a synthetic progestogen that was introduced as an anovulatory agent because of its ability to block gonadotrophin secretion. It lowers androgen levels by reducing the production of testosterone and increasing its metabolic clearance.

A comparison of topical (0.2% ointment) with systemic therapy, either by intramuscular injection of MPA (150 mg every 6 weeks) or subcutaneous injection (100 mg every 6 weeks), was said to give a beneficial response in most patients [33]. MPA given alone may result in menorrhagia.

Desogestrel. This is the progestogen used in the Marvelon® contraceptive pill (Organon Ltd), which contains 30 µg ethinylestradiol and 150 mg desogestrel. All the studies undertaken have reported subjective and/or objective reductions in hair growth of 20–25% after 6–9 months' therapy, with a high degree of patient satisfaction [34].

Ketoconazole. This is a potent inhibitor of adrenal and ovarian steroid synthesis. There have been only isolated reports of its use in hirsutism but these have demonstrated a marked reduction in hair growth after 6 months [35]. However, this treatment cannot be recommended in view of the risks of hepatic toxicity during long-term therapy.

Flutamide [36]. This acts as a pure antiandrogen and works by binding to androgen receptors. However, it has no antigonadotrophic effect, and the result of binding to central androgen receptors is that it prevents the negative feedback effect of testosterone, and consequently androgen levels rise. There has been a single study in hirsutism in which flutamide (250 mg twice daily) was administered

with an oral contraceptive for 7 months; 12 out of 13 patients demonstrated a subjective reduction in hair growth and improvement in acne [37]. Flutamide is potentially hepatotoxic and requires close monitoring to avoid liver complications. This has limited its use.

Gonadotrophin-releasing hormone agonists. Gonadotrophin-releasing hormone (GnRH) agonists inhibit LH production and this results in profound suppression of ovarian androgen production. These agents are presently under investigation, but preliminary studies suggest that they effectively reduce hair growth and acne in women with PCOS [38] and may be superior to finasteride [39]. Drawbacks are cost and the need for monthly injections.

Cimetidine. Cimetidine is an H_2 receptor blocker, and weak antiandrogen as indicated by androgen receptor-binding studies. A study of patients with idiopathic hirsutism demonstrated a marked reduction in hair growth using hair weight, whereas no such effect was seen in controls given only a placebo [40].

Bromocriptine. This is a dopamine agonist, and long-term therapy with bromocriptine regulates menstrual cycle length, but 12 months' therapy produced no measurable effect on linear hair growth in women with polycystic ovaries [41].

Hair pigmentation [1–3]

In humans, hair pigmentation depends entirely on the presence of melanin from melanocytes. The perceived colour will depend also on physical phenomena. The range of colours produced by melanins is limited to shades of grey, yellow, brown, red and black, depending on the amount and ratio of eumelanin (black) and phaeomelanin (red).

It is important to remember that much of the research on melanogenesis and its cellular control is in relation to epidermis outside the follicle. Many aspects of hair bulb melanogenesis are likely to be the same. Hair melanin is formed by melanocytes situated in the hair bulb epithelium around the upper half of the dermal papilla amongst cells destined to form the hair cortex. Ultrastructurally, hair bulb melanocytes appear more melanogenic than epidermal melanocytes and their population density is much greater than in the epidermis (approximately one melanocyte to four basal keratinocytes in the upper hair bulb compared with a ratio of 1 : 25 in the basal layer of the epidermis [4]). Melanocytes are also present in the basal layer of the infundibulum and, in small numbers, in the outer root sheath of the lower part of the follicle. These latter cells are DOPA-negative and non-melanized and are thought to form a melanocyte reservoir in the skin. Under certain circumstances (e.g. during repigmentation of vitiligo), outer root sheath melanocytes proliferate and migrate to the epidermis [5]. In humans, hair bulb melanocytes donate pigment almost exclusively to cells undergoing early differentiation to form the hair cortex (Fig. 63.80). Therefore there is a close spatial and functional relationship between hair bulb melanocytes and the cells that act as pigment receptors (cortical keratinocytes).

Melanogenic activity in the hair follicle is closely linked to the hair cycle. In the telogen follicle, non-melanogenic melanocytes are found in the basal layer of the outer root sheath and in the secondary germ region [6]. These cells are assumed to be the precursors of active melanocytes during the next anagen phase and either migrate or are carried into the hair bulb in early anagen development. They congregate in the upper part of the anagen hair bulb amongst cells destined to form the hair cortex. Melanogenesis begins well after epithelial proliferation has started and coincides with the onset of morphological evidence of cortical differentiation. Tyrosinase activity becomes apparent in Anagen 3 and pigment transfer to cortical epithelium begins in the Anagen 4 stage of development [7–9]. In pigmented hair follicles, intense melanogenesis continues throughout the remainder of anagen (Anagen 5 and 6) and then ceases with the onset of catagen. The close anatomical and functional association of hair bulb melanocytes with cells to which pigment is donated, cells destined to form the hair cortex, suggests that interaction between these two cell types has a key role in regulating pigmentary activity. The fate of hair bulb melanocytes during catagen is uncertain. Non-melanizing melanocytes have been observed in the regressing epithelial column in human catagen follicles [10] but apoptotic deletion of follicular melanocytes has also been described during this stage of the hair cycle [11].

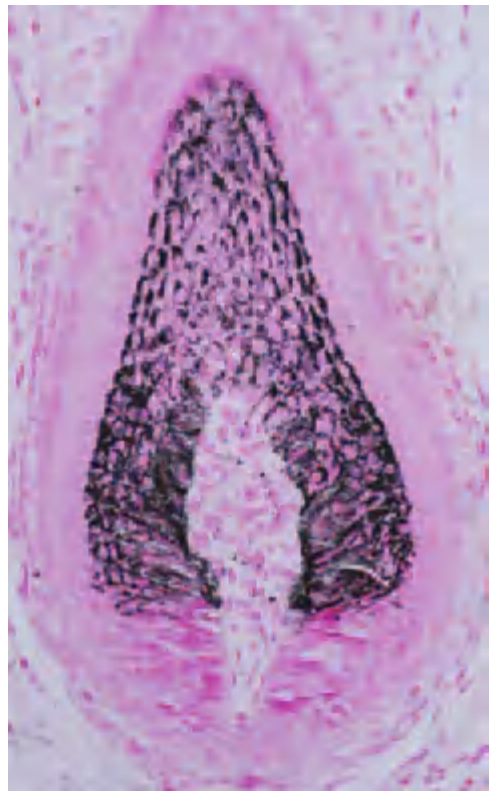

Fig. 63.80 Human anagen follicle showing pigment donation to the hair cortex. There is pigment incontinence in the dermal papilla (Masson–Fontana stain).

Melanogenesis [1–3]

Functional melanocytes respond to the peptide hormones α-melanocyte stimulating hormone (α-MSH) or ACTH through the MC1R receptor to stimulate melanin production. This receptor is a transmembrane G-protein. When bound to melanocortin peptides, intracellular cyclic adenosine monophosphate (AMP) rises, resulting in tyrosinase gene expression, melanocyte proliferation and increased dendricity. There may also be switching of melanin type. Loss of function mutations in the *MC1R* gene are associated with a switch from eumelanin (dark) to phaeomelanin (red) production [4,5]. The phaeomelanosome, containing the key enzyme of the tyrosinase pathway, produces light red-yellowish melanin, whereas the eumelanosome produces darker melanins via induction of additional TYRP1, TYRP2, SILV enzymes, and the P-protein. Intramelanosomal pH, governed by the P-protein, may act as a critical determinant of tyrosinase enzyme activity. There is significant genetic variation in the genes from which these proteins arise. Over 30 variant alleles have been identified in the *MC1R* gene alone. Functional correlation of *MC1R* alleles with skin and hair colour provides evidence that this receptor molecule is a principal component underlying normal human pigment variation.

In black hair follicles, deposition of melanin within melanosomes continues until the whole unit is uniformly dense. Lighter coloured hair shows less melanin deposition, and blonde hair follicles show melanosomes with a moth-eaten appearance. Red and blonde hair follicles have spherical melanosomes; those in brown and black hair are ellipsoidal.

Pigment is incorporated into hair cortex. No pigment is donated to presumptive cuticular and internal root sheath cells, although pigment granules have been detected in the cuticle of human nostril hair and in the coats of many animals [6]. Melanocytes are functional only during the anagen phase of the hair cycle. They were formerly thought to disappear during telogen but it is now known that they remain at the surface of the papilla in a shrunken adendritic form. Jimbow *et al*. [7] found melanocytes with mature melanosomes in resting (telogen) feather follicles. It is possible that the full complement of melanocytes present during successive anagen phases is the result not only of reactivation of 'dormant' cells, but also of new cells resulting from melanocyte replication [8].

Hair colour resulting from physical phenomena

The whiteness of hair seen when melanin is absent is an optical effect resulting from reflection and refraction of incident light from various interfaces at which zones of different refractive index meet. Thus, in general, non-pigmented hair with a broad medulla appears paler than non-medullated hair. Normal 'weathering' of hair along its length may lead to the terminal part appearing lighter than the rest as a result of a similar mechanism—the cortex and cuticle become disrupted and form numerous interfaces from internal reflection and refraction of light. This also applies in trichorrhexis nodosa (excessive 'weathering'), in which patients often note a lightening in colour of the brittle hair, and in the white bands of pili annulati. Because these optical lightening effects are caused by reflection and refraction of incident light, when such hairs are viewed by transmitted light microscopy they appear dark. Newly formed unpigmented hair with no medulla appears yellowish rather than white. This is probably the intrinsic colour of dense keratin as orientated in hair fibres. Findlay [9] showed that the perceived colour is affected by the physical characteristics of the hair shaft and may bear little relationship to the true chromaticity of the shaft.

Hair fibre tryptophan content increases with age and within age groups, and is higher in dark hair than fair hair. The exception is with white hair and the significance of these findings is uncertain [10].

Lanugo hair present *in utero* is unpigmented. Vellus hair is also typically unpigmented but, in men in particular, some vellus fibres may pigment slightly after puberty. Hair colour varies according to body site in most people. Eyelashes are usually the darkest. Scalp hair is generally lighter than genital hair, which often has a reddish tint even in subjects having essentially brown hair. Grobbelaar [11] showed that hair on the lower and lateral scrotal surfaces is lighter than on the pubes. Apart from individuals with red scalp hair, a red tint to axillary hair is most common in brown-haired individuals.

Hairs on exposed parts may be bleached by sunlight. Very dark hair first lightens to a brownish red colour but rarely becomes blonde even after strong sunlight exposure; brown hair, however, may be bleached white.

Variation in hair colour

Genetic and racial aspects [1–3]

Ethnic differences in hair colour are very conspicuous, as are the differences in hair morphology, although colour and hair form are inherited separately [4]. Dark hair predominates in the world. Among white people there is wide variation in colour within geographical regions. Blonde hair is most frequent in northern Europe and black hair in southern and eastern Europe; foci of blondeness are to be found even in North Africa, the Middle East and in some Australoids. Congoid, Capoid, Mongoloid and Australoid hair is mainly black.

Red hair (rutilism)

This has attracted more attention than other colours because it is less common and because it is so distinctive. The pigment is phaeomelanin, not eumelanin. In Italy, and in the UK excluding East Anglia, the distribution of red hair is similar to that of blood group O [5]. The incidence of red hair varies from 0.3% in northern Germany to as high as 11% in parts of Scotland. Like hair of many other colours, red hair often darkens with age from red through brown to sandy or auburn in the adult. The skin of redheads is generally pale, burns easily in sunlight and pigments very little even after prolonged and frequent sun exposure. The loss of eumelanin production is caused by a range of mutations in the *MCR1* gene that alter the function of the receptor and consequently melanin synthesis.

Heterochromia

This implies the growth of hair of two distinct colours in the same individual. A colour difference between scalp and moustache is not uncommon. In fair-haired individuals, pubic and axillary hair, eyebrows and eyelashes are much darker than scalp hair. In humans, eyelashes are generally the most darkly pigmented hairs.

In general, scalp hair darkens with age. Rarely, a circumscribed patch of hair occurs of different colour. This generally has a genetic basis, although the type of inheritance is not known in humans. Patchy differences of hair colour are of six types.

1 Tufts of very dark hair growing from a melanocytic naevus
2 Hereditary, usually autosomal dominant heterochromia (e.g. tufts of red hair at the temples in a black-haired subject or a single black patch in a blonde)
3 Perhaps as a result of somatic mosaicism; partial asymmetry of hair and eye colour may occur sporadically
4 The white forelock of piebaldism
5 The 'flag' sign in kwashiorkor
6 Fair fine woolly hair growing from a scalp woolly hair naevus.

Greying of hair (canities)

Greying of hair is usually a manifestation of the ageing process and results from a progressive reduction in melanocyte function [6]. The larger medullary spaces of older people may contribute to the process.

There is a gradual dilution of pigment in greying hairs: the full range of colour from normal to white can be seen both along individual hairs and from hair to hair. Loss of hair-shaft colour is associated with decrease and eventual cessation of tyrosinase activity in the lower bulb [7]. In white hairs, melanocytes are infrequent or absent [8] or possibly dormant. It has been suggested that autoimmunity plays a part in the pathogenesis of greying; grey hair certainly has an association with the autoimmune disease pernicious anaemia (see below) [9,10].

The age of onset of canities is primarily dependent on the genotype of the individual although acquired factors may play a part. The visual impression of greyness is more obvious (seen earlier) in the fair-haired. In white races, white hair first appears at the age of 34.2 ± 9.6 years, and by the age of 50 years 50% of the population have at least 50% grey hairs [14]. The onset in black people is 43.9 ± 10.3 years, and in Japanese between 30 and 34 years in men and between 35 and 39 years in women. The beard and moustache areas commonly become grey before scalp or body hair. On the scalp, the temples usually show greying first, followed by a wave of greyness spreading to the crown and later to the occipital area.

Rapid onset, allegedly 'overnight', greying of the hair has excited the literary, medical and anthropological worlds for centuries [11,12]. Many reports have been overdramatized but it certainly occurs. Historical examples often quoted include Sir Thomas More and Marie Antoinette whose hair became grey over the night preceding their executions. The probable mechanism for rapid greying is the selective shedding of pigmented hairs in diffuse alopecia areata, the non-pigmented hairs being retained (Figs 63.81 & 63.82).

Despite occasional reports to the contrary, in general, greying of hair is progressive and permanent, although melanogenesis during anagen may be intermittent for a time before finally stopping. Most of the reports of the

Fig. 63.81 Slight greying of hair. (Courtesy of Dr D. Fenton, St Thomas' Hospital, London, UK.)

Fig. 63.82 Rapid greying of the hair. Same patient as Fig. 63.81 taken 1 week later. Caused by alopecia areata. (Courtesy of Dr D. Fenton, St Thomas' Hospital, London, UK.)

Fig. 63.83 Premature greying of hair, which commenced at 19 years of age in this individual.

return of normal hair colour from grey are examples of a pigmented regrowth following alopecia areata, which eventually repigments in many cases. The reported repigmentation of grey hair in association with Addisonian hypoadrenalism may result from a mechanism similar to that in alopecia areata or vitiligo, in view of the known association between these diseases [13–16]. Darkening of grey hair may occur following large doses of *p*-aminobenzoic acid [17].

Premature greying (Fig. 63.83)

Premature greying of hair has been defined as onset of greying before 20 years of age in white people and 30 years of age in black people. It probably has a genetic basis and occasionally occurs as an isolated autosomal dominant condition. The association between premature greying and certain organ-specific autoimmune diseases is well documented. The relationship is probably not one of common pathogenesis but on the basis of genetic linkage. It is often stated that premature greying may be an early sign of pernicious anaemia, hyperthyroidism and, less commonly, hypothyroidism, and all autoimmune diseases that have a genetic predisposition. In a controlled study of the integumentary associations of pernicious anaemia, 11% had premature greying [9]. In Book's syndrome, an autosomal dominant trait, premature greying is associated with premolar hypodontia and palmoplantar hyperhidrosis [18]. In the early stages, it may be partially reversible [19].

The premature ageing syndromes, progeria and Werner's syndrome (pangeria), may have very early greying as a prominent feature. It does not occur in metageria or total lipodystrophy [17]. In progeria it is associated with marked loss of scalp hair as early as 2 years of age.

In dystrophia myotonica the onset of grey hair may precede the myotonia and muscle wasting.

Premature canities is an inconstant feature of the Rothmund–Thomson syndrome; when present, it typically commences in adolescence.

One-third of patients with chromosome 5p syndrome (cri du chat syndrome) have prematurely grey hair [20].

Poliosis

Poliosis is defined as the presence of a localized patch of white hair resulting from the absence or deficiency of melanin in a group of neighbouring follicles. Essentially, the changes in melanogenesis are the same in the hair follicle as in the affected epidermis. Pigment absence can be congenital or acquired. In many cases of the former it is brought about by physically or functionally abnormal melanocytes from birth, or abnormal migration during embryogenesis. Such migratory defects may be restricted to the skin, but there can be associated abnormalities in other organs such as the ear or eye, where melanocytes or related neural crest cells have an important role.

Acquired forms of poliosis have more varied causes, although some of the most significant relate to autoimmunity where the melanocyte has attracted autoimmune attack.

Hereditary defects [21]

Piebaldism (white spotting or partial albinism) is an autosomal dominant abnormality with patches of skin totally devoid of pigment, which remain unchanged throughout life. The borders of unpigmented areas are hyperpigmented. Heterochromia iridis occurs in some. Most commonly, a frontal white patch occurs—the white forelock—which may be the only sign. Melanocytes are decreased in number, but are morphologically abnormal and contain normal non-melanized premelanosomes, and also premelanosomes and melanosomes of abnormal appearance [22]. Piebaldism can be caused by mutation in the *KIT* proto-oncogene [23] mapping to chromosome 4q12. In one kindred with a severe and progressive phenotype, the *KIT* mutation affected function of tyrosine kinase [24].

Similar pathological changes are seen in Tietz's syndrome of generalized 'white spot' loss of skin and hair pigment, complete deaf mutism and eyebrow hypoplasia [25]. This disease can be caused by a mutation in the microphthalmia-associated transcription factor gene, and mutations in other regions of this gene have been found to produce Waardenburg's syndrome (WS) type 2 [26].

WS [27] is a heterogeneous condition, usually divided into four types, with absence of melanocytes from cochlear, skin, eye, hair and other structures. Features are present at birth. Type 1 WS is characterized by dystopia canthorum with lateral displacement of the medial canthi, hypertrophy of the nasal root and hyperplasia of the inner third of the eyebrows with confluent brows [28,29]. Total or partial iridial heterochromia may occur, as may perceptive deafness. The white forelock is present in 20% of cases. Premature greying may develop with or without the white forelock [30]; a minority have piebaldism and congenital nerve deafness but no other overt signs of WS, suggesting that this association may be genetically distinct. Type 1 WS is caused by loss of function mutations in the *PAX3* gene which plays a part in control of neural crest cells during embryogenesis. Type 3 WS (Klein–Waardenburg syndrome, with abnormalities of the arms) is an extreme presentation of type 1, and affected individuals are usually homozygotes. Type 4 WS (Shah–Waardenburg syndrome with Hirschsprung's disease) can be caused by mutations in the genes for endothelin-3 or one of its receptors, EDNRB. Type 2 WS is a heterogeneous group, approximately 15% of whom are heterozygous for mutations in the *MITF* (microphthalmia-associated transcription factor) gene. All these forms show marked variability even within families, and at present it is not possible to predict the severity, even when a mutation is detected.

In vitiligo, the white patches of skin frequently have white hairs within them. The histological changes are consistent with an 'autoimmune injury' to the melanocytes.

Alezzandrini's syndrome combines unilateral facial vitiligo, retinitis and poliosis of eyebrows and eyelashes [31]; perceptive deafness is rarely associated.

In alopecia areata, regrowing hair is frequently white. It may remain so, particularly in cases of late onset. Although absent hair pigment is only evident at the stage of resolution, melanocytes are lost from the hair bulb quite early and migrate to the dermal papilla.

Poliosis occurs in 60% of people with tuberous sclerosis. Depigmented hair may be the earliest sign of the disease [32].

The pathognomonic signs of Von Recklinghausen's neurofibromatosis relate to hyperpigmented areas—café-au-lait macules and axillary and perineal freckling. Scalp hypopigmented patches must not be mistaken for vitiliginous changes.

Acquired defects [33]

Permanent pigmentary loss may be induced by inflammatory processes that damage melanocytes (e.g. herpes zoster). X-irradiation often causes permanent hair loss but less intense treatment leads to hypopigmented and, rarely, hyperpigmented hair. Patchy white hair may develop on the beard area after dental treatment.

The Vogt–Koyanagi–Harada syndrome [34,35] consists of a post-febrile condition comprising bilateral uveitis, labrynthine deafness, tinnitus and vitiligo, poliosis and alopecia areata. It is likely to be an autoimmune disease, with the melanocyte, tyrosinase or tyrosinase-related protein as targets.

Albinism [36]

In autosomal recessive oculocutaneous albinism (complete, perfect or generalized albinism) changes in the hair bulb melanocytes are similar to those in the epidermis [25]. This applies to tyrosine-positive and -negative types. Melanocytes are structurally normal and active in producing melanosomes of grades I and II. However, they are enzymically inactive. The melanocyte system is never completely devoid of melanin. In white people, the hair is typically yellowish white, although it might be cream, yellow, yellowish red or vibrant red. This range of colour parallels that seen in normal blonde white people. In Negroid albinos, the hair colour is white or yellowish brown.

Chediak–Higashi syndrome

This syndrome is basically an autosomal recessive defect of the membrane-bound organelles of several cell types [37]. It combines oculocutaneous hypopigmentation with a defect of leukocytes, which is lethal in some forms, but other affected individuals live to adulthood. The defect lies in the lysosome trafficking regulator gene found on 1q [36]. The hair is silvery grey or light blonde and may be sparse.

Colour changes induced by drugs and other chemicals

Some topical agents temporarily change hair colour. Dithranol and chrysarobin stain light-coloured or grey hair mahogany brown. Resorcin, formerly used a great deal in a variety of skin diseases, colours black or white hair yellow or yellowish brown.

Some systemic drugs alter hair colour by interfering with the eumelanin or phaeomelanin pathway; in others, the mechanism is not known. Chloroquine interferes with phaeomelanin synthesis [38] and affects only blonde and red-haired individuals; the changes are completely reversible. Mephenesin, a glycerol ether used for diseases with muscle spasms, causes pigmentary loss in dark-haired people [39]. Triparanol, an anticholesterolaemic drug, and fluorobutyrophenone, an antipsychotic drug, both interfere with keratinization and cause hypopigmentation and sparse hair. Minoxidil and diazoxide [40,27], two potent antihypertensive agents, both cause hypertrichosis and darkening of hair. The colour produced by diazoxide is reddish, whereas minoxidil darkens hair mainly by converting vellus hair to terminal hair. Hydroquinone and phenylthiourea interfere with tyrosine activity, causing hypopigmentation of skin and hair [41].

Darkening of white hair occurred in a patient with Parkinson's disease following the addition of carbidopa and bromocriptine therapy [42].

Colour changes induced by nutritional deficiencies

Because specific dietary deficiencies are rare in humans, most clinical knowledge of their effects is derived from laboratory and animal studies. Copper deficiency in cattle causes achromotrichia because it is the prosthetic group of tyrosinase; loss of hair colour from this mechanism occurs in humans as Menkes' kinky hair syndrome. In protein malnutrition, exemplified by kwashiorkor, hair colour changes are a prominent feature; normal black hair becomes brown or reddish, and brown hair becomes blonde [43,44]. Intermittent protein malnutrition leads to the 'flag' sign of kwashiorkor (signe de la bandera). Alternating white (abnormal) and dark bands occur along individual hairs. Changes similar to those in kwashiorkor have been described in severe ulcerative colitis and after extensive bowel resection.

The lightening of hair colour from black to brown described in severe iron-deficiency anaemia may be an effect on keratinization rather than on melanocytic function [45].

Noppakun and Swasdikul [46] described a case of reversible white hair in vitamin B_{12} deficiency and commented on a variety of reversible and other hair colour changes in adult coeliac disease.

Hair colour in metabolic disorders

Phenylketonuria is an autosomal recessive disorder in which the tissues are unable to metabolize phenylalanine to tyrosine because of phenylalanine hydroxylase deficiency. Mental retardation, fits and decreased pigmentation of the skin, eyes and hair occur with eczema and dermographism. Black hair may become brown, and older institutionalized patients with phenylketonuria may have pale blonde or grey hair. Tyrosine treatment causes darkening towards normal colour within 1–2 months.

The paling of hair seen in homocystinuria is probably caused by keratinization changes resulting from the error in methionine metabolism.

Light, almost white hair and recurrent oedema are manifestations of the hair condition, 'oast house' disease. Methionine concentration in the blood is raised.

Darkening of grey hair has been reported in porphyria cutanea tarda [47].

Accidental hair discoloration

Hair avidly binds many inorganic elements and thus hair colour changes are occasionally seen after exposure to certain substances.

Exposure to high concentrates of copper in industry or from inadvertently high concentrations in tap water [48] or in swimming pools may cause green hair, particularly visible in blonde-haired subjects [49,50]. Cobalt workers

may develop bright blue hair and a deep blue tint may be seen in indigo handlers [51]. A yellowish hair colour is not uncommon in white- or grey-haired heavy smokers resulting from the tar in cigarette smoke; yellow staining may also occur from picric acid and dithranol. Trinitrotoluene (TNT) workers sometimes develop yellow skin and reddish brown hair.

Hair cosmetics [1,2]

Women and men have always been concerned about their hair, and have sought to modify it by grooming, colouring, cutting and wigs. There are references in Egyptian papyruses to the importance of arranging the hair prior to seduction [3,4]. Now, hair care and hair cosmetics are big business and many of the advances have come from cosmetic science laboratories [5,6]. Some aspects of cosmetic management can lead to secondary hair problems, such as traction alopecia (see p. 63.62) or follicular degeneration syndrome (see p. 63.54).

Shampoos [1–5]

In modern terms, a shampoo may be defined as a suitable detergent for washing hair that leaves the hair in good condition. Originally, shampoos were used solely for cleansing hair, but their range of function has extended in recent years to include conditioning, and the treatment of some hair and scalp diseases.

In principle, to wash hair a shampoo must remove grease, as it is the latter that attracts dirt and other particulate matter. The polar group of a detergent achieves this by displacing oil from the hair surface. The evaluation of shampoo detergency is difficult and complicated. The consumer tends to equate detergency with foaming; in Western society, few shampoos sell unless they possess good foaming power. In the evaluation of detergents as shampoos no single criterion can be used, although instrumental methods have been devised. Efficacy can be based only on the subjective impression of the consumer.

Shampoo formulations

These vary enormously but the basic ingredients can be resolved into a few groups: water, detergent and some fatty material. Soap shampoos are made from vegetable or animal fats and remove dirt and grease as efficiently as detergents; however, a scum forms with hard water and most shampoos contain detergents as the principal washing ingredient. Detergents are synthetic petroleum products and form no hard-water scum.

Shampoos contain:

1 Principal surfactants for detergency and foaming power
2 Secondary surfactants to improve and 'condition' hair
3 Functional additives to control pH and viscosity, or ingredients such as tar or antifungal agents
4 Preservatives
5 Aesthetic additives such as colourants and fragrance.

Whatever the claims of some manufacturers, most special additives end up down the sink [6]!

In general, cosmetic shampoos can be dry (powder types), liquid, solid cream, aerosol or oily. Antidandruff, 'medicated' and scalp treatment shampoos contain antiseptics and active agents such as coal- and wood-tar fractions or selenium sulphide. Clear liquid shampoos are the most popular, including 'cleansing' types, sold for treating greasy hair, and 'cosmetic' types having good conditioning action and popular among women with dry or 'normal' hair. For details of other specific formulas, the reader is recommended to read more specialized texts [3,4,7].

Shampoo safety

Shampoos obviously must be non-toxic, and at concentrations used by the consumer not irritate either skin or eyes. New shampoo formulations are tested exhaustively prior to marketing, particularly to assess their propensity to cause eye irritation, scarring and corneal opacities. Skin irritation is not usually encountered from shampoos that have low eye irritancy potential. Eye safety is assessed by the technique known as the Draize test; standard solutions of shampoo are instilled into the conjunctival sac of an albino rabbit. In general, the eye irritancy of detergents is greatest with cationics, followed by anionics, and least with non-anionics. There are exceptions to this, suggesting that shampoo irritancy may be caused by properties other than detergency including surface activity, pH, wetting power, foaming power (Ross–Miles test), and wetting and foaming power together. Most shampoos are, in fact, irritant but not dangerously so. Allergic contact dermatitis resulting from biocides does occur (see Chapters 20 and 21).

Conditioners

Dry hair lacks gloss and lustre and is difficult to style. This results from natural weathering and is worsened by chemical and physical processes applied to the hair. Conditioners have a range of characteristics that may contribute to shine, reduction of static electricity, protection from ultraviolet radiation and possibly increased hair strength [8]. Conditioners comprise fatty acids and alcohols: natural triglycerides (e.g. almond, avocado, corn and olive oil); waxes (e.g. beeswax, jojoba oil, mink oil, lanolin); phospholipids (e.g. egg yolk and soya bean); vitamins A, B and E, protein hydrolysates of silk, collagen, keratin (horn and hoof), gelatin and other proteins; and cationic polymers. Conditioners are available in a variety of forms and are widely used. They provide lubrication and gloss and render the hair easier to comb and style. The most commonly used are those combined with a shampoo as a 2-in-1 preparation. These cationic chemicals bind with the hair at the negatively charged surface and areas of weathering. In so doing they reduce static by electrically neutralizing the hair and provide a physical coating to the areas of damaged hair shaft with materials such as dimethicone. Other forms of conditioner may be applied as a separate procedure and can take the form of creams and emulsions

applied for a few minutes after washing and then rinsed off. Deep conditioners are left on for up to 30 min, often with damp heat. Fluids, gels and aerosol foams aid styling. Hair oils are traditional conditioners. Men may use brilliantines, greases or oils to leave the hair glossy and sleek [3].

Where the hair is significantly dry or damaged, or the scalp is inflamed or eczematous, conditioner may be used as a shampoo substitute in the same manner that one might advocate an emollient as soap substitute on the skin of someone with eczema. The conditioner will mix with water to remove surface dirt and odour, but will not subject the hair and scalp to the powerful solvent effects of the shampoo.

Cosmetic hair colouring [1–4]

Since the days of the pharaohs, women in particular have used hair dyes to hide grey hair. Use has increased enormously during the past 50 years and now men are using hair dyes. Or perhaps they always did!

The penetration of dyes into hair depends on molecular size and the aqueous swelling of the hair at the time of application of the dye; basicity of the dye is also important. The most successful dyes are relatively small molecules.

Excluding bleaches, hair-colouring materials can be divided into three groups: vegetable, metallic and synthetic organic dyes. Synthetic organic materials are thought to give more 'natural' colours than those obtained with vegetable and metallic hair colourants.

Vegetable dyes

Henna may be used to give reddish auburn shades. It is obtained from shrubs found in North Africa and the Middle East: *Lawsonia alba*, *L. spinosa* and *L. inermis*. The dye is produced from dried leaves, which are removed before the plant flowers. The active principle is an acidic naphthoquinone (lawsone). Traditionally, it is applied as a thick paste 'pack', which is left *in situ* for 5–60 min. The effects last for up to 10 weeks. This process is non-toxic but messy, and fingernails may become stained. Henna rinses are mixtures of henna and powdered indigo leaves that produce blue-black shades. A wide range of products containing compound henna exist [5]. Ground flower heads of a Roman or German chamomile yield a yellow dye: 1,3,4,-trihydroxyflavone (apigenin). It stains only the cuticle and can be used to lighten or brighten hair. Other vegetable dyes include extracts from logwood and walnut shell and these can be used by patients who are *para*-phenylenediamine sensitive. These products are obtainable at herbalists and beauty shops.

Metallic dyes

Traditionally, hair dyes for men have been of this type, as the colour changes occur less rapidly and are not as immediately obvious as with the oxidative dyes. Inorganic salts are used, which are altered by the hair and coat the surface as either oxides from reduction of the metal salts by keratin, or sulphides from the action of the sulphur in keratin on the metal. They all give a rather dull (metallic) appearance and may cause brittle or damaged hair if used too often.

Lead acetate, with precipitated sulphur or sodium thiosulphate, gives brown to black shades; grey hair may be changed through yellow to brown or black. Silver nitrate used alone produces a greenish black colour; pyrogallol is used as developer. Colours from ash blonde to black are possible by mixing silver nitrate variously with copper, cobalt or nickel; brownish black skin staining is the great disadvantage. Bismuth salts give shades of brown. Newer metallic dyes, containing a metal plus an organic ligand, are used on textile fibres and in some hair-dye patents. Metallic dyes cannot be removed without hair damage and should be left to grow out.

Synthetic organic dyes

This group has now been in use for more than 60 years. They are the most important type because of the comprehensive range of 'natural' colours that can be obtained. Most penetrate the hair cuticle so are potentially permanent, but in recent years less permanent types have been introduced.

Synthetic organic colourants are of three types:

1 *Temporary*. These wash out with one shampoo and last no longer than 1 week. Many temporary rinses belong to this group, including fashionable unnatural colours used by avant-garde sects and groups. They are available in aerosol sprays by incorporation into transparent polymeric plastics such as PVP; the disadvantage of such vehicles is their tendency to flake off on to clothing.

2 *Semipermanent*. In the UK, these have the widest appeal. They are used frequently at home and also in salons to brighten or subdue a natural colour, modify a permanent

or bleached colour, or modify white or grey. They are of sufficiently small molecular size to penetrate the cortex. They are intrinsically coloured; no developing is required (see the oxidative permanent group). They are relatively easy to wash out with shampoos containing ammonia; other shampoos must be used 6–10 times to remove them. Some semipermanent dyes have an affinity for thioglycolate-waved hair. Many are now used in colour shampoos.

3 *Permanent* (developed or oxidation dyes). These do not rely on the natural colour of a single chemical dye-stuff, (see semipermanents), but require an oxidative developer —hydrogen peroxide—to produce the final colour:

Paraphenylenediamine (PPD) and/or
paratoluenediamine (PTD)
+
Hydrogen peroxide
↓
Applied to hair
↓
Quinone diamine (small molecule)
↓
Penetrate hair—to cortex
↓
Large molecules produced
(by diamine 'self' condensation and modifiers,
e.g. pyrogallol)

Other substances may be included in specific formulations to give greater intensity to the dye (e.g. resorcinol and polyhidric phenols).

Oxidative dyes are potentially hazardous. The need for hydrogen peroxide enables lighter shades to be obtained and is chiefly responsible for the structural damage to hair that may occur if care is not exercised. Additives such as pyrogallol and resorcinol are potential irritants. The greatest problem is the potential of PPD (less so with PTD) to cause allergic dermatitis. Up to 10% of users may develop type IV allergy [6,7]. All dyes in this group are therefore sold with instructions to carry out preliminary patch testing 24–48 h before the proposed dye is used. Thus, the dye system is applied to skin either behind one ear or on the forearm—any redness, swelling or blistering implies allergy and the dyeing should not therefore proceed. A negative patch test does not mean that subsequent allergy cannot develop; it simply shows the subject is not allergic at the time the test is carried out. If allergy is shown, it is not sufficient merely to stop all future use of oxidative dyes; unfortunately, cross-sensitization also occurs with other aromatic benzenes (e.g. sulphonamides and some local anaesthetics), which must also be avoided for life. Modern formulations seem to cause less problems with allergy [8]. Hair dyes of this group have been incriminated as possible carcinogens [9]. Chromosome breaks have occurred under experimental conditions [10] and an increased incidence of tumours has been found in regular users [11]. It has also been intimated that aplastic anaemia could be produced by hair dyes [12]. None of these reports is sufficiently conclusive to warrant the withdrawal of such dyes.

Permanent dyes last for several months; they must not be applied more frequently than every 2–3 weeks because hair damage will occur. Permanently dyed hair must therefore be allowed to grow out. However, if a light shade has been produced and the subject wishes a darker shade, then temporary rinses may safely be used as these only coat the hair surface and have no propensity to cause structural damage.

For less commonly used permanent dye formulations, such as 'highlights', the reader is referred to specialized texts [4].

Bleaches [13–15]

Women have bleached their hair since Roman times. Bleaching is used both to lighten hair and to prepare it to take up hair dyes. Bleaching is an oxidative alkaline treatment that oxidizes and bleaches melanin. The hair lightens to reddish or yellow tones, depending on the underlying hair colour, and ultimately to platinum. Bleaching is very damaging to the hair, rendering it dry, porous and more prone to tangle. Overuse may cause disruption and fracture of the hair. Thus, it is advisable to perform permanent waving before bleaching. Home bleaching is usually performed with 6% hydrogen peroxide (20 volumes) with ammonia to speed the reaction, which otherwise takes 12 h. Salons use more powerful bleaching creams, powders and pastes, which are much faster. They are often applied to individual strands of hair, others being left untreated to give highlights, which lessens the problem of the darkened roots. Bleaching is terminated by shampooing or an acid rinse. The human eye perceives a more aesthetically acceptable blonde ('platinum' blonde) when the bleached hair is treated with a blue or lilac colourant.

Permanent waving [1–3]

Permanent waving is often referred to as 'a perm'. It has been defined as the process of changing the shape of the hair so that the new shape persists through several shampoos. During the last 70 years, increasing knowledge of keratin chemistry has enabled semipermanent chemical methods to be developed. Whatever the process used, three stages are involved in hair waving:

1 Physical or chemical softening of the hair
2 Reshaping
3 Hardening of fibres to retain the reshaped position.

Softening

Water can extend the hydrogen bonds between adjacent polypeptides in the keratin molecule, allowing temporary reshaping to be carried out—exposure to high humidity or rewetting immediately reverses the process. To obtain a more durable effect from water, steam may be used which, in a limited way, disrupts disulphide bonds. Heat and steam alone are rarely acceptable to modern women because their effects are temporary and the treatment is uncomfortable. Heat can be more effectively employed in conjunction with ammonium hydroxide and potassium bisulphite or triethanolamine as agents to reduce disulphide bonds; great skill is involved in this process as failure to judge the time of application of chemicals and heat may cause severe damage.

Since 1945, cold wave processes using substituted thiosulphates (thioglycolates) have largely superseded hot waving. Thioglycolates are potent reducers of disulphide bonds in the keratin molecule:

—S=S— → 2—SH.

A typical cold waving lotion contains thioglycolic acid plus ammonia or monoethanolamine.

Acid permanent waves have recently become popular for salon use. They contain glyceryl monothioglycolate and produce a softer curl, and can be used on damaged and bleached hair. Their disadvantage is the high frequency of sensitization in the hairdressers using the product and, occasionally, sensitization of the client [4].

Reshaping

The type of rollers or curlers used to reshape the softened hair depends on the training of the hairdresser and the fashion desired. The degree of curl or tightness of the permanent wave depends both on the diameter of the roller and the size of the strand wound round the roller. Increasing the time of the exposure to the perming solution up to 20 min increases the curl, but longer times do not give a further increase. The strength of the solution used depends on the hair type, texture and previous bleaching. Home permanent waves are weaker and cannot achieve the same degree of curl. 'Tepid' waving involves using a weaker thioglycolate solution plus warm air. Neutralization is carried out initially with the curlers in place and again after they have been carefully removed. The reshaping stage is thus a great test of hairdressing skill and experience.

Hardening (neutralizing or setting)

In general, this process involves a reversal of the softening (reduction) stages:

$$2\text{—SH} \xrightarrow{\text{oxidation}} \text{—S=S—}.$$

It is important to note that complete reversal to presoftened 'strength' cannot occur because many free SH groups may not be in a position for oxidation to be effective, for example:

2—SH → —S—C—S— (C = carbon)
2—SH → —S—Ba—S— (Ba = barium)

Atmospheric oxidation may efficiently neutralize the waving process. This method is slow and rollers must be left in position for several hours overnight. Chemical oxidation is now the rule. Hairdressers generally use hydrogen peroxide whereas most solutions for home use contain sodium perborate or percarbonate (UK) or sodium or potassium bromate (USA). This is why hair is lighter after permanent waving. Some neutralizers contain shellac, which may react with alcohol groups to cause hair discoloration.

Practical procedures

Hot waving

This is almost never used. The procedure is:

1 Shampooing
2 Hair divided and rollers or curlers applied under slight tension
3 Waving solution applied
4 Heating.

Heating varies according to the solution used or the type of wave required. Electric rollers or exothermic reactive chemicals may be used. The latter allow free head movement during the waving. The skill of this procedure

lies in good hair sectioning, judging the right amount of solution, correct winding tension and appropriate steaming time.

Cold waving

This also involves initial shampooing, hair division into locks, moistening with waving lotion and application of croquignole curlers. Further solution may then be applied. The softening time is 10–20 min. Occasionally, mild heat is included, using exothermic chemicals or the natural heat from the head by enclosing the scalp in a plastic bag. These may add to the comfort of the process. Rinsing then takes place, followed by neutralization with the oxidizing solution for up to 10 min. After removing the curlers, further 'hardening' solution is usually applied. 'Loose' curl waves last for no more than a few weeks but 'tight' curl styles may persist for 4–12 months.

Hair straightening (relaxing) [1,2]

In principle, the methods used to straighten hair are similar to those used in permanent waving. The practice is almost exclusively used to straighten negroid hair and is also called relaxing. One survey found that relaxing formulations were used in 45% of black American women [3]. These practices are associated with a range of problems and ultimately may contribute to scarring alopecia [4].

Pomades

These are mostly used by men with relatively short hair. They are greasy and act by 'plastering' hair into position.

Hot-comb methods

Shampooing is carried out and the hair is towelled dry; oil is then applied (e.g. petroleum jelly or liquid paraffin), which acts as a heat-transferring agent. Heat pressing with hot combing is then used (148–260°F), causing breakage and reforming of disulphide bonds, allowing the hair to be moulded straight. Structural damage (and breakage) of hair is common with this process and scarring alopecia may occur as a result of hot waxes entering the follicles. Sweating and rain reverse this procedure.

Cold methods

The chemical methods employed use alkaline reducing agents (caustics), thioglycolates, ammonium carbonate or sodium bisulphite. Caustic soda preparations are usually creams and require the application of protective scalp oil or wax. They are combed through the hair and left for 15–20 min; the hair is combed and straightened again, then rinsed and neutralized. These preparations are limited to salon use because of their potential to cause irritant dermatitis and damage to the hair. Thioglycolate creams are the most common agents used; the cream is applied liberally to the hair, which is then combed until it is straight. The cream is then washed off and a neutralizer (oxidizing agent) applied. Other straighteners ('relaxers') do not contain thioglycolates (e.g. sodium bisulphite and ammonium carbonate, acidic ethylene glycol or 1,3-propylene glycol). Bisulphite straighteners are suitable for home use in combination with alkaline stabilizers.

Hair setting [1]

Setting lotions have changed considerably in recent years. The traditional semiliquid gels based on water-soluble gums (e.g. tragacanth, karaya and acasia) have been replaced by various synthetic polymers in a bewildering array of forms—aerosol foams and sprays, liquids and gels. Most are based on PVP in a gelled aqueous solution and give an attractive glossy non-greasy appearance [2]. Some preparations incorporate other ingredients to condition or to add antistatic action, lustre or sheen.

Setting lotion and spray formulations are considered safe, after early reports of foreign body granulomatous inflammation [3,4] had been questioned and not supported by further cases. Hair sprays were incriminated as a possible cause of peripilar casts [5] but this was not confirmed by later work [6].

Methylolated compounds

Many cosmetic preparations, by their action on the keratin molecule, irreversibly weaken the hair. The cosmetic scientist has produced chemicals that attempt to combat this problem. The formulations contain methylolated compounds of varying strength depending on the type of hair under treatment and the solubility of the compound. Most preparations containing alkylated methylol compounds have greater stability and release very little formaldehyde [1].

Complications

Hair loss is often attributed to cosmetics, with relatively little evidence in support [1]. Matting of scalp hair is most commonly a sudden, usually irreversible, tangling of scalp hair resulting from shampooing [2]. Excessive bleaching, permanent waving and straightening procedures may induce excessive weathering and fragility of hair.

Complications from the use of synthetic hair fibre implantation for male pattern balding can be severe [3].

Chapter 64

The Skin and the Eyes

J.N. Leonard & J.K.G. Dart

Introduction

This chapter is not intended to be a comprehensive account of all diseases that affect the skin and eyes, for which there are several reviews [1–6]. The main focus is on those conditions that commonly occur in clinical practice and present a problem with management. It is also intended to alert the dermatologist to conditions that might threaten visual acuity and require urgent referral to an ophthalmologist. Also, many systemic diseases affect both the skin and eyes, and ophthalmic assessment will be of help in making the correct diagnosis and in long-term management of the patient.

Anatomy and physiology of the eye [1,2]

The eye and skin share a common embryological origin. The structure of the lid, conjunctiva, the lacrimal gland and associated drainage apparatus are of surface ectodermal origin while the remainder of the eye arises from epithelium of the ectodermal neural plate. The only mesodermal contribution to the eye is the myoblasts of the extra-ocular muscles. The anatomy of the eye is shown in Fig. 64.1. The eye appendages are as follows.

The eyebrows

This hair-bearing area rests on a very mobile fat and muscle pad overlying the superior orbital ridge. Its mobility is important as a means of facial expression. The eyebrows help protect the eye from bright light and sweat.

The eyelids

The eyelids have distinct anatomical layers, comprising the skin with subcutaneous tissue, the tarsal plate and conjunctiva, and striated muscles that effect lid movement (Fig. 64.2).

The skin is thin and modified in several ways to protect the eyeball. It contains sebaceous glands associated with

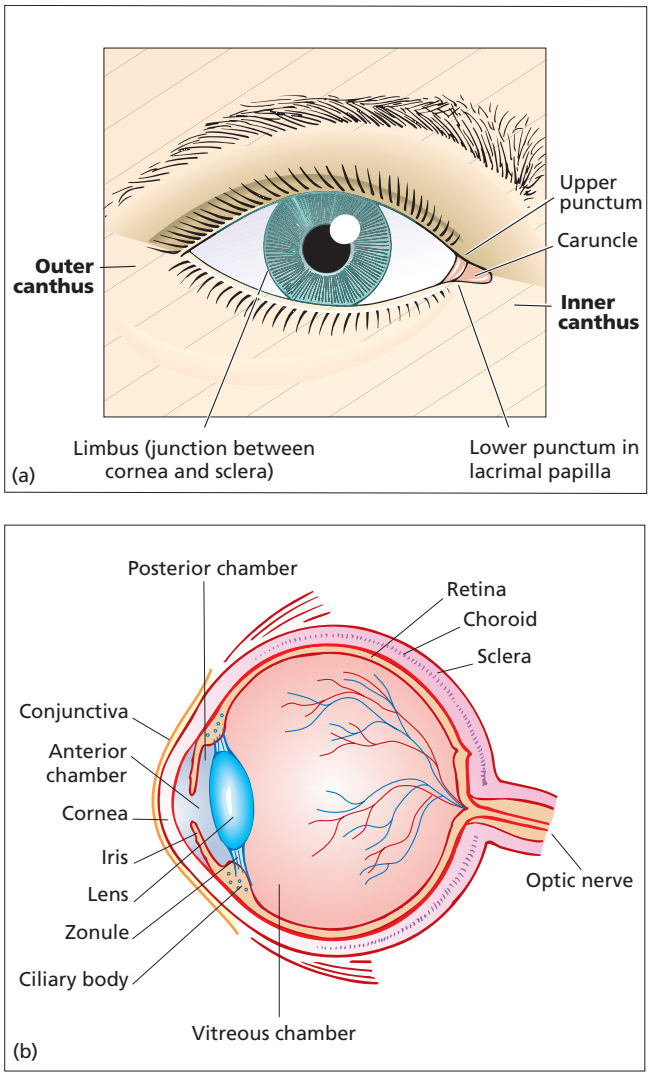

Fig. 64.1 Anatomy of normal eye. (a) The external appearance of the right eye. (b) Cross-section of the human eye.

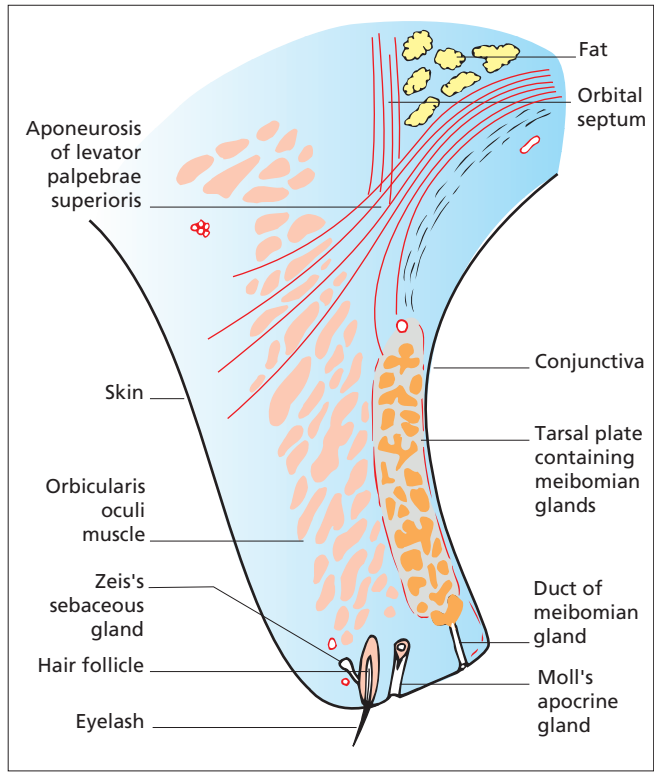

Fig. 64.2 Cross-section of upper eyelid.

the fine hairs of the eyelashes (cilia) and both apocrine and eccrine sweat glands. There are about 300 eyelashes arising in two rows along the eyelid margin, two thirds of which are in the upper lid. They have no associated erector muscles, but rudimentary sebaceous glands (of Zeis) are present. Some lashes, particularly those of the lower lid, are associated with ancillary apocrine sweat glands (of Moll). The ducts of these glands open both into the lash follicles and directly onto the anterior lid margin between the lashes. The eyelashes help to protect foreign bodies from impinging on the eyeball. Each lash follicle has a rich nerve plexus, which is easily excited and light touch initiates reflex closure.

The tarsal plate of each eyelid gives the palpebral aperture shape and stability. They comprise dense, fibrous tissue surrounding modified sebaceous glands (meibomian glands). These secrete the outer lipid layer of the precorneal tear film through openings along the mucocutaneous junction of the eyelid margin. This lipid helps stabilize the tear film and reduce evaporation. There are about 30 glands in the upper tarsal plate and 20 in the lower. Meibomian glands have up to 20 acini surrounding a central vertical duct and are visible through the conjunctiva.

The eyelids are lined by a mucous membrane called the palpebral conjunctiva. It is reflected over the anterior portion of the eyeball up to the edge of the cornea as the bulbar conjunctiva. The folds formed by the reflection of the conjunctiva from the lids onto the eyeball are called the superior and inferior palpebral fornices. The conjunctiva contains numerous goblet cells secreting mucin into the tear film. It also contains about 50 accessory lacrimal glands and its substantia propria contains neural tissue, mast cells, lymphocytes and lymphoid follicles, which are important in mediating local immunological reactions.

The striated muscle of the levator palpebrae superioris opens the eye, and the striated orbicularis oculi muscle closes it. Both are innervated by the facial nerve. Two divisions of the trigeminal nerve supply sensation to the eyelids; the upper lid and medial canthus are supplied by the ophthalmic division, and the remainder of the lower lid by the maxillary division.

The eyelid has a rich blood supply mainly through the medial and lateral palpebral arteries, which are branches of the ophthalmic artery. There is also a rich anastomosis

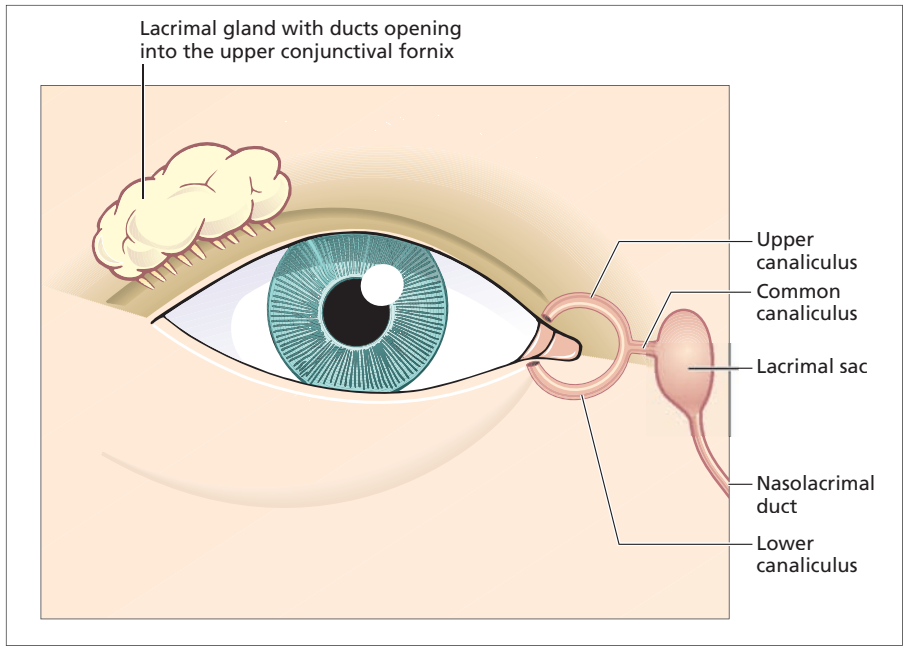

Fig. 64.3 The lacrimal apparatus of the right eye.

between adjacent arteries arising from the internal and external carotid. The blood drains through a network of veins to the facial and orbital veins and the cavernous sinus. Lymphatics drain the conjunctiva and tarsal plate to the post-tarsal plexus and the skin and orbicularis to the pre-tarsal plexus. The medial canthus and lower lid subsequently drain to the submandibular nodes whilst the lateral canthus and upper lid drain to the parotid and preauricular nodes.

The lacrimal glands

The main lacrimal gland is a modified sweat gland located in the lacrimal fossa, a bony depression just under the upper and outer margin of the orbit. It produces an aqueous secretion, which discharges through a network of ductules onto the conjunctiva of the palpebral conjunctiva. In addition, there are a variable number of accessory lacrimal glands in the upper and lower conjunctival fornices. The lacrimal gland is innervated whereas the accessory glands are not.

The pre-corneal tear film

The eyelids make a vital contribution to the composition and stability of the precorneal tear film, which is about 40 µm thick. It is a three-layered structure consisting of a lower hydrophilic mucin layer secreted by goblet cells of the conjunctiva, a central aqueous layer secreted by the lacrimal gland, and a surface hydrophobic lipid layer secreted by the meibomian glands (as discussed above). Blinking consists of a lateral to medial movement of the eyelids, which enables resurfacing of the tear film of the cornea and propels the tears to the punctum of the tear duct; from here, they are actively removed by the lacrimal pump mechanism through the lacrimal canaliculi into the common canaliculius and lacrimal sac, and then via the nasolacrimal duct into the nose (Fig. 64.3).

The tear film has a number of functions:

1 To supply oxygen and other nutrients to the cornea
2 To remove particulate matter from the surface of the eye
3 To prevent drying of the eye
4 To act as a lubricant and prevent adhesion of the palpebral to the bulbar conjunctiva
5 To protect the eye surface through its antibacterial role. It contains white blood cells, various proteins, lysozyme and immunoglobulins.

Glossary of ophthalmological terms

A glossary is provided in Table 64.1.

Disorders affecting the eyebrows and eyelashes

There is a wide variation in the colour distribution and density of the eyebrow hairs. The inheritance of the appearance of the eyebrows is polygenic. Some hereditary variations are of no known significance, but others are

Table 64.1 Glossary of ophthalmological terms.

Astichiasis	Absence of lashes
Anophthalmia	Absence of eye
Blepharitis	Inflammation of the eyelid margin
Blepharochalasis	Elastic tissue atrophy causing loose eyelid skin
Bruch's membrane	The retinal layer sandwiched between the retinal pigment epithelium and the vascular choroid
Coloboma	Congenital cleft created by failure of development of a portion of the eye or adnexal structures
Dermatochalasis	Laxness of the skin of the eyelids
Distichiasis	Accessory row of eyelashes
Ectropion	Eversion of the eyelid
Entropion	Inversion of the eyelid
Epicanthal fold	Accessory fold of skin at the inner canthal region of the eye
Epicanthus inversus	Lower lid fold larger than upper lid fold
Epiphora	Excess tearing
Episcleritis	Inflammation of the superficial scleral tissues
Hypertelorism	Increased distance between the two eyes measured radiologically
Hypopyon	The presence of pus in the anterior chamber
Keratopathy	Corneal abnormalities including: *exposure keratopathy*—from corneal exposure and drying of the cornea
Keratitis	Inflammation of the cornea—various types are recognized, including *filamentary keratitis*—the development of epithelialized mucous filaments on the corneal surface; *interstitial keratitis*—inflammation of the corneal stromal layer
Keratoconjunctivitis sicca	Corneal and conjunctival inflammation associated with impaired tear secretion and ocular dryness
Keratoconus	Conical distortion of the central cornea as a result of a degenerative process in the stroma
Lagophthalmos	Persistent exposure of the eyeball despite closure of the eyelid
Limbus	Boundary between the cornea and sclera
Madarosis	Loss of the eyelashes
Pannus	Vascularized corneal scar
Phlyctenule	Wedge-shaped, peripheral corneal or conjunctival, nodule
Preseptal cellulitis	Cellulitis of the eyelids that has not penetrated through the orbital septum to involve the orbit
Symblepharon	Adhesions between the bulbar and palpebral conjunctiva resulting in complete or partial obliteration of the eyelid fornices
Telecanthus	Increased distance between the inner canthi
Trichiasis	Lashes that turn inward toward the cornea usually as a result of entropion
Uveitis	Inflammation of the uveal tract. It is subdivided into anterior uveitis, which is the most common, intermediate uveitis, posterior uveitis and pan uveitis. *Anterior uveitis* is subdivided into iritis, in which the inflammation predominantly affects the iris, and iridocyclitis, in which both the iris and the anterior part of the ciliary body (pars plicata) are equally involved. *Intermediate uveitis* involves the posterior part of the ciliary body (pars plana) and the extreme periphery of the choroid and retina. *Posterior uveitis* is inflammation located behind the vitreous base. *Pan uveitis* is involvement of the entire uveal tract

associated with other development defects or are part of a recognized syndrome.

Disorders of the eyebrows [1]

Synophrys

This term is applied when the eyebrows are profuse with a tendency to meet in the centre of the face. Synophrys is a feature of some genodermatoses (Chapter 12). The eyebrows also tend to become more bushy in the ageing male for reasons that are unknown. Bushy eyebrows may also occur in other acquired forms of hypertrichosis, for example due to drugs such as diazoxide, and fusion of the eyebrows has been reported in kwashiorkor.

Hypoplasia of eyebrows

Some inherited diseases are characterized by hypoplasia of the eyebrows (Chapter 12). Acquired conditions can cause sparsity of the eyebrows. They may be the only site affected in alopecia areata. Thinning of the eyebrows also occurs in hypothyroidism, erythroderma, follicular mucinosis and secondary syphilis. Lepromatous leprosy causes thinning of the outer third of the eyebrows in the early stages, often with depigmentation, and this progresses to total loss of the brows and lashes. Tuberculoid leprosy, by contrast, does not cause loss of the eyebrows. Plucking the eyebrows for cosmetic reasons is common, but true trichotillomania of the eyebrows is unusual.

Inflammatory disorders affecting the eyebrows

The eyebrows are often involved in seborrhoeic dermatitis and psoriasis. Post-inflammatory cicatricial alopecia from discoid lupus erythematosus, folliculitis decalvans, lupus vulgaris or tertiary syphilis may cause eyebrow loss. Scarring with loss of eyebrows may also follow chemical

and thermal burns or radiation. Loss of eyebrows can be camouflaged by the use of eyebrow pencils, permanent tattooing or by a hair prosthesis glued in place daily.

Disorders of the eyelashes

Trichomegaly [2–4]

This may be due to a genetic trait. Increased growth of the eyelashes has also been described in human immunodeficiency virus (HIV) infection and related to various drugs including ciclosporin, zidovudine or interferon. Long lashes also occur in some patients with phenylketonuria.

Madarosis [1]

Madarosis is a decrease in the number or complete loss of lashes. A number of causes have been recognized and include alopecia areata, chronic anterior lid margin blepharitis, infiltrating tumours of the lid, burns, cryotherapy and radiotherapy, trichotillomania and discoid lupus erythematosus. Systemic diseases such as hypothyroidism and syphilis may also be responsible.

Abnormality of the eyelids

These include dermatochalasis, blepharochalasis and lid laxity. Numerous developmental defects can affect the palpabral fissure or size and shape of the eyelids. A number of hereditary dermatoses affect the eyelids (Chapter 12).

Ptosis

Drooping of the eyelids on one or both sides is a common genetic defect. Mild ptosis commonly develops in the elderly due to the laxity of the connective tissue. There are many important acquired causes, such as third nerve palsy, Horner's syndrome and myasthenia gravis, which require neurological referral. Ptosis may be associated with other ocular abnormalities.

Skin diseases affecting the eyelids

A large number of dermatological conditions can affect the eyelids as part of a generalized process. Usually there is little diagnostic difficulty as the diagnosis is made by examination of the rest of the skin. Psoriasis and lichen planus can both involve the lids and cause considerable irritation. These are chronic diseases and management can become a problem with use of potent topical corticosteroids on the eyelids over a prolonged period of time. Use of the new topical immunosuppressants such as tacrolimus and pimecrolimus may offer some promise for the future in reducing topical corticosteroid exposure. Unilateral involvement of an eyelid raises the possibility of infective conditions, including tinea and mycobacterial infections.

Psoriasis [1]

Eyelid involvement can occur in about 10% of patients with psoriasis. Men are more susceptible to ocular disease. Involvement of the eyelid gives rise to blepharitis, madarosis and development of psoriatic plaques. Chronic non-specific conjunctivitis may occur over time and lead eventually to keratoconjunctivitis sicca with symblepharon formation and trichiasis. Conjunctivitis usually complicates eyelid margin involvement; white or yellow psoriatic plaques can spread from the lid on to the conjunctiva itself. Corneal changes are rare and are most commonly related to exposure and trichiasis. Anterior uveitis is rare but has been reported in patients with psoriatic arthritis and is similar to that seen in Reiter's syndrome. Ocular psoriasis is treated with use of lubricants and topical corticosteroids. Patients with chronic eyelid involvement should be referred for ophthalmological assessment.

Contact dermatitis [2–8]

Contact dermatitis is the responsible cause in approximately half of patients with an eyelid dermatitis. The remainder have manifestations of atopic or seborrhoeic dermatitis. The eyelid skin is very sensitive to primary irritants. These can cause a dermatitis in their own right or can aggravate an underlying constitutional tendency in patients with either atopic or seborrhoeic dermatitis.

Allergic contact dermatitis can present after many years of exposure to the culpable allergen. Clinically it is characterized by severe itching, erythema and swelling of the eyelid, progressing to formation of vesicles. A large variety of allergens have been reported as causing an allergic contact dermatitis of the lid and include preservatives (used in cosmetics, topical medications and contact lens cleaning solutions), fragrances and the resin used in nail polish. Patients with suspected contact dermatitis of the eyelids should be patch tested. Careful history taking is of paramount importance to make sure the relevant allergens are included in the test battery. The possibility of transferring antigen from the hands to the eyelids needs to be considered. Maibach described the upper eyelid dermatosis syndrome in which patients have discomfort

of the eyelids with or without dermatitis; it is thought to be unrelated to use of cosmetics.

Periorbital oedema [9]

The subcutaneous tissue of the eyelids is lax and prone to oedema. There are many systemic and dermatological causes of eyelid oedema that need to be considered. Systemic causes include angio-oedema, glomerulonephritis, hypoalbuminaemia (especially nephrotic syndrome), cardiac failure, superior venocaval obstruction and thyroid disease. Some systemic infections such as infectious mononucleosis and scarlatina cause periorbital oedema. It may be the presenting feature of dermatomyositis and has been reported in systemic lupus erythematosus.

The most common dermatological causes of periorbital oedema are angio-oedema, lymphoedema, allergic contact dermatitis and blepharochalasis; they are usually distinguished by the history. Angio-oedema is transient and often part of a more generalized urticarial eruption. Lymphoedema is permanent and tends to be worse first thing in the morning and improves during the day; it may be associated with underlying sinus disease or a chronic inflammatory condition such as granulomatous rosacea. Allergic contact dermatitis presents acutely with swelling, redness and itching. Blepharochalasis is an uncommon condition which may be inherited (autosomal dominant) or sporadic; it presents in the second decade with recurrent episodes of painless lid oedema, resulting in the development of excess skin and thickened subcutaneous tissue which may require treatment by blepharoplasty. Senile orbital fat prolapse through a deficient orbital septum may mimic periorbital oedema but is differentiated by the fact that there is minimal fluctuation in the associated swelling.

Changes in pigmentation [10–14]

There are considerable racial and familial variations of the degree of pigmentation of the eyelids (Chapter 39). Marked periorbital melanosis is seen as a genetic trait. Pigmentation of the periorbital skin can also be post-traumatic, post-inflammatory or can accompany melanocyte-stimulating hormone-induced melanosis of any cause. Chemical pigmentation can occur from prolonged use of a mercurial or silver preparation producing a slate-blue or grey-brown discoloration. Mauve discoloration of the eyelids and periorbital area is an early part of chrysiasis from parenteral gold therapy. A grey discoloration can complicate long-term treatment with minocycline. Local increase in pigmentation may also be due to cosmetics containing phototoxic agents, usually psoralens. Increased pigmentation can also follow inflammatory dermatoses such as eczema and lichen planus. The eyelids may be involved in vitiligo. Hypopigmentation can complicate the use of topical medications including thiotepa eye drops and mercurial ointments.

Chronic blepharitis, rosacea and seborrhoeic dermatitis [1–4]

Description. Chronic blepharitis is a term that is used to describe a group of disorders in which the lid margin is always involved. These disorders often occur simultaneously. Not all of them result in inflammation of the lid margin. They are frequently associated with a conjunctivitis or keratoconjunctivitis. Chronic blepharitis may occur in the absence of any significant dermatological association and its classification is further complicated, both by the variable association of chronic blepharitis with rosacea and seborrhoeic dermatitis, and also by the term ocular rosacea, a condition which may occur in the absence of dermatological rosacea.

It is hardly surprising that this classification causes confusion amongst practitioners. This situation has arisen partly because there is no consensus about the terminology (although most modern authors use similar classifications based on McCulley's modification of Thygeson's classification) and, more probably, because the pathogenesis is very poorly understood with few unifying concepts.

Table 64.2 summarizes a current classification, associations and features. It includes ocular rosacea amongst the meibomian gland disorders with which it is always

Table 64.2 Classification of types of chronic blepharitis (lid margin disorders).

Anterior lid margin*		Posterior lid margin*		
Staphylococcal blepharitis	Seborrhoeic blepharitis	Meibomitis/ocular rosacea	Meibomian gland dysfunction	Meibomian seborrhoea
Associations with other types of blepharitis				
Secondary meibomitis	Any posterior lid margin condition	Staphylococcal & seborrhoeic blepharitis	Seborrhoeic blepharitis	Seborrhoeic blepharitis
Associated skin disease				
Atopic eczema Impetigo Rosacea (rare)	Seborrhoea Rosacea (rare)	Acne rosacea in up to 50% of cases	Acne rosacea in up to 50% of cases	
Associated eye disease				
Dry eye Atopic kerato-conjunctivitis		Scleritis and episcleritis in ocular rosacea		
Main features				
Symptoms				
Burning Itching Photophobia	Minimal	Foreign body sensation Burning Discomfort Photophobia with ocular rosacea	Variable: Foreign body sensation Burning Discomfort	Variable: Foreign body sensation Burning Discomfort
Lid signs				
Unilateral/patchy lid margin involvement (Fig. 64.4d) Brittle fibrinous scales bleed when detached, form collarettes at lash base (Fig. 64.4a) Dilated vessels, styes Poliosis and madarosis (Fig. 64.4b)	Bilateral greasy scales (not fibrinous)	Chalazia (Fig. 64.5b) Irregular lid margins Distorted meibomian orifices Inspissated secretions Expression difficult Surrounding inflammation For lid signs in ocular rosacea see Table 64.3		Plugged and elevated orifices without inflammation
Conjunctival & corneal signs				
Follicles, papillae and hyperaemia of lower tarsal conjunctiva and fornix (Fig. 64.4c) Coarse punctate keratitis in lower third of cornea. Marginal keratitis (Fig. 64.4e) and vascularization. Conjunctival scarring (Fig. 64.5a)		Early tear break up time Foam/debris in tears Punctate keratitis (dry eye) For conjunctival and corneal signs in ocular rosacea see Table 64.3		Minimal injection ± Foamy tear film

* The anterior lid margin is the portion anterior to the meibomian gland orifices and the posterior lid margin is behind this, including the meibomian glands. Anterior and posterior lid margin disorders are commonly mixed; frequent associations are shown in the table.

associated. Table 64.2 classifies the five types of blepharitis (including ocular rosacea) into those principally affecting the anterior lid margin structures (cutaneous margin with lash-bearing skin and associated glands) or the posterior lid margin (mucocutaneous junction, meibomian orifices). This classification simplifies the treatment because this differs between the anterior- and posterior-lid margin disorders but not between the individual conditions within the anterior- and posterior-lid margin groups. The commoner clinical signs of staphylococcal blepharitis are shown in Fig. 64.4. Ocular rosacea (Table 64.3, Fig. 64.5) is an important condition because of its severity and wide spectrum of clinical features.

In addition to these very common types of blepharitis, there are other chronic causes in which the pathogenesis is clear. These are all uncommon and are often misdiagnosed as one of the types of chronic blepharitis described in Table 64.2. They include fungal infection (e.g. *Candida*), parasitic infection (e.g. phthiriasis), protozoal infection (e.g. leishmaniasis), some neoplasms, and autoimmune conditions such as lupus erythematosus; some of these are illustrated in Fig. 64.6. They should be considered when therapy for conventional blepharitis fails.

Acute blepharitis is a clearly defined group of conditions, which may overlap with the chronic blepharitis causes summarized in Table 64.4.

(b) Fibrinous scales on the anterior lid margin with the madarosis (loss of lashes) and poliosis (white lashes) that accompanies chronic blepharitis. (c) Follicular conjunctivitis with arrows showing the white/yellow follicles. (d) Localized ulcerative blepharitis. Sectoral disease like this is quite common in staphylococcal blepharitis which can also be largely unilateral. (e) Marginal ulceration, a common corneal complication of staphylococcal blepharitis.

Epidemiology

The epidemiology has been dogged by difficulties of disease definition and the different perspectives of dermatologists and ophthalmologists. Chronic blepharitis is one of the commonest disorders in both ophthalmic and general medical practice. In general medical practice it makes up about 70% of ophthalmic referrals, which themselves account for between 2% and 7% of all outpatient consultations. Meibomian gland dysfunction is probably the commonest type of blepharitis and affects 20–40% of all patients consulting ophthalmologists for routine eye examinations. Between 3% and 58% of patients with rosacea have ocular involvement, this wide variation being the result of differences in disease definition. Approximately half the patients with rosacea have signs of ocular rosacea whereas one quarter of patients with ocular rosacea have no dermatological disease.

Table 64.3 Clinical signs of ocular rosacea.

Signs	Common	Uncommon	Rare
Lid	Meibomitis (Fig. 64.5a) Seborrhoeic blepharitis Lid margin telangiectasia Lid notching Retroplacement of the mucocutaneous junction Chalazia (Fig. 64.5b) Hordeoleum	Entropion	
Conjunctiva	Conjunctival hyperaemia Papillary conjunctivitis	Reticular and linear tarsal scarring and fornix shortening	
Cornea	Phlyctenular keratoconjunctivitis Marginal corneal infiltration and ulceration (Fig. 64.5d,e)	Pseudopterygium	Corneal perforation
Sclera and episclera		Episcleritis	Scleritis

Immunopathogenesis [5]

There is some evidence to support hypotheses of pathogenesis in staphylococcal blepharitis and in meibomian dysfunction, but the pathogenesis is even more poorly understood in the other types of chronic blepharitis.

Staphylococcal blepharitis

In staphylococcal blepharitis [6–13] there is an association with *Staphylococcus aureus* and *S. epidermidis* colonization of the lid margins, although colonization by *S. aureus* is often transient and the numbers of either organism are often no greater than in normal controls. Although folliculitis, styes and lid margin ulcers may be due to infection by *S. aureus*, the persistence of lid inflammation after treatment and the sterile marginal ulcers are not explained by infection alone. The importance of cell-mediated immunity in the pathogenesis of the disease was shown by experimental studies in rabbits; when these were immunized with either whole *S. aureus* or with cell wall ribitol–teichoic acid, both ulcerative keratitis, phlyctenules and marginal corneal ulcers developed after secondary challenge, providing evidence for the hypothesis that these changes were due to the development of hypersensitivity to both viable and killed organisms. These finding could not be reproduced for *S. epidermidis*. However the evidence for a similar pathogenesis in humans is lacking; the relationship between the clinical signs of staphylococcal blepharitis and hypersensitivity to subcutaneous injections of either whole *S. aureus* or of *S. aureus* cell wall protein A is poor. *Staphylococcus epidermidis* is more often isolated than *S. aureus* from the lids of patients with staphylococcal blepharitis, but the evidence of the role of a hypersensitivity response is assumed and not supported by any data. The pathogenesis of the, often severe, follicular and papillary conjunctivitis that accompanies this condition is assumed to be due to a combination of transient infection and hypersensitivity.

Meibomian gland disease (MGD) [14–16]

The meibomian lipids (meibum) are a complex mixture of cholesterol esters and esterified unsaturated fatty acids. These lipids are responsible for maintaining a stable tear film, reducing tear film evaporation and, therefore, drying of the ocular surface, preventing tear spill over the lid margins by lowering surface tension and reducing ocular surface contamination, by sebum, from the cutaneous surface of the lids which otherwise forms dry spots.

Three factors have been invoked as contributing to MGD: (i) keratinization of the meibomian ductules; (ii) the effect of bacterial lipases on the meibum at the lid margin; and (iii) primary abnormalities in the production of meibum by individuals with MGD.

Normal meibomian gland ducts open just anterior to the mucocutaneous junction. As the duct lining is partially keratinized, abnormalities of keratinization, analagous to those present in the sebaceous glands of patients with rosacea, may be important in the pathogenesis of MGD by altering gland function. Bacterial lipases are produced by all the bacteria that colonize the lid margin and have the potential to break down meibum into free fatty acids that will destabilize the tear film. These bacteria colonize the gland orifices and expression of lipid from deeper within the glands can stabilize the tear film. Meibomian lipids differ between individuals and, as analytical methods increase in sensitivity, the relative roles of primary abnormalities of meibum, and those secondary to the effects of bacterial lipases in the pathogenesis of MGD, are likely to become clearer.

Neither the pathogenesis of the conjunctival inflammation that is common in meibomitis (and which is a feature of ocular rosacea), nor that of the keratitis in ocular rosacea, has been explained.

Entropion and trichiasis may result from this degree of scarring. (b) Meibomian dysfunction with blocked glands and small chalazia. (c) Marginal ulceration complicated by frank bacterial superinfection with an hypopyon ulcer. (d,e) Rosacea keratitis showing the right cornea (d) of the patient whose eyes are shown in (e).

Treatment [17–23]

The treatment of blepharitis is that of the underlying cause, if a specific cause can be identified. Treatment for the principal causes of chronic blepharitis is outlined in Table 64.5. The blepharitis should initially be classified into either anterior or posterior lid disease or both (Table 64.2). It is important to decide whether blepharitis is the cause of the symptoms; seborrhoea rarely causes symptoms and should not be used as a scapegoat to explain away symptoms possibly due to other, or undiagnosable, conditions. Other conditions that give rise to similar symptoms and signs (Table 64.2) should be excluded or treated. Symptoms of dry eye and associated skin disorders should also be treated.

Diffuse folliculitis is generally caused by *S. aureus* and requires a course of an appropriate systemic antibiotic. Laboratory investigations are of limited value—bacteriology

Fig. 64.6 Rarer causes of chronic blepharitis. (a,b) Sebaceous carcinoma of the upper lid. Basal cell carcinomas (BCCs) may also 'masquerade' as chronic blepharitis. (c,d) Blepharitis due to *Phthirus pubis*, showing the louse in (c) and the eggs ('nits') in (d). (e) Typical lid lesion of discoid lupus.

Table 64.4 Causes of acute blepharitis.

Acute anterior lid margin	Folliculitis (infected lash follicles) External hordeoleum (stye) Angular (at lateral canthus) Impetigo Pustular (herpes infections)
Acute posterior lid margin	Chalazion Internal hordeoleum
Generalized anterior and posterior	Necrotizing fasciitis

samples can be taken from lid margins using swabs dipped in trypsin digest broth, but are usually only performed for recurrent disease that has not responded to initial therapy.

Chalazion will resolve in time, approximately 60% of lesions will resolve in 6 months and the remainder will resolve spontaneously given longer. Resolution of chalazia can be hastened by incision and curettage; the lid is incised, usually from the conjunctival surface under local anaesthesia, and the necrotic granulomatous tissue in the

Table 64.5 Treatment of chronic blepharitis.

Aims of treatment	Therapeutic guidelines
For anterior lid margin disease (ALMD)	
Treat infection	Staphylococcal and mixed staphylococcal/seborrhoeic groups Topical antibiotics—chloramphenicol or fucidic acid—four times daily to lid margins Oral oxytetracycline or erythromycin 500 mg b.d. for 10 days
Clean lid margins	'Lid scrubs': 1–2 times daily with cotton wool bud dampened in boiled water or with proprietary lid cleaning pads, to remove debris
Lid hyperaemia and exudate	Topical chloramphenicol and hydrocortisone 0.5–1.0% to lid margins 2–4 times daily for 1 month
For posterior lid margin disease (PLMD)	
Mechanically unblock meibomian glands	Apply hot compresses for 3–5 min to liquefy meibomian secretions, followed by massage* of tarsal plate with cotton wool bud (or finger), to express lipid from glands, 1–2 times daily
Alter meibomian secretions	Oral oxytetracycline (doxycycline 100 mg o.d.) or erythromycin 250–500 mg b.d. for 12 weeks minimum
For the tear film	
Restore tear film	Artificial tears—drops 2–4 hrly, or Viscotears 3–4 times daily
For associated conjunctivitis (papillary or mixed follicular and papillary)	
Reduce inflammation	Fluoromethalone 0.1% four times daily for 1 week, progressively reducing to one time daily over a further 4 weeks
Treat associated skin disease	Seborrhoea—medicated soap and shampoo (ideally containing glycolic acid 10–15%) Rosacea—oral oxytetracycline (or doxycycline 100 mg) or erythromycin 250–500 mg b.d. for 12 weeks
For keratitis	
Coarse punctate keratitis and/or marginal keratoconjunctivitis	Fluoromethalone 0.1% four times daily for 1 week, progressively reducing to once daily over a further four weeks†
Corneal thinning and perforation	Exclude and treat any concomitant microbial keratitis and establish disease control by methods summarized above, apply tissue glue to perforations. Carry out tectonic keratoplasty, if necessary, once the inflammation is controlled.

* Lid scrubs, lid massage and low dose systemic antibiotics take about 4–6 weeks to start to work. DO NOT assume treatment has failed until at least 8 weeks on treatment has elapsed, and continue the regime for a minimum of 2–3 months if benefit is shown. Then advise a maintenance regime of lid scrubs (for ALMD), hot compresses and tarsal massage (for PLMD), ± artificial tears. In the case of relapse, repeat a 3-month course of oral antibiotic treatment.
† More prolonged courses of corticosteroid or more potent corticosteroids may be needed under specialist ophthalmological supervision.

centre of the lesion removed with a curette. This leaves a linear conjunctival and tarsal scar. It is only recommended for cosmetic reasons or to improve vision in large lesions affecting the upper lid which can cause temporary astigmatism.

Practice points for dermatologists are that the association between blepharitis and skin disease is variable, that treatment with tetracyclines may be beneficial for both the ocular and dermatological manifestations of these disorders, and that ocular rosacea and staphylococcal blepharitis may produce sight-threatening complications.

Atopy and atopic eye disease

Description and epidemiology [1–5]

This group of disorders, usually known as the allergic eye diseases, is better termed the atopic eye diseases to distinguish them from disorders which result from other hypersensitivity mechanisms. The atopic eye diseases comprise a group of disorders which have in common a papillary conjunctivitis and evidence of a type 1 allergic mechanism; the immunopathogenesis has recently been shown to be more complex than this. Table 64.6 summarizes these disorders and Fig. 64.7 shows the commoner clinical signs.

Of these disorders only atopic keratoconjunctivitis (AKC) (Figs 64.7b,g), atopic blepharoconjunctivitis (ABC) and vernal keratoconjunctivitis (VKC) (Figs 64.7c,d) are of interest to the dermatologist because of their association with atopic dermatitis and will be described here. Of these AKC and VKC are sight-threatening disorders that are often difficult to treat; VKC occurs in children and 90% of cases resolve in adult life. All of these diseases are uncommon. Only a small proportion of patients with atopic dermatitis have ocular disease. The severity of symptoms is closely related to disease activity, and patients with minimal symptoms will respond to simple treatment with antihistamines and/or mast cell stabilizers that have an excellent safety profile. However, acute exacerbations of AKC and VKC must be recognized and treated promptly as these may develop within hours and can lead to blinding corneal complications within 1–2 days.

Symptoms are similar for all of these atopic eye diseases. Typically there is itching, watering and the production of a sticky white and stringy mucous discharge. During exacerbations the symptoms increase in severity very rapidly—the itching may be superseded by extreme discomfort with soreness and a foreign body sensation, and the vision deteriorates. The lids may be difficult to open in the morning because of a combination of discomfort and discharge.

Signs that can be seen without a slit-lamp examination are thickened lids; in AKC and ABC the lid margins are usually inflamed, crusted and excoriated with madarosis (Fig. 64.7g). Lid margin signs are uncommon in VKC. The bulbar conjunctiva is inflamed during exacerbations but otherwise grossly normal except for the limbal region which may be thickened and nodular (Fig. 64.7d) with the presence of pinpoint Trantas' dots at the apices of the nodules; these may be present in AKC and in the limbal type of VKC. The distinction between limbal and palpebral VKC is principally of interest to the ophthalmologist; in the UK the limbal form of the disease is generally easier to manage although this may not be the case in Africa. The lower tarsal conjunctiva is usually less abnormal than that of the upper lid, which can be seen to be thickened and velvety when the lid is everted. In VKC, and in some cases of AKC, 'giant' compound papillae are easily seen (Fig. 64.7c). In adults with long-standing disease there is sheet-like scarring of the upper tarsal conjunctiva and shortening of the lower conjunctival fornix. During exacerbations the tarsal conjunctiva becomes very inflamed and covered in adherent mucous. The corneal signs, with the exception of plaque (Fig. 64.7e) or ulceration due to superadded infection (Fig. 64.7f), are difficult to see without a slit lamp but fluorescein staining is diffuse during flare-ups of disease.

Diagnosis

The clinical features, together with a personal or family history of atopy, are usually sufficient for diagnosis. Laboratory investigations are only needed in patients who do not respond to therapy or who require topical (or systemic) immunosuppressive therapy for relief of symptoms, or when the diagnosis is uncertain. Serum IgE and skin prick tests have no value in the diagnosis of atopic conjunctivitis as the results do not indicate the antigens precipitating the eye disease. Ophthalmic investigations are the province of the ophthalmologist and are summarized in Table 64.6.

Immunopathogenesis [6–9]

Recent advances in the understanding of these diseases have come from investigations of the humoral mediators of inflammation in the tears, and analysis of the cellular components by immunostaining and *in situ* hybridization. These techniques have shown that seasonal allergic conjunctivitis (SAC) and perennial allergic conjunctivitis (PAC) are primarily typical type 1 hypersensitivity diseases, whereas the others show varying degrees of a coexisting type 4 hypersensitivity response. SAC and PAC show mast cells and eosinophils in the conjunctival mucosa and submucosa, with high levels of locally produced IgE to specific allergens being present in the tears.

Table 64.6 Clinical characteristics and distinguishing features and diagnosis of the atopic eye diseases.

Disease	Disease course	Conjunctival signs	Corneal signs	Disease associations	Diagnostic tests
Seasonal allergic conjunctivitis (SAC)	Onset 5–20 years Spontaneous remissions common Rare in old age Strikingly seasonal	Hyperaemia. Stringy white discharge. Oedema Micropapillae if severe	None	Personal or family history of atopy including atopic dermatitis	*Cytology*: usually normal. Serum & tear IgE often elevated but not diagnostic
Perennial allergic conjunctivitis (PAC)	As for SAC but symptoms all year round with seasonal exacerbations	Hyperaemia, stringy white discharge, micropapillae common	None	Personal or family history of atopy including atopic dermatitis	
Atopic keratoconjunctivitis (AKC)	Onset between 20–50 years. Chronic course over many years (Fig. 64.7g). Spontaneous resolution in old age Non-seasonal	Micropapillae with intense infiltrate (Fig. 64.7b). Reticular and sheet scarring. Shortened fornices in some cases Trantas' dots*	Punctate epithelial keratopathy, pannus, macroerosion† and plaque‡ Pseudogerontoxon§. Herpes keratitis and bacterial keratitis (Fig. 64.7f) common	*Systemic*: atopy and atopic dermatitis in all cases *Ocular*: staphylococcal lid disease, cataract, keratoconus, herpes simplex keratitis (often bilateral)	*Cytology*: shows eosinophils and mast cells. Serum IgE elevated. Skin prick tests positive to many allergens but not diagnostic *Upper tarsal conjunctival punch biopsy*: the gold standard for disease confirmation after a 2 week abstention from use of topical corticosteroids *Tear IgE*: useful unless the serum IgE is very high; an office test is now available (*Lacrytest* from Adiatec SA, France)
Atopic blepharoconjunctivitis (ABC)	As for AKC	Micropapillae with intense infiltrate, reticular scarring	None	Personal or family history of atopy	
Vernal keratoconjunctivitis (VKC)—*palpebral, limbal and mixed forms*	Onset between 5–15 years. Spontaneous resolution in 95% after 10 years Seasonal exacerbations usual	*Palpebral form*: giant upper tarsal papillae (Fig. 64.7c) often bilaterally asymetrical *Limbal form*: micropapillae on upper tarsus but gelatinous macropapillae at limbus (Fig. 64.7d). Trantas' dots in both *Mixed form*: combines features of both diseases	*Palpebral form*: punctate epithelial keratopathy affecting upper half of cornea. Adherent mucous appearing as superficial syncytial opacity progressing to macroerosion and vernal plaque (Fig. 64.7e) *Limbal form*: keratopathy extending in from limbus with associated epithelial dysplasia	*Ocular*: keratoconus and cataract *Systemic*: atopy in variable proportions from 0–100% depending on geographical location (atopy common in Northern Europe but rare in Middle East)	

* Trantas' dots: white pinhead sized dots consisting of eosinophils and necrotic epithelial cells.
† Macroerosion: large epithelial erosions usually in upper half of cornea.
‡ Plaque (vernal plaque): laminated structure of protein and polysaccharide adherent to the anterior stroma with destruction of Bowman's layer.
§ Pseudogerontoxon: arcus-like appearance in relation to limbal pannus; may disappear in remissions.

Fig. 64.7 Atopic eye disease. (a) Normal upper tarsal conjunctiva; the tarsal vessels are clearly visible through the healthy conjunctival epithelium and substantia propria. (b) Atopic keratoconjunctivitis with an infiltrated, papillary, upper tarsal conjunctiva. Compare with the normal tarsal conjunctiva in (a). (c) Showing 'giant' or compound upper tarsal papillae and the mucous exudate that develops during an exacerbation. (d) Vernal keratoconjunctivitis (VKC) (limbal form) showing the typical pale limbal papillae. (e) Fully developed vernal plaque. (f) Bacterial keratitis complicating atopic keratoconjunctivitis (AKC) showing a corneal infiltrate. The eyes of this patient are shown in (g), with atopic eczema localized to the eyelids; the eczema is often generalized. The right eye shows the infection in (f).

The diseases can be mimicked by topical instillation of antigen; this reaction is blocked by drugs that are active against mast cells. AKC and VKC show both the cellular components present in SAC and VKC but also connective tissue hyperplasia, CD4 T lymphocytes and plasma cells, together with different subsets of mast cells. The T cells are probably important inducers of the cellular inflammatory response in these diseases. Differences in AKC and VKC phenotypes may be explained by differences in the predominance of T-helper subsets; the Th1 subset, predominant in delayed type hypersensitivity responses and inactivated by ciclosporin, is more predominant in AKC than in VKC, in which the Th2 subset, with a B-cell-helper role, may be more important. Mast cells and eosinophils are found in larger numbers in VKC than in AKC and functional heterogeneity in their populations may also be determinants of disease phenotype.

These effector cell types are known to cause atopic eye diseases by the following mechanisms. Mast cells release preformed mediators by exocytosis when they degranulate in response to binding of IgE with allergen. The important mediators released are histamine, resulting in hyperaemia, oedema and mucous production, and prostaglandins. Histamine has been detected in the tears in these diseases. Eosinophils release cationic proteins including major basic protein, which is epitheliotoxic and has been identified in the tears in VKC. It is probably a major factor responsible for the development of corneal epithelial erosions and macroerosion. The presence of the latter, with the mucous and debris present in an acute exacerbation of keratopathy, accounts for the formation of plaque. B cells produce IgE locally in atopic conjunctivitis; locally produced IgE is an important factor in the pathogenesis of SAC, PAC and some cases of VKC, but less so in AKC and ABC.

Management [10,11]

The management of VKC and AKC requires specialized ophthalmological care, as these diseases are uncommon, and some of the management strategies are outside the remit of the general ophthalmologist. Topical cromones (sodium cromoglycate 2–4% or the more recently introduced nedocromil or lodoxamide) are the first-line treatment given 1–4 times daily depending on symptoms. The newer cromones have been more effective in trials of SAC. Addition of a potent topical antihistamine (levocabastine or emedastine) or a systemic antihistamine may help relieve itch. These treatments are very safe and do not require ophthalmological supervision but are only effective for very mild disease. Cromones are often not tolerated until the inflammation is brought under control with high dose topical corticosteroids such as dexamethasone 0.1% or prednisolone acetate 1%. These will precipitate glaucoma in 10% of patients as well as contributing to cataract; as soon as the disease is brought under control, a 'safe' corticosteroid with a lower risk of precipitating glaucoma (about 1% risk) should be substituted (fluoromethalone, rimexolone or clobetasone). Cromones are used topically, whenever possible, as corticosteroid-sparing drugs.

Topical ciclosporin is not yet available commercially, although a preparation designed for use in dry eye is expected to be available soon (Restasis, Allergan, USA). It has shown promise in trials for AKC. Trials of ciclosporin 2% (available from some hospital pharmacies) have been very encouraging and a 0.02% veterinary ointment (Optimmune, Schering) has been successfully used by the authors. Adverse effects, apart from stinging, are infrequent and introduction of the drug as a corticosteroid sparing agent, for patients requiring high doses of topical corticosteroids, has allowed reduction or complete withdrawal of corticosteroids in many cases. Topical ciclosporin is most successfully tolerated if introduced during remissions.

Systemic immunosuppression is needed in severe exacerbations of disease; a 3–4 week course of systemic corticosteroids starting at a prednisolone dose of 60 mg daily, may be necessary to bring the disease under control while topical therapy is introduced. These also carry a risk of glaucoma. Patients with a previous history of labial or ocular herpes simplex (HSV), or serological evidence of previous exposure to HSV, should be aware that they may develop herpetic keratitis while on systemic or topical corticosteroids. Patients who have had previous episodes of ocular HSV should receive prophylaxis with oral aciclovir 400 mg b.d. (or valaciclovir 500 mg o.d.); topical prophylaxis is unnecessary and may complicate the clinical signs in patients with a complex keratoconjunctivitis. Patients with AKC are predisposed to bilateral herpes keratitis and prophylactic antivirals are advisable when they are using corticosteroids.

For a small number of patients, systemic ciclosporin (usually starting at 5 mg/kg) can be very helpful. Patients who need systemic ciclosporin for management of their atopic eczema will usually obtain substantial collateral ocular benefits.

Severe staphylococcal blepharitis often accompanies AKC and ABC and can be treated with a course of azithromycin followed by local therapy with an antibiotic ointment to which the skin flora is sensitive, usually chloramphenicol, together with a topical ophthalmic corticosteroid ointment such as hydrocortisone 0.5% or 1.0%. Combined preparations often contain aminoglycosides which frequently cause toxicity or allergy and should be avoided.

The management of the corneal complications that often accompany these conditions (vernal plaque, bacterial keratitis and herpes keratitis) are beyond the scope of this summary but present challenging management problems in the context of these conditions.

Practice points for dermatologists are that the dermato-

logist should be aware that any sudden deterioration in vision may herald one of the blinding complications of these diseases and should be treated as an emergency. Good control of the underlying condition aims to reduce the frequency with which the blinding corneal complications develop, whilst minimizing the potentially serious side effects of corticosteroid treatment.

The interaction of drugs used for the management of atopic eye disease and atopic dermatitis

Most cases of atopic eye disease are managed with topical ocular therapy which has no effect on the dermatological aspects of the disorder. However treatment with courses of systemic corticosteroid and/or ciclosporin, when needed either for the dermatological or ophthalmological aspects of atopy, are beneficial to the management of both. The risk of glaucoma from systemic corticosteroids, while occurring, is very low whereas topical application of corticosteroid around the eyelids probably constitutes a higher risk; patients who chronically use corticosteroid cream around the eyes should have glaucoma screening.

Cicatrizing conjunctivitis and the immunobullous disorders

Description and epidemiology [1–4]

Cicatrizing conjunctivitis, although uncommon, is one of the most difficult management problems in ophthalmology because of the widespread effects on the ocular surface leading to corneal blindness in many victims. The classification of the conjunctival disorders follows the dermatological classification although not all the dermatological disorders are associated with conjunctivitis (Table 64.7).

Table 64.7 Immunobullous diseases (those associated with conjunctivitis are shown in italics).

Intraepithelial	Subepithelial
• Pemphigus *vulgaris* vegetans sebhorreic	• Pemphigoid *Bullous* *Cicatricial* (Fig. 64.8a–f)
• Pemphigus foliaceous	• Pemphigoid gestationis
• Pemphigus erythematosis	• *Epidermolysis bullosa aquisita*
• Brazilian pemphigus	• Bullous systemic lupus erythematosis
• *Paraneoplastic pemphigus*	• *Linear IgA disease*
	• *Dermatitis herpetiformis*
	• *Lichen planus*
Graft-versus-host disease	
Erythema multiforme • Minor • *Major (Stevens–Johnson syndrome)*	
Toxic epidermal necrolysis (Lyell syndrome)	

The severity of the conjunctival involvement varies but is mild, without scarring, in pemphigus vulgaris, and with variable degrees of scarring and severity in the remainder.

Cicatricial pemphigoid (CP) [5–9]

CP is the commonest of these rare disorders. It is a systemic disease with involvement of the skin (25% of cases), oro-pharyngeal mucosa (85% of cases) and conjunctiva (65% of cases) and may be localized to one of these sites alone. About 70% of patients presenting to a dermatologist will have conjunctival involvement, in addition to skin disease, whereas disease confined to the conjunctiva alone is found in 50% of patients in ophthalmology clinics and is known as ocular cicatricial pemphigoid (OCP). Some authorities feel that the term mucous membrane pemphigoid should be adopted but this belies the scarring nature of the disease when it affects the eye and will not be used in this discussion.

Epidemiology of CP

Unambiguous data on the epidemiology of the disease is difficult to obtain because studies have been based on the site of involvement. However the incidence of dermatological disease is about 1/million/year. This is likely to be an underestimate of the disease as a whole because mucosal presentations are more common. In ophthalmology centres CP affects between 1 : 8000 and 1 : 46 000 patients. The male : female ratio is 1 : 3 and age range

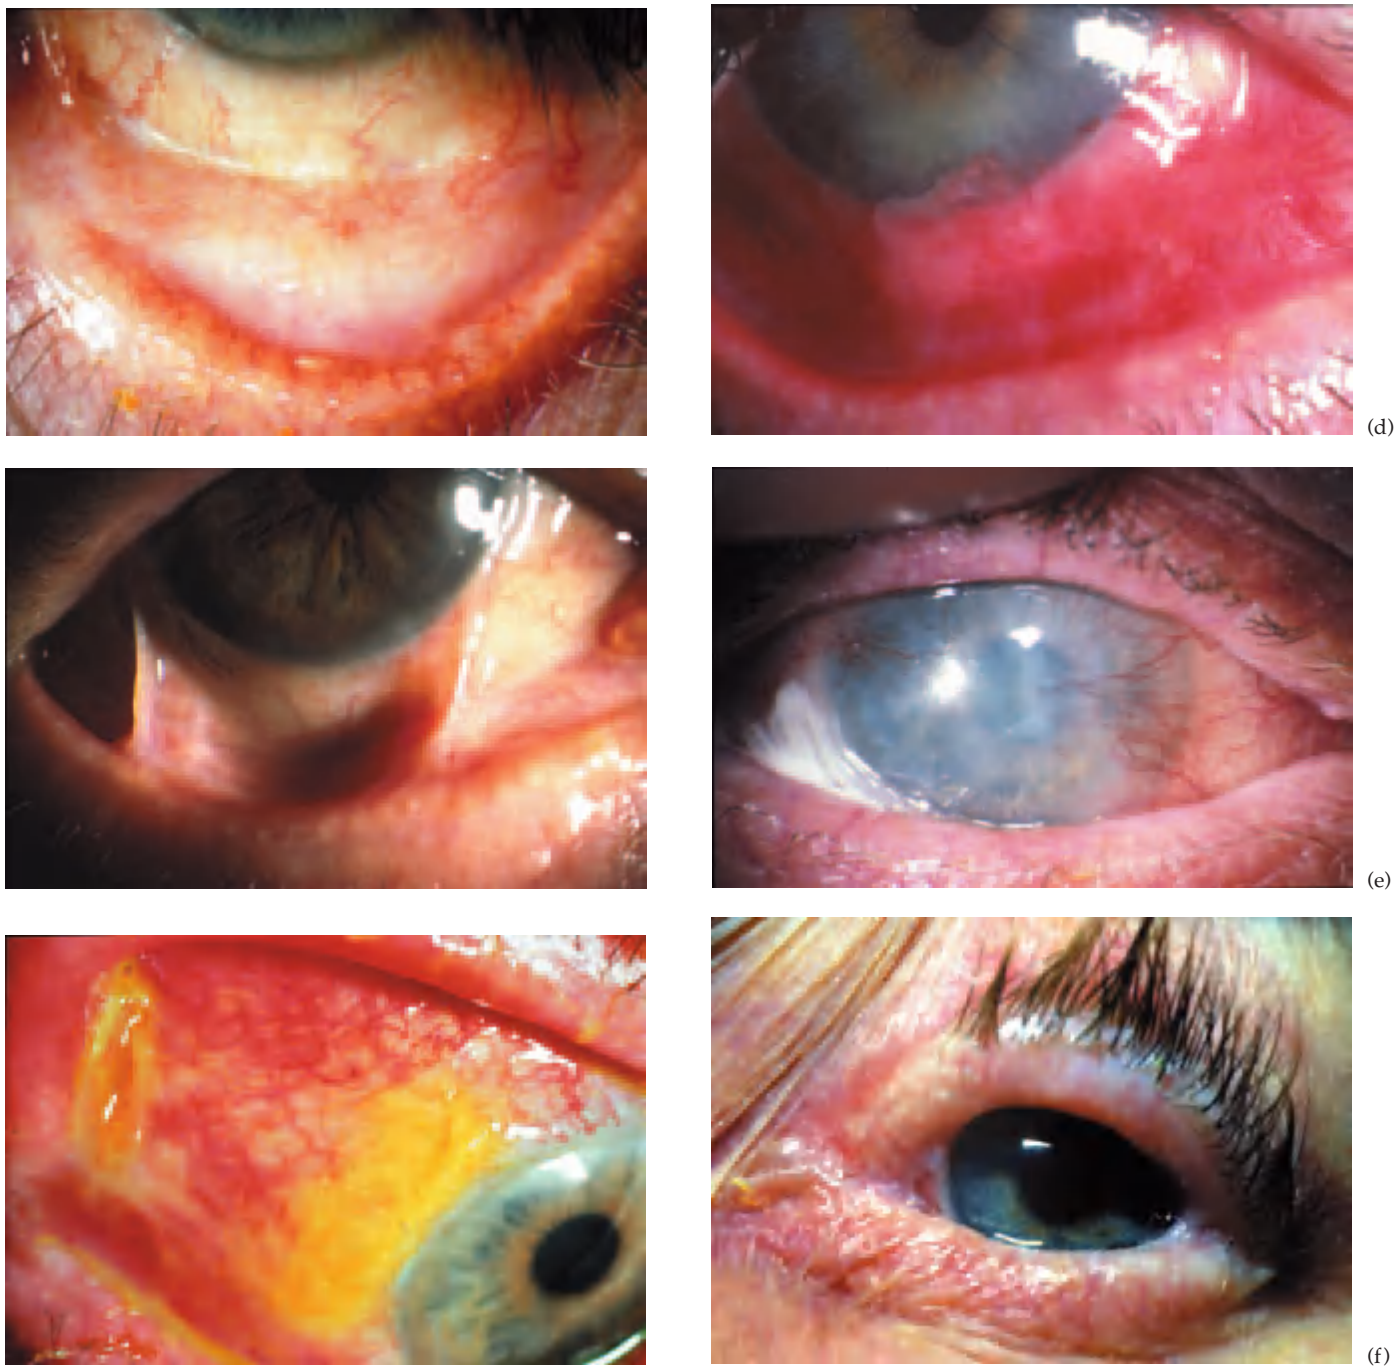

Fig. 64.8 Ocular signs of cicatricial pemphigoid (CP). (a) Inferior fornix shortening and subconjunctival scarring. (b) Conjunctival symblepharon tethering the globe to the lower lid. (c) Acute exacerbation of conjunctival CP showing conjunctival ulceration. This occurs in only 10% of patients presenting with CP affecting the eye. (d) Severe conjunctival inflammation and limbitis. This leads rapidly to the ocular surface failure and corneal blindness shown in (e) unless it is promptly controlled with adequate immunosuppressive therapy. (e) Ocular surface failure and keratinization (the white area) in advanced pemphigoid. This eye is blind. (f) Advanced ocular pemphigoid showing loss of the medial canthal structures (plica and caruncle) with a reduced interpalpebral aperture secondary to shortening of the fornices (as in (a)) and fusion of the tarsal and bulbar conjunctiva.

30–90 years with peak onset in the seventh decade, although patients may rarely present in childhood and in extreme old age. At presentation between 25 and 38% of patients with ocular disease have significant visual loss and about 30% become legally blind. Treatment has been shown to slow disease progression. A genetic predisposition has been found in an association with the *DQw7* gene and expression of the HLA-DR4 antigen.

Clinical features [10]

Most patients with OCP have progressive disease. However, early presenting disease is usually milder and progresses more slowly than late-presenting disease. Current aggressive treatment regimens, with systemic immunosuppression, have been shown to reduce the rate of progression by about 50%. Because patients can occasionally progress to blindness within months from the onset, both early diagnosis and effective treatment are critical in improving the prognosis.

In most patients the onset is insidious, with non-specific conjunctival symptoms including irritation, hyperaemia and discharge. Dry eye and mucous deficiency are late signs. Acute disease occurs in about 20% of new patients with severe inflammation and conjunctival ulceration; this presentation may follow lid surgery for entropion on undiagnosed cases.

Signs, in order of progression, often start at the medial canthus with loss of the plica and later of the caruncle (Fig. 64.8f), subepithelial reticular fibrosis of tarsal conjunctiva (Fig. 64.8a), conjunctival infiltrate due to increased cellularity and collagen formation (Figs 64.8c.d), hyperaemia, shortening of the fornices (Fig. 64.8a), symblepharon (Fig. 64.8b), blepharitis, trichiasis and entropion, punctate keratopathy, limbitis, conjunctival and corneal keratinization, and corneal surface failure (Fig. 64.8e). Late disease results in fusion of the lids and globe (Fig. 64.8f), and may obscure the cornea completely. Persistent epithelial defect, microbial keratitis and corneal perforation are common and, with the corneal surface failure, account for the management challenges posed by the disease. Cicatricial pemphigoid is associated with the autoimmune diseases rheumatoid arthritis, systemic lupus erythematosus and polyarteritis nodosa.

Diagnosis

Laboratory investigations [11–13] require specialized services and are only positive in 40–60% of cases so that for practical purposes a clinical diagnosis, based on a history of progression and the presence of the typical clinical signs, is adequate in most cases outside a clinical research setting. However, laboratory investigations for OCP may be useful. Indirect immunofluorescence for circulating antibodies to conjunctival basement membrane are present in 50% of cases of CP but the ability to perform this test requires a constant source of conjunctival substrate. The sensitivity of indirect immunofluorescence can be significantly increased using 1.0 mol/L sodium chloride split skin as the substrate.

Bulbar conjunctival biopsy is easy and safe providing the inferior fornix is avoided. Routine histopathology is of little value in the diagnosis because the conjunctiva is fragile and detection of basement membrane zone cleavage unreliable. Squamous metaplasia of the conjunctival epithelium and a reduction in goblet cells are non-specific findings as is an increased inflammatory cell infiltrate. In acute disease there is a neutrophil-rich infiltrate. Direct immunofluorescence for IgA, IgG, IgM, and complement is positive with linear staining at the conjunctival basement membrane in 50% of cases and is characteristic of OCP. However biopsies are often negative in acute disease and may revert to normal in time or after treatment.

Table 64.8 Causes of non-autoimmune cicatrizing conjunctivitis.

Chemical, thermal or mechanical trauma
Factitious (self-induced) conjunctival trauma
Others
Ocular rosacea
Staphylococcal blepharoconjunctivitis

Differential diagnosis

The conjunctival signs in CP and OCP may be identical to those produced by the other immunobullous disorders that are summarized in Table 64.7. However, in these conditions the skin disease precedes the ocular disease so that there is rarely any confusion. In erythema multiforme major, exacerbations of conjunctival inflammation can occur many years after the acute disease leading to a condition indistinguishable from OCP both in terms of the clinical signs and immunopathology. The principal problems in differential diagnosis relate to diseases other than the immunobullous disorders, that may also cause cicatrizing conjunctivitis (Table 64.8). Patients with conjunctival cicatrization secondary to infective causes are sometimes referred for investigation of what has been longstanding conjunctival scarring, following a long forgotten episode of infection, in whom the absence of a recent history of inflammation, or of progressive symptoms, usually indicates static disease. Patients with sarcoidosis or systemic sclerosis normally have a well-established diagnosis by the time conjunctival scarring develops. However, Sjögren's syndrome may mimic early OCP but can usually be differentiated by the presence of Sjögren's

specific antibodies and/or a positive labial biopsy. AKC can occasionally be difficult to differentiate from slowly progressive OCP but the history and clinical signs of severe eczema, and a tarsal conjunctival biopsy (performed after withdrawal of topical corticosteroids for 2 weeks) that shows excessive numbers of mast cells and eosinophils, can confirm the diagnosis. Iatrogenic conjunctivitis is non-progressive, except in the case of drug-induced OCP, which is indistinguishable from classical OCP. Awareness that conjunctival scarring can occur in ocular rosacea and in staphylococcal bleph-aroconjunctivitis (see Fig. 64.5a) is usually enough to distinguish these conditions from OCP. Factitious conjunctival trauma is rare and usually more focal than classical OCP but can mimic OCP while the self-trauma is active.

Pathogenesis [14,15]

OCP is probably primarily an autoimmune disease directed at the conjunctival basement membrane; progression occurs as a result of inflammatory disease and cicatrization, secondary ocular surface disease, infection and treatment toxicity. Drug-induced pemphigoid (pseudopemphigoid), and Stevens–Johnson syndrome lead to an identical situation, suggesting that conjunctival damage may precipitate OCP. OCP may be the final common pathway for one type of conjunctival insult.

Inflammatory mechanisms in OCP are reasonably well understood and provide a rationale for immunosuppressive therapy. In chronic disease macrophages and T cells are present, of which the Th1 subset is active, as demonstrated by the presence of the cytokines, interleukin-2 and interferon-γ, as opposed to the Th2 subset that is involved in B-cell activation. This, coupled with the low numbers of B cells but increased number of plasma cells, suggests that B-cell activation must be occurring in the extraocular tissues with homing of mature plasma cells to the conjunctiva. Major histocompatibility complex (MHC) class II expression is increased, suggesting the potential for local antigen presentation to T-helper cells. There is a slight increase in activated T cells, which are involved in the recruitment of fibroblasts and macrophages. In acute disease, neutrophils and antigen-presenting (dendritic) cells are also present together with an increase in CD4 (helper) T cells, which probably reflects their role in recruiting other inflammatory cells.

Growth factors including fibroblast growth factor (FGF), platelet-derived growth factor (PDGF) and transforming growth factor-β (TGF-β) are all present in OCP. PGDF up-regulates the extracellular matrix component (ECM) thrombospondin, which is itself important in activating latent TGF-β. PDGF is a powerful chemoattractant for macrophages and fibroblasts and is probably pivotal to the scarring response. However only TGF-β is capable of stimulating fibroblasts to produce collagen and ECM components. It also blocks matrix degradation by decreasing protease synthesis and increasing protease inhibition. In acute disease, TGF-β is significantly increased and is produced by macrophages and fibroblasts in OCP conjunctiva. Once macrophages and fibroblasts are present in large numbers and activated they may become self regulating; T-cell deficient models have shown that T cells are not necessary for wound healing to occur, and fibroblasts from OCP conjunctiva display abnormal activity in cell culture after several passages.

This inflammatory cell infiltrate is also associated with the presence of increased amounts of an abnormal type II 'curly' collagen.

Implications of immunopathological findings for therapy

Inflammation is important in acute disease; severe inflammation is associated clinically with rapid scarring and therefore demands effective immunosuppression to reduce scarring. Inflammation may also play a role in chronic disease although scarring often continues even in the presence of minimal inflammation, suggesting that growth factor production by macrophages and fibroblasts is relatively independent of the other inflammatory cells. Therefore modulation of growth factor activity, collagen metabolism or fibroblast activity may be necessary to halt the disease process. Of these, growth factor activity can potentially be specifically blocked or inhibited, thus holding promise for new treatments.

Other subepithelial immunobullous disorders and conjunctivitis [16]

Other immunobullous disorders are much less frequently associated with conjunctival cicatrization. As a result little is known about the pathogenesis of the conjunctival disease as opposed to the events in the skin. Bullous pemphigoid generally results in mild conjunctivitis although severe cicatrization has been reported. Epidermolysis bullosa aquisita, linear IgA disease, dermatitis herpetiformis and lichen planus may all be associated with progressive conjunctival scarring indistiguishable from that of CP.

Erythema multiforme major and toxic epidermal necrolysis [17–21]

The ocular complications of these two conditions are identical (Table 64.9); about 70–80% of patients admitted for treatment of these diseases will develop eye disease. It is the eye disease which leads to the most profound long-term morbidity in many such patients. In addition the eye disease, unlike the lesions affecting the remaining

Table 64.9 Ocular effects of Stevens–Johnson syndrome and toxic epidermal necrolysis.

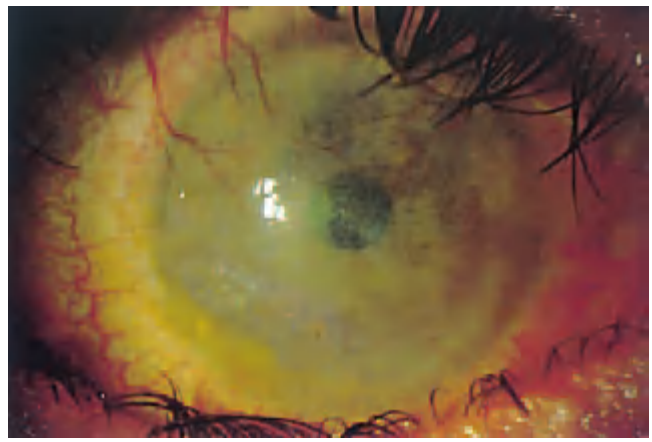
Ocular effects	Resulting symptoms and signs
Loss of goblet cells	Disrupted tear film leading to poor vision and punctate keratopathy (Fig. 64.9b)
Loss of accessory lacrimal glands	
Scarring of meibomian gland orifices	
Metaplasia of meibomian gland epithelium with development of metaplastic lashes	Trichiasis secondary to metaplastic lashes (Fig. 64.9b)
Conjunctival scarring and obliteration of lacrimal gland ductules	Very dry eye with secondary conjunctival and corneal squamous metaplasia (Fig. 64.9b)
Keratinization due to squamous metaplasia	Exacerbates drying and discomfort
Conjunctival scarring with fornix shortening and symblepharon formation	May cause lagophthalmos
Retroplacement of meibomian gland orifices	Disrupts tear film
Entropion of upper and lower lids with trichiasis of both metaplastic and normal lashes	
Lid shortening	
Corneal epithelial failure secondary to limbal inflammation	Blindness

mucosal surfaces, may progress years after the acute episode has resolved.

Acute ocular complications usually occur concurrently with the skin disease but may sometimes precede it by several days. The conjunctivitis varies from a papillary reaction with watery discharge (Fig. 64.9a) to a membranous conjunctivitis with sloughing of the conjunctival epithelium. Corneal epithelial defects are common and may progress to corneal ulceration with or without bacterial superinfection. The morbidity of the disease may be due to the acute corneal complications but is more usually due to conjunctival scarring.

Chronic ocular complications are numerous. The severe conjunctival inflammation leads to loss of goblet cells and the accessory conjunctival lacrimal glands as well as disruption of the meibomian gland orifices leading to MGD. This results in a disrupted tear film and a secondary punctate keratinopathy. In mildly affected patients this causes chronic mild discomfort, photophobia and slightly reduced vision. In more severely affected patients the conjunctival inflammation leads to cicatrization of the lacrimal ductules resulting in a severely dry eye accompanied by squamous metaplasia and keratinization of both the conjunctival and corneal components of the ocular surface, resulting in more severe discomfort and loss of vision (Fig. 64.9b). In addition the meibomian gland ductal epithelium undergoes metaplasia resulting in the development of fine metaplastic lashes. The conjunctival shortening leads both to entropion, resulting in ocular surface abrasion by normal as well as by any metaplastic lashes, and may also cause lid shortening leading to reduced eye closure (lagophthalmos) which is easily overlooked. Lash abrasion and trichiasis lead to the development of corneal epithelial defects which, as

(a)



(b)

Fig. 64.9 Ocular disease in Stevens–Johnson syndrome. (a) Acute conjunctivitis in a patient with mild Stevens–Johnson syndrome. The conjunctiva is hyperaemic with a papillary reaction and mucopurulent discharge. (b) The late ocular complications of Stevens–Johnson syndrome showing entropion, a dry eye with ocular surface failure (in this case an opaque keratinized epithelium).

a result of the poor tear film, may persist. Persistent epithelial defect predisposes to corneal stromal melts and perforation, which are often precipitated by infection. The severe inflammation may also lead to ocular surface failure, not only as a result of squamous metaplasia, but also by loss of corneal epithelial progenitor cells (stem cells). This evolution of changes is not the direct consequence of the acute disease but is secondary to the effects on the tear film and lids, compounded in some cases by chronic or acute episodes of inflammation for which the pathogenesis is obscure. Late onset scleritis may also occur.

Graft-versus-host disease [22–28]

Ocular complications are common in patients with graft-versus-host disease (GVHD) and result from involvement of both the conjunctiva and the lacrimal gland. In acute GVHD, conjunctivitis ranges from hyperaemia through chemosis to a pseudomembranous conjunctivitis, with or without corneal epithelial sloughing. Severe conjunctival involvement is a marker for the severity of acute GVHD and was found to occur in 12% of patients in one study; this subset had 90% mortality [26]. In chronic GVHD the same study found conjunctival involvement in 11% of patients for whom it was also associated with disease severity. Some of these patients develop a severe scarring response like that of CP. Lacrimal gland involvement occurs in about 50% of patients with chronic GVHD who develop a Sjögren type picture of dry eyes.

The pathogenesis of the conjunctival disease has been examined in a few cases and appears to be similar to that in the skin.

Treatment of cicatrizing conjunctivitis and the ocular complications of the immunobullous disorders [29–35]

The same strategies can be used to treat the ocular aspects of all these disorders. The three principal treatment aims are: (i) management of the ocular surface disease; (ii) eliminating or minimizing treatment toxicity; and (iii) suppressing inflammation.

These three components of the treatment strategy are not required for all of these diseases. For example, in Stevens–Johnson syndrome most patients have relatively little inflammation once the surface disease has been treated, and any treatment toxicity eliminated, so that it is the minority of these patients, with recurrent inflammation or progressive cicatrization, who require suppression of inflammation. On the other hand most, but not all, OCP patients require use of all three components with 80% of patients requiring systemic immunosuppressive therapy to control inflammation that persists once the surface disease and toxicity has been controlled.

Successful management demands identification and treatment of all of the components of the disorder, including surface disease, treatment toxicity and inflammation related to activity of the underlying disease, as well as the early detection and treatment of secondary corneal infection.

Management of the ocular surface disease

The ocular surface disease is secondary to previous or current lid and conjunctival scarring and inflammation. The surface disease causes much of the damage to the cornea and is responsible for additional inflammation. Trichiasis and entropion, blepharitis, dry eye and filamentary keratitis, keratinization, persistent epithelial defect, microbial keratitis and corneal perforation may all result from a combination of a poor tear film, poor lid closure, and corneal damage secondary to trichiasis. These are treated as follows:

Trichiasis: epilate in the short term, use electrolysis or laser for odd lashes, cryotherapy for misdirected lashes and surgery for entropion (inferior retractor plication for lower lid and anterior lamellar reposition for upper lid).

Blepharitis: use oral tetracyclines and institute a lid hygiene regimen.

Dry eye and filaments: use non-preserved lubricants, topical acetylcysteine 5–10% as a mucolytic, and punctal occlusion to conserve tears (once any blepharitis has been controlled).

Keratinization: topical retinoic acid is effective in 30% but only available in specialized centres.

Persistent corneal epithelial defect: exclude infection, treat ingrowing lashes, use non-preserved lubricants, therapeutic lenses (silicone rubber or silicone hydrogel in dry eyes) and, if these measures are unsuccessful, close the eye with a botulinum toxin protective ptosis or with temporary tarsorraphy. Other more specialized treatments may be needed.

Corneal perforation: temporize with therapeutic contact lenses and/or corneal glue followed by keratoplasty only if absolutely necessary.

Eliminating or minimizing treatment toxicity

Treatment toxicity results principally from the preservative benzalkonium chloride, a component of most reusable bottles of eye drop preparations as well as of topical glaucoma medications and aminoglycoside eye drops.

Unnecessary topical treatment should therefore be avoided and unpreserved drops or saline used as far as possible. The effects of topical treatment toxicity are hard to distinguish from those of the ocular surface disease. After withdrawal of toxic topical therapy the mean recovery period is 2 weeks but may extend to 3 months.

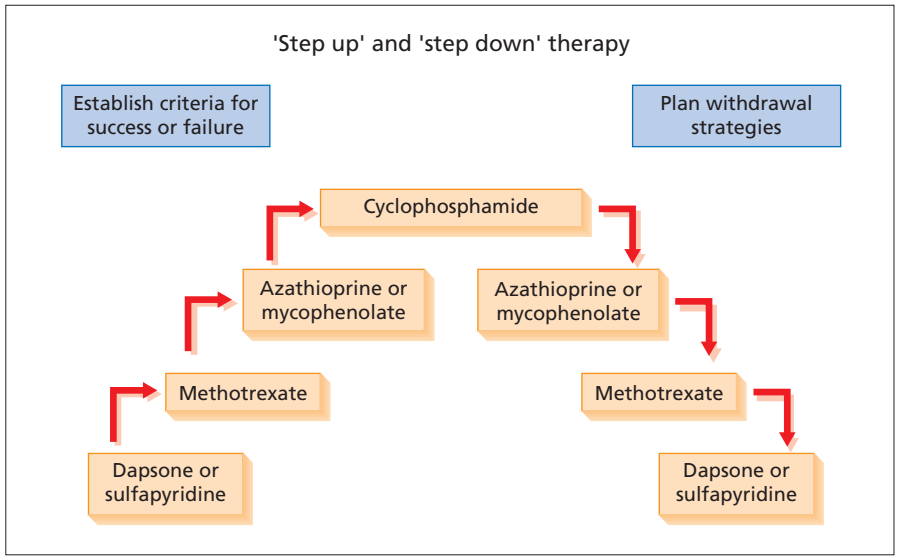


Fig. 64.10 Immunosuppressive therapy for progressive conjunctival cicatrization. 'Step up' and 'step down' therapy. For acute severe disease start at the top of the stepladder and 'step down' to the right (the withdrawal strategy). For less severe disease step up from the bottom left of the figure. The criterion for success is a reduction in inflammation when the surface disease, that may be contributing to it, has been controlled.

Suppressing inflammation—immunosuppressive therapy

Monitoring and side effects of the main immunosuppressive agents are discussed in Chapter 72 and are not repeated here.

In *mild disease* (*hyperaemia and oedema*), low-dose topical corticosteroid may be helpful for a few cases.

For *moderate disease* (*hyperaemia, intense infitration*), sulphapyridine 500 mg daily for 2 weeks then 1 g daily (sulfasalazine 1–2 g daily is an alternative). Fifty-five per cent of patients respond in 1–2 months, but 15% develop an allergic reaction. If response is poor, dapsone 75 mg daily, increased each month by 25 mg daily to 125 mg, can be used; there is a 70% response in 1–2 months reducing to 50% after 1 year. Other agents that may be considered are azathioprine (1–2 mg/kg/day), methotrexate (7.5–25.0 mg once weekly) or mycophenolate mofetil (1–2 g daily) depending on the severity of the disease.

For *severe disease* (*hyperaemia, limbitis, conjunctival ulceration*), start prednisolone 1 mg/kg/day, reduce the dose after 2 weeks and tail off after 2–4 months. This is ineffective at low doses in the long term and a steroid-sparing immunosuppressive agent is generally added for long-term disease control. The most effective currently is cyclophosphamide 1 mg/kg/day. The dose is adjusted until the lymphocyte count is between 0.5 and 1.0×10^9; other haematological parameters should remain normal. Cyclophosphamide therapy is usually discontinued after 1 year and substituted by sulphonamides or immunosuppressive agents as described above.

Most of this therapy is empirical and a sulphonamide (dapsone or sulphapyridine) is often used together with an alkylating agent (cyclophosphamide) or an antimetabolite (azathioprine, methotrexate or mycophenolate) to control inflammation. This immunosuppressive strategy is summarized in Fig. 64.10, and can be modified as necessary for all these disorders; generally any systemic therapy will benefit the underlying disease.

Systemic diseases with skin and eye involvement

Some multisystem diseases affect both the skin and the eye [1–23]. It is not possible to catalogue every complication of all these diseases but the most frequent are summarized in Table 64.10.

Infections

A number of infections involve the eyelids, but the following are important to recognize because they are common or require urgent therapy or referral to an ophthalmologist [1].

Viral infections

Warts

These are common and are found on the eyelid margins often as a long thin projection. Lesions in this site are best treated with careful cryotherapy and accurate application of liquid nitrogen to the tip of the lesion using a cotton wool bud rather than cryospray.

Molluscum contagiosum [2]

This condition mainly affects children and young adults. It is also prevalent in patients with acquired immune deficiency syndrome (AIDS), who may develop multiple lesions around the eyelids. Lesions may grow in the lash line as well as on the lid skin and, occasionally, on the mucocutaneous junction. Lesions can be easily overlooked or mistaken for a sebaceous cyst; this condition must always be considered in the differential diagnosis of

Table 64.10 Systemic diseases with skin and eye involvement.

Systemic disease	Eye disease
Sarcoidosis *Epidemiology*: ocular involvement the presenting feature in 10%. 20–30% of patients have eye disease at some stage [1–7]	*Lids & orbital findings*: clusters of granulomatous eyelid swellings. Proptosis from orbital granulomas. Dry eye from lacrimal gland involvement *Heerfordt's syndrome*: (uveo-parotid fever) consists of uveitis and parotid gland enlargement, fever and facial nerve palsy. *Lofgren's syndrome*: acute iritis, bilateral hilar lymphadenopathy, erythema nodosum and arthralgia. *Mikulicz's syndrome*: bilateral swelling of lacrimal and salivary glands *Anterior segment findings*: *conjunctivitis*: occasionally a granulomatous conjunctivitis mimicking a follicular conjunctivitis. *Uveitis*: usually, but not always, bilateral granulomatous anterior uveitis in 80% of patients with eye manifestations with redness, pain, photophobia and blurred vision with floaters *Posterior segment findings*: rare
Systemic lupus erythematosus [8–10]	*Anterior segment findings*: dry eye, peripheral corneal ulcers. Scleritis is rare. Episcleritis occurs in 10% causing a red eye *Posterior segment findings*: retinal vasculitis common during exacerbations of systemic disease with flame shaped haemorrhages and cotton wool spots. May be associated with severe central nervous system vasculitis or lupus nephritis
Sjögren's syndrome [11]	*Lids & orbital findings*: lacrimal gland inflammation causing dry eye *Anterior segment findings*: *symptoms*: often severe with chronic discomfort, foreign body sensation, dryness and blurred vision. *Conjunctiva*: conjunctivitis and scarring in some cases. *Cornea*: punctate keratopathy, persistent corneal epithelial defects leading to corneal ulceration and perforation or corneal infection
Reiter's syndrome *Epidemiology*: ocular involvement in about 30% of patients [1]	*Anterior segment findings*: *symptoms*: red irritable eyes resolving spontaneously within 7–10 days *Conjunctiva*: bilateral mucopurulent conjunctivitis is the most frequent manifestation affecting approximately 30% of patients; this usually follows a urethritis by about 2 weeks and precedes the onset of arthritis. *Cornea*: keratitis may occur in isolation and is rare. *Uveitis*: anterior uveitis (iritis) occurs in about 20% of patients either with the first attack of Reiter's syndrome or during a recurrence
Behçet's syndrome *Epidemiology*: ocular involvement in 60% to 70% of patients [12, 13]	*Anterior segment findings*: *external eye diseases*: conjunctivitis, keratitis and episcleritis may occur but are not specific for the condition. *Uveitis*: is the commonest manifestation of the disease *Posterior segment findings*: visual impairment or blindness is a frequent complication of Behçet's syndrome as a result of the retinal ischaemia
Inflammatory bowel disease *Epidemiology*: ocular manifestations in about 5% of patients [14,15]	*Anterior segment findings*: *external eye diseases*: conjunctivitis, limbitis, peripheral corneal infiltrates and episcleritis may occur. *Uveitis*: acute iritis in about 5% of patients which may occur at the same time as exacerbation of colitis
Acquired immune deficiency syndrome (AIDS) *Epidemiology*: ocular complications occur in about 75% of patients [16,19]	*Common features*: (i) opportunistic infections with viruses mycobacteria and fungi; (ii) malignancies e.g. Kaposi's sarcoma; (iii) retinal microangiopathy; and (iv) neuro-ophthalmic lesions with intracranial infections and tumours. *Anterior segment findings*: *external eye diseases*: *Molluscum contagiosum* is a common ocular finding in patients with AIDS, they tend to be large and when located on the lid margin can give rise to follicular conjunctivitis. The lesions can be complicated by epithelial keratitis with associated pannus formation. Kaposi's sarcoma may involve the lids and conjunctiva. *Herpes simplex* keratitis tends to be severe with more frequent relapses. The peripheral cornea is more often involved in contrast to central disease in immunocompetent patients. *Herpes zoster ophthalmicus* is common and may be a presenting feature of HIV infection, especially if severe disease presents in young patients *Posterior segment findings*: retinal microangiopathy is common and characterized by retinal haemorrhages, microaneurysms and cotton wool spots. *Cytomegalovirus* retinitis and *Pneumocystis carinii* choroiditis are serious ophthalmic complications signifying severe systemic involvement
Porphyria [20, 21]	*Common feature*: ocular involvement results from either photosensitization and/or neurological dysfunction. Photosensitization can affect the eyelids, conjunctiva, cornea, sclera and possibly the retina. *Lids & orbital findings*: inflammation can lead to vesicle and bulla formation, secondary infection scarring with ectropion and hyperpigmentation *Neuro-ophthalmic complications*: include optic neuritis, optic atrophy, ptosis and cranial nerve palsies
Wegener's granulomatosis [22]	Episcleritis is very common in active stages. Also retinal vasculitis, optic neuritis, orbital pseudotumour
Polyarteritis nodosa	Episcleritis scleritis and keratitis

HIV, human immunodeficiency virus.

Fig. 64.11 Molluscum contagiosum. Molluscum contagiosum at medial aspect of the upper lid margin with an associated follicular conjunctivitis.

patients with unilateral or bilateral follicular conjunctivitis. There is associated conjunctival discharge and a variable, often severe, follicular conjunctival response (Fig. 64.11). A superficial epithelial keratitis may develop in long-standing cases, which can progress to pannus formation across the cornea. Treatment involves removal of the lesions by curettage; cryotherapy is also effective, but either of these will cause depigmentation in pigmented skins and are unnecessary for the management of a few localized lesions. In a co-operative adult this can be done under local anaesthetic, but for children a general anaesthetic is required.

Herpes simplex virus [3,4]

Primary HSV infection is asymptomatic in many patients; in others it causes blepharoconjunctivitis. However most of the ocular manifestations of HSV infection are due to reactivation of latent infection in the trigeminal ganglion. Both the primary infection, and reactivation of latent disease, may be particularly severe in patients with atopic dermatitis or with immunodeficiency. The blepharoconjunctivitis of HSV usually results in crops of small vesicles, which may be associated with mild oedema of the lids with or without a conjunctivitis. As with HSV elsewhere, the vesicles dry to a crust and heal within a few days. The conjunctivitis can be treated with aciclovir ointment five times daily for 5 days or with oral aciclovir 400 mg three times daily. Neither the blepharitis nor conjunctivitis present a serious problem for most patients. The serious and sight-threatening ocular complications of HSV infection of the eye are due to recurrent keratitis or keratouveitis. Herpetic keratitis may affect the epithelium alone (dendritic keratitis), the stroma (in stromal herpetic keratitis, geographical corneal ulceration and metaherpetic keratitis), or the endothelium (disciform keratitis or herpetic endotheliitis). Dendritic keratitis is in itself a benign disease unless treated with topical corticosteroids when the disease will rapidly spread, resulting in geographical keratitis, which may cause destructive corneal disease. Most cases of corneal disease represent reactivation of latent HSV and patients may develop any of the corneal manifestations. Stromal and endothelial disease can progress to blinding corneal vascularization, scarring and ulceration. Fortunately the disease is normally unilateral except in atopic individuals when it may often be bilateral. The management of the stromal and endothelial keratitis is beyond the scope of this review except to state that this involves the judicious use of topical corticosteroids with systemic or topical antivirals. Keratouveitis involves the endothelium and stroma and may also be associated with secondary glaucoma. Dendritic keratitis may occur during treatment with topical corticosteroids. Because of the difficulties of managing the ocular manifestations of this disease, patients with suspect HSV involvement of the eye should be referred for urgent ophthalmological assessment. Topical corticosteroids must not be used alone as these will mask the symptoms and signs, leading to spread of the ulcer and corneal perforation with catastrophic consequences for the patient's vision.

Herpes zoster [5]

Herpes zoster of the ophthalmic division (HZO) of the trigeminal nerve is an important condition to recognize. As with other sites, it often presents with a non-specific flu-like illness with fever and malaise and symptoms of unilateral neuralgia. This develops over the distribution of the affected nerve and varies in severity from a mild tingling in the skin to a deep severe pain. The characteristic lesions of herpes zoster may appear up to a week after the initial symptoms. Erythematous macules develop into clusters of papules and vesicles becoming pustular and haemorrhagic after 3–4 days. The lesions then scab and are dry by 7–14 days, separating to leave pitted scars. Involvement of the nasociliary nerve, which supplies the skin on the side of the nose (Hutchinson's sign), occurs in about 35% of patients and carries a high risk of ophthalmic complications. Ocular involvement may occur in the absence of nasociliary involvement but it is usually milder. Patients whose eyes cannot be examined due to persistent lid oedema, or those with ocular signs and symptoms, should be referred for urgent ophthalmological assessment. The disease can affect any part of the eye, including the orbit, extraocular muscles, optic nerve and cornea, and may give rise to long-term complications including severe relapsing keratitis, glaucoma and cataract.

Oral aciclovir is indicated when given within 3 days of the onset of the rash; using it later in the course of the disease is probably valueless. Topical aciclovir is also unhelpful. Topical corticosteroid therapy is needed to control the numerous corneal manifestations of the disease and may need to be continued for several years. Some

of these complications may be delayed and occur months after the initial skin eruption.

Prolonged or severe post-herpetic neuralgia is a painful and unpleasant sequel to herpes zoster infection. It occurs in about half of elderly patients but is rare in children. There is some evidence that the use of amitriptyline in the early stages of infection is helpful in reducing the incidence and severity.

Bacterial infection

Staphylococcal infection

Impetigo

Impetigo is a common skin infection that mainly affects children. It can involve the eyelids, but usually as part of a general infection over the face. It presents as rapidly spreading erythematous macules, developing into flaccid vesicles that subsequently rupture to give rise to surface crusting. The lesions need to be swabbed for bacteriology and appropriate oral and topical antibiotics given.

Hordeolum

External hordeolum (stye) is caused by staphylococcal infection of an eyelash follicle and its associated glands. It presents with a tender, red, inflamed swelling on the lid margin, which subsequently points anteriorly and discharges close to the lash roots. No treatment is usually required beyond the application of local soothing compresses and removal of the affected lash. If there is a local cellulitis then systemic antibiotics should be given. An internal hordeolum is a staphylococcal abscess of the meibomian glands and needs incision and drainage.

Streptococcal infection

Erysipelas [6]

This represents subcutaneous spreading cellulitis, usually caused by β-haemolytic *Streptococcus*. It usually presents with a rigor followed by a red, raised, erythematous plaque with a well-demarcated edge that spreads rapidly over the skin. Erysipelas is a serious skin infection that needs to be treated urgently with appropriate systemic antibiotics.

Necrotizing fasciitis [7]

This is a very rare condition, most commonly caused by *Streptococcus*, which mainly affects elderly or debilitated patients. A spreading purple discoloration of the eyelid rapidly progresses to gangrene. Unlike erysipelas the periorbital tissue is not usually affected. Early recognition, immediate institution of intravenous antibiotics and referral to an ophthalmic plastic surgeon for debridement of the necrotic tissue are mandatory as the condition carries a high mortality.

Mycobacterial infection

Tuberculosis [8,9]

There are no specific ocular findings in tuberculosis, and diagnosis is often based on indirect evidence such as intractable uveitis that is unresponsive to corticosteroid therapy, with negative findings for other causes of uveitis, and in the presence of tuberculosis at a distant body site. Chronic iridocyclitis, which is usually granulomatous, is the commonest feature. Choroiditis and retinal vasculitis may occur.

Leprosy [8,9]

Ocular complications of leprosy are common, most frequently madarosis, conjunctivitis, episcleritis or scleritis. Keratitis results from a combination of corneal anaesthesia, lagophthalmus, trichiasis and secondary infection. Iritis and its complications are the most common causes of blindness and leprosy. Lepromatous disease is more commonly associated with uveitis than is tuberculoid leprosy.

Treponemal infection

Syphilis [10]

Ocular syphilis is very rare and there are no pathognomonic signs. Eye involvement mainly occurs during the secondary and tertiary stages, though primary chancre of the conjunctiva may occur. External features include madarosis, scleritis and interstitial keratitis. Uveitis and chorioretinitis are rare but serious complications of syphilis and lead to blindness. Neuro-ophthalmic features include Argyll Robertson pupils, optic nerve lesions, and palsies of the third and sixth cranial nerves. Gummatous involvement of the brain can cause visual field defects.

Lyme disease [11,12]

Ocular manifestations of Lyme disease involve all parts of the eye. As with syphilis, the ocular manifestations vary according to the stage of the disease. In stage 1, a localized conjunctivitis with photophobia occurs in 10% of patients. This is mild and brief and ophthalmologists are rarely consulted. In stage 2, various ophthalmic complications have been described including cranial nerve palsies; these may occur within 1 month of the rash appearing. It is in the late stage 3 that most of the severe ocular complications are seen, including episcleritis, symblepharon, interstitial keratitis, uveitis, chorioretinitis and retinal vasculitis.

Parasitic infection

Phthiriasis (lice) [13]

An infestation of the eyelashes by the pubic louse, *Phthirus pubis*. It mainly affects children and causes chronic itching, irritation and rubbing of the lids. As with louse infection elsewhere, the adult lice can be difficult to see, though nits and their shells are visible adhering to the eyelashes (see Fig. 64.6c,d). The skin nearest to the base of the lashes may show small bluish spots due to the louse bites (maculae caeruleae). A number of measures have been used to treat louse infestation of the eyelids, including mechanical removal with forceps, epilation of infested lashes, and application of fluorescein, yellow mercuric oxide ointment, physostigmine or aqueous malathion.

Filiriasis (onchocerciasis) [14]

Onchocerciasis or river blindness is caused by the filarial organism, *Onchocerca volvulus*. It is the second most common cause of preventable blindness in sub-Saharan Africa with an estimated prevalence of 500 000 cases with visual impairment and 270 000 with blindness. It appears that *Wolbachia endobacteria*, a bacterial symbiont, produces an endotoxin-like product which constitutes a major pro-inflammatory stimulus in the eye, causing corneal inflammation and sclerosing keratitis.

Protozoal infection

Ocular disease may complicate leishmaniasis. In *Leishmania donovani* infection, bilateral retinal haemorrhages may be a feature. In *L. tropica* and *L. braziliasis* infection, eyelid and corneal lesions occur, and subsequent destruction may lead to loss of the eye. In trypanosomiasis, unilateral oedema of the lids may occur.

Inherited disorders

A large number of inherited disorders affect the skin and eyes. Major reference texts are cited [1–3]. The main ocular features are summarized in Table 64.11 [4–51].

Table 64.11 Inherited disorders affecting the skin and eyes.

Group	Condition	Inheritance	Ocular features
Bullous disorders	Acrodermatitis enteropathica [4]	AR (MIM #201100)	Loss of eyebrows and eyelashes, conjunctivitis, blepharitis, photophobia
Connective tissue disorder	Ehlers–Danlos syndrome [5]	Mainly AD (see MIM 130000)	Lax eyelid skin with redundant folds, epicanthal folds, hypertelorism, strabismus, blue sclera, corneal abnormalities including keratoconus, angioid streaks, ectopic lens. Retinal detachments occasionally occur
	Marfan's syndrome [6]	AD (MIM #154700)	Subluxation of lens—60–80% of patients in early childhood. Amblyopia, myopia, cataract, corneal abnormalities, glaucoma. Retinal detachment is most serious complication
	Pseudoxanthoma elasticum [7]	Types I & II AR (MIM #264800, 264810) Types III & IV AD (MIM #177850, 177860)	Angioid streaks (breaks in Bruch's membrane) in majority. Haemorrhagic maculopathy after trauma may cause visual loss
Dysplasias, hyperplasia, atrophies and aplasias	Ablepharon macrostomia [8] syndrome	Unknown (MIM 200110)	Absent eyelids and ectropion
	Aplasia cutis congenita [9]	AD (MIM #107600) AR (MIM 207700)	Congenital absence of skin leading to eyelid colobomas, corneal opacities, scleral dermoids and lamellar cataracts
	Blepharophimosis ptosis epicanthus inversus syndrome [10]	AD (MIM #110100)	Blepharophimosis, ptosis, epicanthus inversus, telecanthus. Amblyopia in 50% of patients
	Cockayne's syndrome [11]	AR (MIM *216400)	Corneal opacities, cataracts in 30%, retinitis pigmentosa, optic atrophy, strabismus, photophobia
	Dyskeratosis congenita [12]	XR (MIM #305000)	Obliteration of the lacrimal puncta in 80% of cases, conjunctivitis, blepharitis, ectropion, loss of eyelashes and eyebrows
	Ectodermal dysplasias—a complex group of disorders with various inheritance patterns and a variety of ocular findings [13] Examples are given:		
	(i) Christ–Siemans–Touraine syndrome	XR	Photophobia dry eye
	(ii) Fischer–Jacobson–Clouston syndrome	AD	Usually normal
	(iii) Ellis–van Cleveld syndrome	AR (MIM #225500)	Coloboma of iris, microphthalmia occasional cataract
	Focal dermal hypoplasia (Golz's syndrome) [14]	XD (MIM *305600)	40% have ocular abnormalities, the commonest being colobomas of iris choroid retina or optic nerve
	Fraser's syndrome [15]	AR (MIM *219000)	Bilateral or unilateral absence of palpebral fissure with loss of eyebrows, anophthalmia, microphthalmia
	Frydman's syndrome [16]	AR	Synophrys, blepharophimosis, weakness of extra-ocular and frontal muscles
	Hallerman–Streiff syndrome [17]	Unknown (MIM *264090)	Loss of hair of eyebrows and eyelashes, microphthalmos, cataracts, amblyopia and nystagmus
	MIDAS syndrome [18]	XD	Microphthalmia, sclerocorneal
	Pachyonychia congenita [19]	AD (PC1 MIM #167200 PC2 MIM #167210)	Cataract and corneal dyskeratosis
Hair disorders	Brachmann–Lang syndrome [20]	AR	Synophrys thick, long eyelashes, narrow palpebral fissure, myopia, nystagmus and strabismus
	Monilethrix [21]	AD (MIM #158000)	Loss of eyebrows and lashes

(*continued overleaf*)

Table 64.11 (*cont'd*)

Group	Condition	Inheritance	Ocular features
	Pili torti [22]	AR (MIM 261900)	Loss of eyebrows and lashes
	Chondrodysplasia punctata [23]	AD (MIM 215105) XR (MIM #302950)	Cataracts Ocular albinism, cataracts, microphthalmia
Keratinization disorders	The ichthyoses [24]		
	(i) Ichthyosis congenita gravis	AR (MIM *242500)	Severe ectropion
	(ii) Ichthyosiform erythroderma	AD (MIM 242100)	Early development of ectropion is characteristic
	(iii) Lamellar ichthyosis	AR (various types)	Cicatricial ectropion with exposure keratitis Direct conjunctival involvement may occur
	(iv) X-linked ichthyosis	XL (MIM *308100)	Deep corneal opacities
	KID syndrome [25]	XD (MIM #148210)	Keratitis
	Refsum's syndrome [26]	AR (MIM #266500)	Night blindness, posterior subcapsular cataracts develop in most cases
	Sjögren–Larson syndrome [27]	AR (MIM *270200)	Blepharitis, conjunctivitis, punctate corneal erosions and pigmentary degeneration of the retina
	Ulerythema ophryogenes [28]	AD	Erythema and perifollicular papules on eye to eyebrows spreading medially causing thinning of eyebrows
Metabolic disorders	Alkaptonuria [29]	AR (MIM #203500)	Scleral pigmentation is early sign, eyelid pigmentation
	Angiokeratoma corporis diffusum [30]	XL (MIM *301500)	Angiokeratomas of conjunctiva, corneal opacities, posterior capsular cataracts
	Homocystinuria [31]	AR (MIM *236200)	Myopia, cataracts, subluxation of lens, secondary glaucoma, retinal detachment
	Hurler's syndrome [32]	AR (MIM *252800)	Early clouding of cornea
Neurocutaneous syndromes	Richner–Hanhart syndrome [33]	AR (MIM 276600)	Corneal lesions vary from erosions to deep ulcers Nystagmus and lens opacities
	Neurofibromatosis type I [34]	AD (MIM *162200)	Neurofibromas of eyelid, corneal clouding, Lisch nodules of iris, optic nerve glioma, palsies from cranial nerve involvement
	Neurofibromatosis type II	AD (MIM #101000)	Cataract fundus lesions. Extraocular motility abnormalities
Photosensitive disorders	Tuberous sclerosis [35]	AD (MIM #191100)	Tumours of the lids or nodules on conjunctiva and retina
	Basal cell naevus syndrome [36]	AD (MIM #109400)	Basal cell carcinoma of eyelid and periorbital area, hypertelorism, strabismus, colobomas of the choroid, cataracts, glaucomas in 5–10%
	Bloom's syndrome [37]	AD (MIM #210900)	Telangiectasis on lower lids, blistering and scarring lower eyelids
	Rothmund–Thomson syndrome [38]	AR (MIM #268400)	Sparse eyebrows and eyelashes, degenerative changes in cornea, 50% of patients have bilateral cataracts which develop in childhood, strabismus
	Xeroderma pigmentosum [39]	AR (various types)	Angiomas, keratoses, papillomas, carcinomas develop on eyelids, sometimes extending on to conjunctiva and cornea, scarring and atrophy of lids with exposure keratitis leading to corneal ulceration symblepharon formation. Ocular melanoma
	Chediak–Higashi syndrome [40]	AR (MIM #214500)	Oculocutaneous albinism, corneal opacities

(*continued*)

Table 64.11 (*cont'd*)

Group	Condition	Inheritance	Ocular features
Pigmentation disorders	Cross syndrome [41]	AR (MIM *257800)	Microphthalmia, small opaque cornea, coarse nystagmus
	Epidermal naevus syndrome [42]	Sporadic	Ocular melanocytic naevi, coloboma of the lids, iris and choroid. Lipodermoid of conjunctiva or choroid
	Incontinentia pigmenti [43]	XD (MIM #308300)	35% of patients have eye abnormalities including strabismus, cataract and microphthalmia. Retinal detachment may occur
	Hypomelanosis of Ito [44]	Sporadic (MIM *300337)	Hypertelorism, strabismus, myopia
	Oculocutaneous albinism [45]	AR (various types; Chapter 39)	Total loss of pigment in eyes, nystagmus, absence of binocular vision
	Piebaldism [46]	AD (MIM #172800)	Absent pigmentation medially of eyebrows, eyelids and eyelashes, heterochromia of iris
	Waardenberg's syndrome [47]	AD (MIM #193150)	Telecanthus, synophrys, partial albinism, heterochromia of iris
Vascular and haematological syndromes	Congenital telangiectatic cutis marmorata [48]	Unknown (MIM 219250)	Clouding of cornea, glaucoma
	Fanconi pancytopenia syndrome [49]	AR (MIM #227650)	Microphthalmia strabismus, nystagmus and colobomas
	Lymphoedema–distichiasis syndrome [50]	AD (MIM #153400)	Double row of eyelashes on upper and lower eyelids
	Sturge–Weber syndrome [51]	Sporadic (MIM 185300)	50% of patients have angiotomatous changes of the ipsilateral choroid causing glaucoma

Ocular complications of dermatological therapy

A number of drugs used by dermatologists have significant side effects on the eye and require careful monitoring.

Corticosteroids [1–15]

The use of corticosteroids can cause significant side effects on the eye. Both systemic and topical corticosteroids are responsible, though the greatest risk is to those receiving prednisolone at a dose of 10–15 mg a day for over a year.

Continuous therapy is more likely to cause side effects than intermittent therapy.

Posterior subcapsular cataracts are induced by long-term systemic corticosteroids in as many as 30% of patients. They rarely occur at doses less than 10 mg/day and for less than 1 year. Children are particularly vulnerable. Reversibility of cataracts is not common and progression of cataracts may occur in spite of reduction or discontinuation of corticosteroid therapy.

Patients also risk developing open angle glaucoma, particularly if genetically predisposed. The precise mechanism is unknown, though it is thought to be due to decreased aqueous outflow. Particular risk factors include type 1 diabetes, high myopia, connective tissue disorders and a family history of glaucoma. Topical corticosteroids induce a rise in intraocular pressure more quickly than systemic corticosteroids. Medium or high potency dermatological corticosteroids applied for long periods to, or near, the eyelids may spread over the lid margin and are absorbed through the cornea, reaching sufficient concentrations to elevate ocular pressures. Patients on long-term topical or systemic corticosteroids need to have their eye pressures monitored regularly at 1–6 monthly intervals depending on their degree of risk.

Topical corticosteroids predispose patients to cataract, glaucoma and secondary surface infection. Injudicious use in HSV infection masks the clinical signs of dendritic ulcer and risks perforation. Wearing a soft contact lens is a contraindication to topical ocular corticosteroid usage. Other ocular complications from corticosteroids include angioneurotic oedema, papilloedema from raised intracranial pressure and toxic amblyopia. Systemic treatment with corticosteroids may cause serous chorioretinopathy or diffuse retinal pigment epitheliopathy.

Oral retinoids [16–22]

Both isotretinoin and acitretin can cause ocular side effects. The most common is dry eye with associated conjunctivitis and blepharoconjunctivitis giving rise to blurred vision. The blepharoconjunctivitis is frequently associated with staphylococcal infection. Exposure keratopathy and corneal ulceration rarely occur; asymptomatic corneal opacities may develop but resolve after 6–8 weeks. Patients should be warned that they may be unable to tolerate contact lenses whilst on retinoid therapy. Use of tear substitutes, humidification of the environment and lid hygiene measures help. Retinal abnormalities may also occur, with poor night vision and increased sensitivity to glare, and can be a significant problem in those who drive at night. The cause is unknown but may be due to competitive inhibition of ocular retinol dehydrogenase causing local vitamin A deficiency and reduction in rhodopsin formation. More serious side effects include papilloedema from raised intracranial pressure, optic atrophy and cataract. Although these are rare, a history of visual disturbance should be asked for when patients come for follow-up. Severe headache early in the course of treatment is significant. The ocular manifestations are dose-dependent and usually reversible, provided they are recognized and the treatment regimen adjusted. However, there have been reports of the dry eye syndrome and night blindness persisting after retinoids have been discontinued.

Antimalarials [23–27]

The most serious potential side effect of antimalarial drugs is retinopathy. The mechanism is uncertain but seems to depend on the ability of the drug to bind the retinal pigment epithelium. Ocular side effects from antimalarials are much less common now that hydroxychloroquine rather than chloroquine is the drug of choice. However, both drugs should be used with caution in patients with hepatic or renal impairment. The Royal College of Ophthalmologists and American Academy of Ophthalmologists have issued clear guidelines on screening protocols for use of chloroquine and hydroxychloroquine. Baseline ophthalmic assessment of patients, for whom these drugs are proposed, is carried out by the dermatologist and requires questioning the patient about any known visual impairment (uncorrected by spectacles) and the recording of near visual acuity using a test type. If visual impairment is reported or detected then referral to an optometrist is advised; the optometrist will refer any patient with abnormal findings to an ophthalmologist. Patients should not be treated with more than the maximum daily dosage (hydroxychloroquine at a maximum dosage of 6.5 mg/kg or chloroquine phosphate not exceeding 4 mg/kg daily) and should have this visual screening repeated annually and recorded in their notes. Referral to an ophthalmologist is appropriate if visual impairment is detected at baseline, if changes are detected on the annual screening or if the patient develops visual symptoms. The ophthalmologist will then carry out a range of tests including visual acuity, colour vision, visual fields, Amsler fields, corneal and retinal examinations. If long-term treatment is required, for more than 5 years, the risks of ocular complications are increased; in this instance, individual arrangements for screening should be agreed with a local ophthalmologist. No screening is recommended for mepacrine as it is not associated with ophthalmological side effects.

Antibiotics for acne [28–32]

Oxytetracycline, minocycline and doxycycline can all cause raised intracranial pressure. The mechanism is unknown but is thought to be related to interference with energy-dependent absorption mechanism of cereb-

rospinal fluid, which is mediated by cyclic adenosine monophosphate (AMP) at the arachnoid granulations. Patients who complain of headache should be examined carefully with fundoscopy through dilated pupils to look for papilloedema, and should have formal testing of visual acuity and of visual fields. The condition is far from benign; permanent visual field loss can occur if the condition is not recognized early and the drug stopped. Sometimes treatment with acetazolamide is required to reduce the pressure. Erythromycin or trimethoprim may cause erythema multiforme and associated ocular changes. Pigmentation due to minocycline can occur in the skin (Chapter 39) and has also been reported in the sclera.

Psoralens [33–44]

Psoralens have been shown to bind to the lens proteins, and some animal studies have shown induction of anterior cortical opacities though others have not. 8-Methoxypsoralen can be detected in the human lens 12 h after oral ingestion. There has been a longstanding concern about the risk of cataract in patients having psoralen and long-wave UV radiation (PUVA) therapy. Although PUVA has been used in treatment of skin diseases for 30 years, and clinical studies have not yet shown any convincing evidence of an increase in cataract as compared with the general population, it is still recommended that ultraviolet light A (UVA)-filtered spectacles are used for 12 h after ingestion of psoralens in case significant long-term sequelae eventually develop. Care must be taken to ensure that the spectacles are suitable for ultraviolet protection.

Botulinum toxin [45]

With the increased use of botulinum toxin for the treatment of facial wrinkling and eyebrow position dermatologists need to be aware of the potential side effects. These include haematoma, ptosis, ectropion, diplopia and eyelid drooping, and are often related to poor injection technique.

Tumours

Benign tumours of the eyelid

As would be expected of such complex tissue, the eyelid gives rise to a large number of skin tumours. Tumours can arise from the epidermis and dermis in addition to the adnexal structures, which include the meibomian and Zeis sebaceous glands, eccrine and Moll's apocrine sweat glands, and the specialized hair follicles of the eyelashes. They may also originate from lymphoid neural and vascular tissue found in the preseptal tissues of the eyelid. Although optimal treatment of the tumours begins with accurate diagnosis, many are rather non-specific in their appearance and are only diagnosed with certainty by histology.

Keratoses

Both seborrhoeic and actinic keratoses occur on the eyelid. They have similar clinical features to those elsewhere on the skin and are treated in the same way with local destructive measures, using carefully applied cryotherapy, curettage and cautery or laser ablation under local anaesthetic. Recurrent actinic keratosis should be biopsied and sent for histological examination to make sure it is not a deceptive manifestation of an early skin cancer.

Xanthelasma [1,2]

These present as yellowish cutaneous plaques, most commonly located on the medial part of the eyelids. They are usually bilateral and are much more common in elderly patients. About 60% of patients have an associated hypercholesterolaemia and lipid levels should be measured. Patients often request treatment for cosmetic reasons. Although 90% trichloroacetic acid applied with a cotton wool bud is used there is a significant risk of spillage into the eye. More effective treatment is by surgical excision or ablation with carbon dioxide laser. Necrobiotic xanthogranuloma may look similar to xanthelasma but they are thicker and more nodular. These lesions may involve the conjunctiva and sclera. On the rare occasions that they infiltrate the orbit they may cause proptosis.

Fig. 64.12 Cyst of Moll. Small translucent cyst on anterior lid margin. (Courtesy of Mr N. Joshi, Chelsea & Westminster Hospital/Medical Illustration UK, London, UK.)

Juvenile xanthogranuloma [3]

These lesions occasionally involve the eyelid, conjunctiva or uveal tract. They may be associated with glaucoma and threaten sight. Patients need screening by an ophthalmologist.

Adnexal tumours [4]

Syringomas, milia, trichoepitheliomas and tricholemmomas present as small papules around the eyelids. They can be very difficult to distinguish from each other. Syringomas are the most common, but histology from a biopsy is the only way to make a definite diagnosis. Treatment is by local destruction of the lesions. Eccrine hidrocystomas can present in an eruptive fashion on the face and eyelids; they may respond to topical atropine.

Benign cysts of the eyelid

Retention cysts may arise from either the glands of Moll or of Zeis. A cyst of Moll usually presents as a small translucent lesion on the anterior lid margin close to the lacrimal punctum (Fig. 64.12). Glands of Zeis are sebaceous glands and their retention cysts contain oily secretions and are more opaque than a cyst of Moll. An eccrine gland hidrocystoma is similar in appearance to a cyst of Moll but is not confined to the lid margin. These cysts are treated by excision.

Chalazion [5]

This lesion represents a chronic granulomatous inflammatory reaction around a blocked sebaceous gland.

Fig. 64.13 Capillary haemangioma. Enlarging lesion on right upper lid starting to occlude vision. (Courtesy of Mr N. Joshi, Chelsea & Westminster Hospital/Medical Illustration UK, London, UK.)

Patients with seborrhoeic dermatitis and rosacea are at increased risk of chalazion formation. A chalazion presents as a firm lump in the eyelid, which is clearly visible when the lid is everted; an association with chronic posterior blepharitis is common. Large and troublesome lesions can be treated by everting the lid with a special clamp, incising the cyst and curetting the contents through the tarsal plate. Patients who develop recurrent chalazion associated with seborrhoeic dermatitis and rosacea benefit from long-term antibiotic treatment using tetracyclines. Hot saline compresses reduce the inflammation.

Pigmented naevi

The skin on the eyelid can develop pigmented naevi. Their appearance, classification and potential malignant change applies as elsewhere on the skin.

Naevus of Ota

This lesion affects the eyelids, conjunctiva and sclera. Occasionally the pigmentation is confined to the eye with no cutaneous involvement. Naevus of Ota carries an increased risk of ocular melanoma and glaucoma and patients need to be referred for ophthalmic examination and long-term review.

Melanoacanthoma [6]

These are small, shining, black papules situated along the line of the lashes and are a form of dermatosis papulosa nigricans.

Vascular naevi [7–10]

Strawberry naevus (capillary haemangioma) can affect the eyelids. It is more common on the upper lid and presents as a unilateral red raised lesion, which grows quickly during the first year of life (Fig. 64.13). Spontaneous involution occurs usually by age 9 years. Amblyopia is the main complication of larger periorbital lesions and results either from physical closure of the eye and occlusion of the pupil, giving rise to stimulus deprivation, or from refractive errors caused by changes in local pressure. Both systemic and intralesional corticosteroids can reduce the bulk of the haemangioma. Surgical resection or laser therapy is helpful in certain cases.

Port-wine stain

This is a rare congenital vascular lesion, which may affect the eyelids. It presents as a sharply demarcated red patch. Extensive lesions involving the periocular region have a high risk of central nervous involvement and of ipsilateral glaucoma (especially if the upper lid is involved), which may not develop until adult life.

Keratoacanthoma

Keratoacanthomas may develop on the eyelid. They present as a small papule, which grows rapidly developing a characteristic keratin-filled crater and may reach up to 3 cm in diameter (Fig. 64.14). The lesions then stop growing and remain static for 2 or 3 months before spontaneously involuting, which can lead to significant scarring of the eyelid. Because of this, the lesion should be excised at an early stage.

Malignant tumours of the eyelid [11,12]

Basal cell carcinomas (BCCs), squamous cell carcinomas (SCCs) and malignant melanomas all occur on the eyelid as on other areas of the skin. The same rules for management apply on the eyelid as at any site, but the eyelid poses specific problems in preserving good cosmesis and residual function. Clinical examination is an unreliable way of determining the extent of many of these lesions, particularly sclerosing BCC. Early referral to an oculoplastic surgeon is advisable with a view to Mohs micrographic surgery if appropriate.

Fig. 64.14 Keratoacanthoma. Keratin-filled crater on lid margin. (Courtesy of Mr N. Joshi, Chelsea & Westminster Hospital/Medical Illustration UK, London, UK.)

Basal cell carcinomas [13–16]

These are the most common skin malignancy and in most series account for 90% of malignant tumours. They rarely metastasize but cause problems by local tissue destruction and invasion of periorbital tissue. Over 70% arise on the lower eyelid followed in order of frequency by the medial canthus, upper eyelid and lateral canthus. Tumours located near to the medial canthus can invade the orbit and sinuses. They are more difficult to excise than those elsewhere, because of the high risk of damaging the tear duct. The majority of BCCs are solid or cystic and fairly straightforward to recognize (Fig. 64.15). Sclerosing or morphoeic BCCs are less common and can be difficult to diagnose as they infiltrate beneath the epidermis forming a flat indurated plaque with indistinct margins, which may simulate a localized area of chronic dermatitis. The paucity of reticular dermis and subcutaneous fat to resist deep invasion presents a particular problem with the eye. Once the orbital septum is penetrated the BCC can rapidly invade, threatening the orbit. At the medial canthus the lacrimal sac and the rich anastomosis of blood vessels offers little barrier. Curettage and cautery is generally not advised for the treatment of eyelid lesions. The skin is thin and tears easily and the sensitivity of the curette is lost in the soft tissue. Successful initial treatment with surgery and accurate margin assessment to ensure complete excision is mandatory in management of these tumours. Mohs' micrographic surgery is usually the treatment of choice where margins are in doubt. Radiotherapy damages and scars the eyelid tissues and lacrimal system and should be reserved for situations when surgery is otherwise inappropriate. Cryotherapy is best avoided due to the risk of leaving residual tumour.

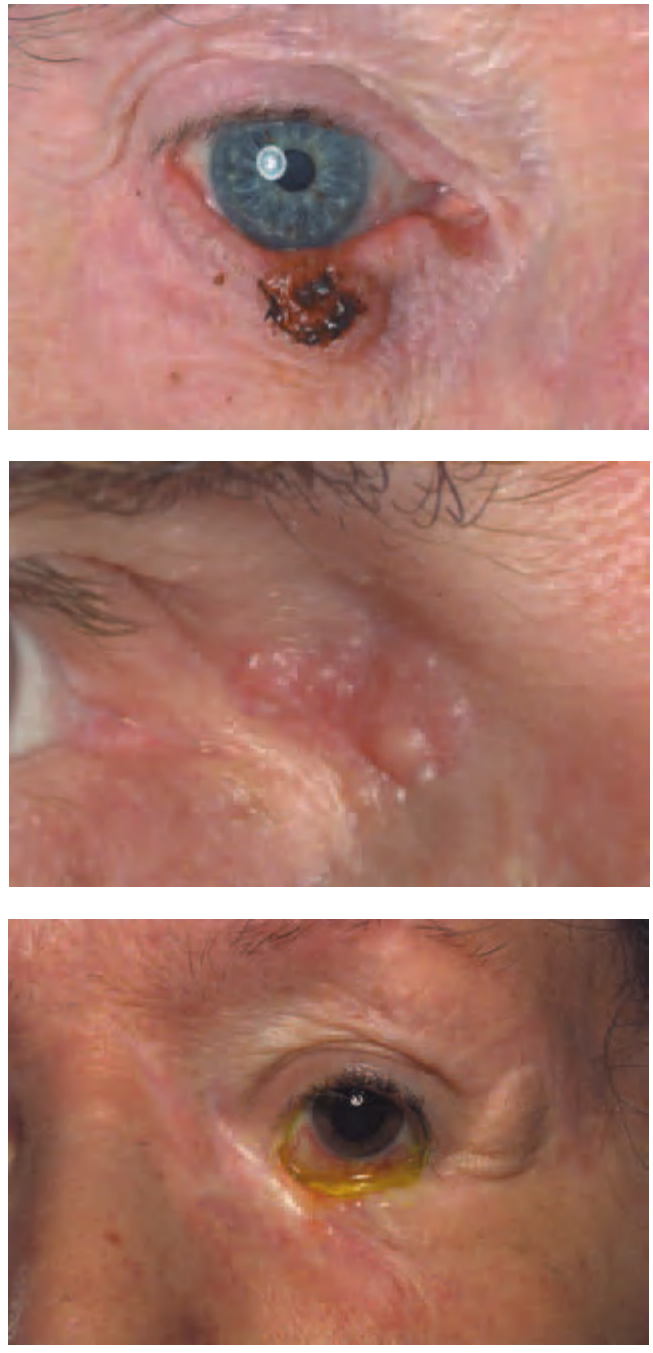

Fig. 64.15 Basal cell carcinoma (BCC). (a) Ulcerated BCC on lower lid. (b) Poorly defined BCC at medial canthus. (c) Morphoeic BCC along lower lid. (Courtesy of Mr N. Joshi, Chelsea & Westminster Hospital/Medical Illustration UK, London, UK.)

Squamous cell carcinomas [17]

This is much less common than BCCs, accounting for between 5 and 10% of eyelid malignancies. SCCs occur on a background of marked actinic damage. They mainly affect the lower eyelid and lid margin, and may arise *de*

Fig. 64.16 Squamous cell carcinoma (SCC). Infiltrating ulcerated SCC on lower lid. (Courtesy of Mr N. Joshi, Chelsea & Westminster Hospital/Medical Illustration UK, London, UK.)

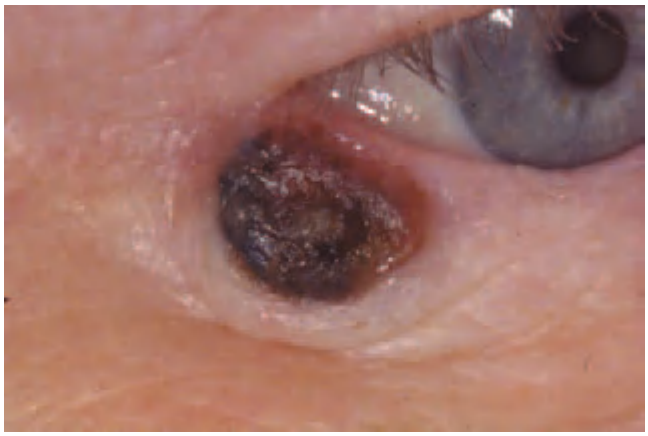

Fig. 64.17 Malignant melanoma. Irregularly pigmented lesion on lower lid. (Courtesy of Mr N. Joshi, Chelsea & Westminster Hospital/Medical Illustration UK, London, UK.)

novo or from pre-existing actinic keratoses. SCC of the eyelids may be nodular, plaque like or ulcerated (Fig. 64.16). Excision with adequate margins is the treatment of choice. Tumours greater than 2 cm in diameter and those with deep penetration have a higher risk of metastasis. Histological evidence of poor differentiation or of perineural invasion are also poor prognostic factors requiring more aggressive treatment. Mohs' surgery is indicated where the initial margins are not free of tumour and offers a good long-term prognosis. As with BCC, cryotherapy and radiotherapy are reserved for situations where surgery is inappropriate.

Malignant melanoma

This may occur on the eyelids or conjunctiva. As elsewhere, melanomas are characterized by a change in size, shape or colour of a pigmented lesion (Fig. 64.17). However, a significant proportion of lid melanomas are amelanotic and this may give rise to difficulties with clinical diagnosis.

Fig. 64.18 Sebaceous gland carcinoma. Infiltrating lesion on upper lid. (Courtesy of Mr N. Joshi, Chelsea & Westminster Hospital/Medical Illustration UK, London, UK.)

Sebaceous gland carcinoma and epithelioma [18,19]

These are very rare tumours, accounting for less than 1–5% of malignant tumours of the eyelid. Sebaceous gland carcinoma usually arises from the meibomian glands, occasionally from the glands of Zeis. In contrast to BCC or SCC, the majority of lesions affect the upper lid. Most lesions are nodular and look very much like a chalazion (see Figs 64.6a, 64.6b & 64.18), causing delay in diagnosis; a sebaceous tumour should always be suspected if a 'chalazion' lasts for more than 6 months, and a 'chalazion' that recurs should be viewed with great suspicion, excised and sent for histology. Because of late diagnosis, sebaceous gland carcinoma carries a significantly mortality. Wide local excision is the treatment of choice. The multicentric nature of the tumour may limit the use of Mohs' surgery.

Eccrine carcinoma [20]

These are rare cancers of the eye and may present as an indurated thicking of the lid or with a signet-ring appearance. They are commonest in middle-aged or elderly men and recur after excision.

Merkel cell carcinoma

A very rare tumour. It can also mimic a chalazion in its early stages, with delay in diagnosis. It is highly malignant and has often metastasized by the time of excision.

Kaposi's sarcoma

A vascular malignancy. It presents as a purple lesion on

the eyelid or conjunctiva and can be mistaken for a benign haemangioma. However, it grows rapidly and may ulcerate and bleed. When it presents on the eyelid it is associated with AIDS, of which it may be the sole manifestation at the time of presentation. These lesions are very radiosensitive, and this is the preferred mode of treatment once a biopsy has been taken to confirm the diagnosis.

Chapter 65

The External Ear

C.T.C. Kennedy

Anatomy and physiology [1–3]

The external ear consists of the auricle, the external auditory canal and the outer layer of the tympanic membrane.

The auricle, or pinna (Fig. 65.1), is a convoluted, elastic and cartilaginous plate covered by skin which is continuous medially with the lining of the external auditory canal. Except on the non-cartilaginous lobe and at the back of the ear, the skin is bound firmly to the cartilage. The auricle is attached to the head by fibrous ligaments and three vestigial auricularis muscles. The size and general detail of the auricle can vary greatly between individuals, and may be characteristically affected in a number of congenital syndromes. In humans, the auricle is largely functionless and motionless.

The epidermis of the ear has a complex dermal–epidermal junction, a conspicuous stratum granulosum and a thick, compact stratum corneum [4]. The dermis contains abundant elastic tissue. Sebaceous glands are numerous, particularly on the tragus and lobe, and fine vellus or terminal hairs occur over the entire surface, but are especially prominent on the helix and tragus. Coarser terminal hair is seen in some men as a Y-linked and androgen-dependent inherited trait (Fig. 65.2). Eccrine sweat glands are sparsely and irregularly distributed except in the external auditory canal, which has, instead, a large number of modified apocrine or ceruminous glands. The pinna has a variably thick fatty layer that extends between the perichondrium and the reticular dermis and that also forms the main fibrofatty core of the lobe of the ear.

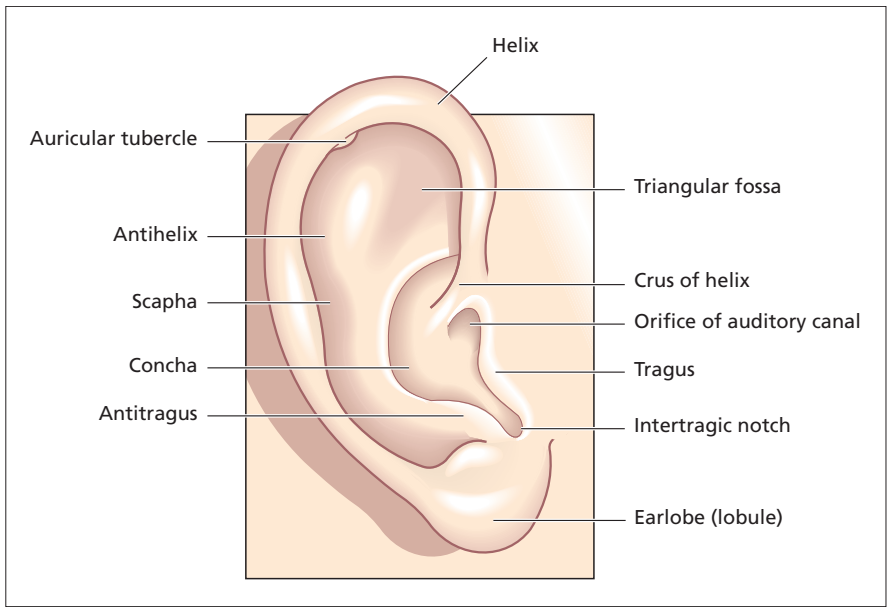

Fig. 65.1 Anatomical landmarks of the auricle.

Fig. 65.2 Coarse terminal hair on the auricle: a trait associated with the Y chromosome.

The blood supply to the auricle is provided by anastomosing branches of the superficial temporal and posterior auricular arteries, which drain via posterior auricular and superficial temporal veins into the external jugular vein and via the superficial temporal, maxillary and facial veins into the internal jugular vein. Lymphatic drainage is to the superficial parotid, retro-auricular and superficial cervical lymph nodes. Embryonic fusion planes and minute deficiencies in the cartilaginous portion of the external auditory canal provide potential pathways for the spread of infection and tumours.

There is a complex nerve supply to the ear involving elements of the Vth, VIIth, IXth and Xth cranial nerves as well as cervical branches of the greater and lesser auricular nerves. The back of the ear is supplied by the greater auricular nerve (C2,3), the concha by the auricular branch of the vagus (Xth) and the anterior part of the pinna and the external auditory canal by the auriculotemporal branch of the Vth cranial nerve. Intercommunicating branches of the VIIth, IXth and Xth supply the deeper parts of the ear. With this complicated nerve supply, otalgia is more commonly due to referred pain than to disease in the ear itself [5]. Within the dermis, the nerve supply is abundant, especially around hair follicles where there are complicated basket-like networks of acetylcholinesterase and butyrylcholinesterase nerve fibres [4]. Free nerve endings are also present, but there are no organized nerve endings as occur on glabrous skin elsewhere [6].

The external auditory canal extends upwards and backwards in an S-shaped curve from the concha to the tympanic membrane. The angle of curvature varies between races and individuals, being more marked in white people than in black people or Polynesians. This has a bearing on trauma, infection and the retention of moisture. The length of the canal is 2.5 cm as measured from the concha to drum. The outer third of the canal is cartilaginous and is lined by a thicker layer of skin than the inner portion within the temporal bone. Anteroinferiorly there are two horizontal fissures in the cartilaginous canal, the fissures of Santorini. These can allow infection or tumour to pass beyond the external auditory canal, for example to the parotid gland. Subcutaneous tissue is scanty, and the epithelium is firmly bound to the perichondrium. Sebaceous glands are plentiful, and open into the follicles of extremely fine vellus hairs. Occasionally, larger terminal hairs (tragi) arise in the canal or around the meatus and these, if they become matted with wax or debris, may interfere with normal epidermal 'migration' and ventilation of the ear and hence may play a part in the development of 'hot-weather ear' (see p. 65.22).

Eccrine sweat glands are not present in the auditory canal but modified apocrine (ceruminous) glands are numerous. They increase in size and activity at puberty. There is great individual and racial variability, and although concentrated in the cartilaginous part of the canal, they may also occur, albeit sparsely, in the osseous portion.

The inner osseous part of the acoustic canal constitutes two-thirds of its total length. The skin is firmly bound to the periosteum, subcutaneous tissue being nearly absent and only 30–50 μm thick. The epidermis here is thin and easily traumatized, and rete ridges are absent [1]. The skin of the external auditory canal and tympanic membrane is unique in that there is no frictional loss of stratum corneum; cerumen (wax) and epithelial debris have therefore to be removed by a special 'migratory' property of the external ear canal epithelium [7]. A slight narrowing of the canal, the isthmus, occurs at or just medial to the junction of the two parts. When marked, it may impede the flow of cerumen to the exterior. Just medial to the isthmus, inferiorly and anteriorly, is the tympanic sulcus. Debris often collects here, especially in patients with chronic external otitis.

The surface pH of the auditory canal varies from 5.6–5.8 at the concha to 7.3–7.5 at 5–10 mm within the canal. With inflammation, the pH becomes slightly more acid [8].

Microbiology

The skin of the external auditory canal in most healthy

individuals supports the growth of multiple bacterial species, especially *Staphylococcus epidermidis*, *Corynebacterium* spp., *Bacillus* spp. and less often *Staphylococcus aureus*. *Pseudomonas aeruginosa*, often relevant to external otitis, and fungi are not normally found [3]. The normal flora can include organisms such as *Turicella otidis*, which can cause otitis media [9].

Cerumen (wax) [10]

Cerumen is the combined product of sebaceous and apocrine glands. It contains both squalene and insoluble fatty acids. Analysis by flash pyrolysis–gas chromatography/mass spectrometry has shown numerous diterpenoids [11]. Its main function is to waterproof the external auditory canal. Extrusion is aided by mastication and by the peripheral movement and desquamation of the epithelial cells of the canal. It is impeded if the ear canal is too narrow or tortuous, or when inflammation interferes with the normal process of 'migration'.

There are genetically determined differences in cerumen composition and character: so-called 'dry' ear wax is light grey, dry and flaky; 'wet' ear wax is golden brown and sticky. The former is very common in Asians. Wax phenotype is determined by a single gene pair, the wet wax allele being dominant [10]. Cerumen darkens with exposure to air.

Although not bactericidal, cerumen does not encourage bacterial or fungal growth. Possible reasons include the presence of lysozyme, immunoglobulins and polyunsaturated fatty acids.

Two populations have been shown to have excessive production and/or impaction of cerumen: individuals with mental retardation and the elderly [10]. An increased secretion of cerumen occurs in patients treated with aromatic retinoids [12,13].

If wax becomes impacted or adherent, it can cause various symptoms such as hearing loss, tinnitus, vertigo, pain and itching, and can be a contributory factor to external otitis. It may be removed by irrigation techniques or suction under direct vision [14]. Although it is generally thought that cerumenolytics such as 10% aqueous sodium bicarbonate or 2.5% aqueous acetic acid are of little value, they may have a use in children [15]. Docusate sodium is more effective than some traditional agents [16]. Although not yet studied in controlled trials, the bile acids may be very effective for removing ear wax [11].

Contact dermatitis from medicaments or irritant cerumenolytics [17] is well recognized. Inflammation interferes with normal epidermal migration and tends therefore both to induce and to encourage the retention of scale. The pruritus associated with excess cerumen, and the low-grade inflammation that often accompanies this, frequently leads to a persistent form of low-grade neurodermatitis.

Examination [1]

As well as examining the pinna, the dermatologist may need to examine the ear canal. Equipment available should include a headlight or equivalent, otoscope, several sizes of ear speculae, ear curettes, metal applicators, bayonet forceps, ear irrigation apparatus and cotton.

General inspection of the auricles should take account of their symmetry, size, shape and position, and completeness of development.

The ear canal is best inspected when the auricle is pulled gently upwards, outwards and backwards, and the largest possible speculum is used. It is essential to avoid traumatizing the thin skin of the canal, particularly beyond the isthmus. If inspection reveals accumulation of cerumenous debris, this can sometimes be removed carefully using a curette or wire loop along the posterior wall. If the material is against the drum, gentle suction may be feasible. Irrigation should only be used if the drum is known to be intact.

Samples may need to be taken for bacteriology, mycology and histology. If a biopsy is required from the canal, this should be devolved to a surgeon with the necessary expertise.

Developmental defects

The auricle begins to develop at the end of the fifth week of embryonic life in the first branchial groove, contributed to by the first (mandibular) and second (hyoid) arches [1]. Six hillocks appear on these arches and later fuse to form the complex shape of the fully developed auricle.

Developmental defects are considered in detail in Chapter 15. Only those defects of the ear sufficiently common to constitute a part of general dermatological practice are therefore considered here, together with some general principles relating to congenital ear abnormalities and their more important medical and otological associations [2–6]. Pinna abnormalities are associated sufficiently often with conductive hearing loss that screening tests should be carried out [7].

About 30% of infants with external ear anomalies have a renal anomaly identifiable by ultrasound examination, and this combination is a strong pointer towards a multiple congenital anomaly syndrome, in particular Townes–Brocks, CHARGE, branchio-oto-renal, Nager and diabetic embryopathy syndromes [8].

Many developmental defects are of unknown aetiology. Some, however, are associated with chromosomal abnormalities, for example those occurring in Down's syndrome, or are associated with syndromes that have well-recognized Mendelian inheritance patterns, for example the *e*ctrodactyly, *e*ctodermal dysplasia and *c*left lip–palate (EEC) syndrome. Environmental factors may be implicated as in fetal alcohol syndrome and fetal hydantoin syndrome, and maternal exposure to isotretinoin and thalidomide.

Congenital ear abnormalities exhibit great variability, even within syndromes or families, and any one aetiological factor may be associated with a variety of ear malformations. External ear malformations as part of a genetic syndrome account for less than 10% of all external ear abnormalities; isolated cases of ear malformation may either be non-genetic in origin or have a genetic basis but with poor gene penetrance [9].

Microtia (small ears)

Microtia designates a spectrum of underdevelopment of the pinna, from small ears to absence of an ear or ears. Small ears are often associated with hearing deficit and may be a feature of many syndromes. In addition to being small, the pinna may be rudimentary, resembling the hillocks from which it is embryologically derived. The more primitive the appearance, the greater the likelihood of hearing abnormalities, usually due to defects or atresia of the ossicles. There may also be a narrowing or atresia of the auditory canal [9–11] and various abnormalities of the middle ear [12] and inner ear [5]. A wide variety of non-aural abnormalities are associated with small ears, multiple malformations occurring in 56% in one large series [13]. Small ears are a feature of many syndromes, including Down's syndrome, Treacher Collins syndrome, Goldenhar's syndrome, Apert's syndrome, various first and second branchial arch and first branchial cleft syndromes, Mohr's orofaciodigital syndrome, Duane's retraction syndrome and thalidomide embryopathy [5,6,14].

Familial microtia inherited as an autosomal dominant trait has been described [15]. Microtia is one of the birth defects that occurs more on the right than the left side [16].

Macrotia (large ears)

Macrotia is a developmental variation in which the amount of tissue between the helix and antihelix is increased, causing the ears to wing out. The ear may also be diffusely enlarged, or elongated. Such changes are common in Turner's syndrome, and there may be associated sensorineural deafness. Larger ears are well described in fragile X syndrome [17] and Kabuki's syndrome, although in the latter they may also be smaller than normal [18]. Generally enlarged ears are sometimes seen in patients with the XXXXY chromosome defect. The cartilaginous parts of the ears are enlarged and soft in Laband's syndrome [19,20]. In this rare disorder the ears are large and floppy, in association with a bulbous soft nose, gingival fibromatosis and a variety of other findings including absence or dysplasia of nails and/or of terminal phalanges, hyperextensibility of joints, hepatosplenomegaly, and rarely hypertrichosis and mental retardation.

Low-set ears

Normally, the top of the helix is at the same level as the eyebrow, the earlobe is above the angle of the mandible and the external auditory meatus is at the level of the ala nasi. Low-set ears may in addition be posteriorly rotated, and are often small. The condition is usually bilateral. Although it may be isolated, it is often associated with major middle-ear or systemic malformations, appearing for example in Turner's, Noonan's, Patau's and Crouzon's syndromes.

Peri-auricular anomalies

Pre-auricular pits, sinuses (Fig. 65.3) and tags are relatively common, with an incidence of approximately 1% [9,21]. Lesions on or near the tragus are probably best

Fig. 65.3 Pre-auricular sinus.

termed 'accessory tragus' [22]. The term 'accessory auricle' is sometimes used for this, and for similar firm elevations of skin and cartilage just near the ascending crus of the helix. They may be single or multiple and may occur anywhere in a line from the tragus to the angle of the mouth. Accessory auricles, congenital fistulae and other external ear manifestations may occur alone or may be associated with more widespread first and second branchial arch abnormalities, for example Treacher Collins and Goldenhar's syndromes [3,4,8,21], or with developmental abnormalities of the genito-urinary tract [8,21], as well as with isolated hearing defects.

Variations in the shape of the pinna

Minor variations in size and shape are common and not usually associated with any other abnormality. These include *bat ear* or protruding ear, in which the antihelix lacks the usual bulge; *lop ear*, in which there is an unrolled helix, a poorly developed antihelix and scapha, and a large concha resulting in a somewhat floppy ear; and *prominent auricular* (*Darwin's*) *tubercle*. Variations in the contour of the helix and antihelix to produce a bulge of the anterosuperior part of the pinna account for so-called *Mozart's ear*, and in *Wildemuth's ear* the antihelix is prominent and the formation of the helix is poor. These minor ear anomalies can be a syndromic feature or can be associated with conductive and occasionally sensorineural hearing loss, but in most instances they are isolated. They may, however, be inherited, as in the Mozart family. A distinctive *railroad track abnormality* with marked prominence of the crus of the helix is said to occur in up to 30% of children with fetal alcohol syndrome [10,14] and a protruding auricle may, rarely, be a sign of neuromuscular disease [23]. Various abnormalities of the configuration of the pinna have been described in the distinctive *lumpy scalp syndrome* [24], in which other features include absent or rudimentary nipples and dermal nodules on the scalp [25]. The lobule can show isolated abnormalities, for example pits and clefts. Absence of the lobule is, however, usually associated with a syndrome of a more serious nature [6]. Diagonal linear creases in the lobule are seen in Beckwith–Wiedemann syndrome, and in adult life in association with some degenerative diseases (see p. 65.6), although they are a common finding in normal individuals.

Developmental anomalies of ear hair

Hypertrichosis of the pinnae was originally described as a Y chromosome-linked trait [26]. An autosomal dominant genetic basis for hairy ears has also been noted in South Indians [27] and Maltese [28]. Acquired hairy ears have been described in infants born of diabetic mothers [29,30] and in association with human immunodeficiency virus (HIV) infection [31].

Management [32]

The infant with obvious malformation of the pinna that might have auditory system or other associations should be assessed by a paediatrician. The history may reveal exposure to a teratogen (e.g. isotretinoin) or family history of a syndrome and examination may show evidence of other anomalies. Investigations may include radiological evaluation [33], an auditory brainstem evoked response hearing test and a renal ultrasound. It may be appropriate for an ear, nose and throat (ENT) specialist and plastic surgeon [34,35] to become involved with correction of complications and the physical deformity, respectively.

Ageing changes

Many changes seen on the skin of the pinna attributed to ageing are a result of its exposure to environmental factors, especially UV radiation, cold (perniosis) and infrared radiation. The elderly exposed pinna often shows varying degrees of dermal and epidermal atrophy, solar keratoses and lentigines, solar elastosis, telangiectasia and venous lakes. If the pinna is at least partially light protected, as in many women, the skin may still appear somewhat thinned due to intrinsic ageing changes.

Ear length

It is recognized in Chinese culture that length of the ear in men is a predictor for longevity [1]. Two studies would appear to confirm this: one from Kent, UK [2], and one from Japan [3]. The increase in length of the male ear from the age of 30 years onwards may have a 7-year periodicity [4].

Earlobe creases

First described in 1973 [5], and now known as Frank's sign, a diagonal crease in the earlobes of adults has been associated in many studies with an increased risk for atherosclerotic coronary artery disease. A meta-analysis in 1983 gave a relative risk of 2.06 for heart disease if there are bilateral creases [6] and there is approximately double the risk for death from heart disease [7,8]. The crease can be graded in terms of length and depth, and deeper longer creases have the strongest association. The ear crease appears to be separate from other risk factors for coronary artery disease, and is not simply a function of age [9]. A more recent case–control series suggests a relative risk of 1.37 for myocardial infarction [10] and a lower specificity for the sign than previously estimated [11].

Diagonal earlobe creases are seen in other contexts, for example Beckwith–Wiedemann syndrome [12] (Fig. 65.4),

Fig. 65.4 Diagonal earlobe crease in an infant with Beckwith–Wiedemann syndrome.

and do not seem to be associated with coronary artery disease in Hawaiians [13], native Americans [14] or Chinese [15].

Earlobe creases have also been associated with primary open-angle glaucoma [16].

Traumatic conditions

Contusion and haematoma

Bruises of the ear are usually due to blunt trauma and are common in contact sports, such as boxing, wrestling and rugby. In children, physical abuse may need to be excluded [1,2]. A distinctive condition known as *tin ear syndrome* has been considered pathognomonic of child abuse: a triad of isolated ear bruising, haemorrhagic retinopathy and a small ipsilateral subdural haematoma [3].

Following trauma, blood and serum collects in the plane between perichondrium and cartilage, and will undergo fibrosis if not removed early. The patient should be carefully examined for concurrent auditory canal, middle ear, parotid and central nervous system trauma.

Repeated trauma may result in the distorted nodular deformity known as *cauliflower ear*, which is due to varying degrees of cartilage necrosis, fibrosis and dystrophic calcification.

Treatment. Subperichondrial haematomas must be treated promptly, with full aseptic technique to avoid secondary perichondritis. Small collections of fluid can sometimes be aspirated by syringe, but usually need to be drained through a small incision and a laterally placed pressure dressing applied to prevent reaccumulation [4,5]. Another useful technique is to use a through-and-through suture technique to maintain bolsters over the area where the haematoma has been evacuated [6]. Other approaches include a posterior incision and suction drainage [7], or fenestrations in the cartilage to promote adhesion of the opposing perichondrial layers [8]. Prophylactic antibiotics are sometimes given. Improvement of cauliflower ear usually requires multiple corrective procedures.

Laceration and avulsion

Lacerations of the pinna vary from the trivial to amputation [1]. Because of the risk of cartilage infection, potentially dirty wounds should always be carefully cleaned and a course of prophylactic antibiotic given. It is probably best to avoid suturing the cartilage itself unless pieces overlap or are severely displaced [2]. Injuries that expose cartilage will need to be covered with a skin graft, for example taken from behind the ear or the upper eyelid. If the anterior perichondrium is destroyed, cartilage may need to be excised so that the graft can be placed on the posterior perichondrium. If the post-auricular area is not injured, a pedicled island flap of post-auricular skin may be pulled through the area of excised cartilage and sutured into place. If the helix or antihelix is exposed, it may be possible to cover it with an advancement or rotation flap from the posterior surface of the auricle. Large areas may need to be covered with a pedicled flap of temporoparietal fascia, which in turn is covered with a split-skin graft. The lobule of the ear can be repaired by direct closure, although a cosmetically superior result may be obtained by a broken line repair or Z-plasty [3]. Many techniques have been described for repair of major

trauma, including even complete avulsion of the pinna [1,4,5], but these are likely to be beyond the scope of the dermatologist. Following total ear replantation there is lack of cutaneous sensation and this may explain the cold intolerance that can occur [6].

Dermatitis artefacta

The ear is occasionally the sole site for self-mutilation and there may be underlying psychodynamic reasons for this [1].

Ear piercing

Earrings have been worn by men and women since antiquity, and tend to follow the dictates of fashion. Current trends include using rings or studs in almost all parts of the body, the use of up to 10 or more in a single ear, and the piercing of cartilage.

Complications are very common, with rates of about 30% whether the procedure is carried out by medical personnel, friend or relative, or in a store; they are also independent of technique, there being little difference in frequency of complications from piercing by needle, staple gun or sharpened stud [1]. Minor infection is the most common adverse effect, with contact dermatitis, keloid and traumatic tear occurring less often [2]; other consequences occur occasionally. Although case series indicate that so-called 'high' ear piercing, i.e. through cartilage, has a significant risk for perichondritis [3,4] and chondritis [5], such events were not found in a population study of 1000 nurses [2]. Embedding of the earring seems to be a common problem in children [6].

The ear is also pierced in acupuncture as used in traditional medicine, and complications have been reported [7,8].

Complications. Various infections and reactions may occur after ear piercing.

Localized bacterial infection, usually with Gram-positive cocci, is common; predisposing factors include skin disease, such as atopic or contact dermatitis. Life-threatening septicaemia has been described [9]. Infants with unsuspected immunodeficiency and individuals with valvular heart disease may be at particular risk. When cartilage is pierced the usual bacterial infection is with *Ps. aeruginosa*, which causes perichondritis [3] or chondritis [5], and for which the best treatment is ciprofloxacin [4]. Any purulent material should be cultured, since other pathogens have been described (e.g. *Lactobacillus* [10]). Primary tuberculosis has been described [11].

Viral hepatitis may also be a hazard [12,13].

Oedema and haematoma [1,14] usually respond to cold compresses, pressure and removal of the earring. Haematoma may require incision and drainage [15].

Trauma can occur from pressure on the lobe and postauricular skin, or from inaccurate insertion of the post of the earring. Heavy earrings can tear the earlobe, sometimes making it bifid. Repair of the latter is probably best by excision of the cleft and simple closure with eversion of the edges [16], although a staggered repair such as a Z-plasty may be appropriate in some cases.

Sensitization to nickel from earrings remains a major problem, and ear piercing is one explanation for the higher incidence of nickel allergy in females [17]. Even stainless steel studs and clasps, which can produce irritant as well as allergic effects, may release sufficient nickel to elicit contact dermatitis [18]. Gold sensitization, although less common [19], can be a protracted cause of dermatitis even after the earrings are removed [20]. Contact dermatitis from other materials used in earrings, such as olive wood [21], copper [22], cobalt [23,24] and chromium [25], has been described, and may also occur from the use of topical antiseptics, antibiotics and dressings used to treat infection.

Granulomatous and lymphoid reactions. Reddish brown and purple papules and nodules at sites of ear piercing may denote a granulomatous response to gold [26,27] and a lymphocytoma cutis-like reaction has been described [28–30]. Sarcoidosis has presented after ear piercing [31].

Embedded earrings. The spring-loaded gun method of ear piercing can result in the earring backing becoming embedded in the back of the ear [32]. The 'vanishing earring' [33] can resemble a keloid [34]. The embedded metal can usually be pulled out, or if necessary an incision can be made to locate it.

Epidermoid cyst formation. Implantation epidermoid cysts due to ear piercing often present as tender, chronic,

Fig. 65.5 Keloids following ear piercing.

inflammatory swellings, sometimes with drainage. There is usually an epithelial lined track as well as cysts, and all epithelial tissue must be removed, for example with a skin punch [35].

Keloids quite commonly follow ear piercing, especially in those ethnic groups with a predisposition (Fig. 65.5). The keloids seem to occur more on the back surface than the front of the earlobe [36]. As well as being unsightly, they can itch and be painful.

Treatment options include intralesional steroid, pressure [37], and excision with or without concurrent use of intralesional steroid [38] or radiotherapy (see Chapter 76) [39]. Prospective controlled trials are needed to assess these approaches.

A recent study has shown efficacy and acceptability of intralesional steroid followed by Zimmer splints which can be decorated to look like earrings [40].

Localized argyria. Bluish macules have been described on the posterior surface of the earlobe [41,42].

Frostbite has followed the use of ethyl chloride topical anaesthesia [43].

Measures to prevent complications [44]. Many of the complications of ear piercing are avoidable. The procedure is best not carried out on children under the age of 5 years or those with immunodeficiency, valvular heart disease or sarcoidosis, and there is clearly a risk if the individual has a tendency to keloid formation. For a dermatologist who wishes to pierce ears or instruct others, a simple method with a low likelihood of complications has been described [45]. The use of a surgical-grade, stainless steel, one-piece earring with an interlocking groove has been recommended. Gold-plated or gold-alloy earrings should be avoided for at least 6 weeks after the ear has been pierced. Sterile technique is important. Piercing of cartilage should be avoided. Only nickel-free earrings should be used. Large or heavy earrings should be removed prior to activities that may result in tearing the earlobes. A technique using a piece of intravenous catheter to avoid reactions in metal-sensitive individuals has been described [46].

Acanthoma fissuratum

This chronic response to friction and pressure from the spectacle frame can present with papules or nodules, sometimes with ulceration, in the supra-auricular or retro-auricular folds (Fig. 65.6); even when bilateral, basal cell carcinoma is a differential diagnosis. Acanthoma fissuratum is discussed in Chapter 22.

Fig. 65.6 Acanthoma fissuratum. Nodular thickening behind the pinna superficially resembling basal cell carcinoma.

Cold injury

The ears are extremely susceptible to cold, and the pinna may be affected by chilblains in winter (Fig. 65.7). Extreme cold will cause frostbite (see Chapter 23). Similar changes have also been reported as a consequence of using excessive amounts of ethylchloride spray for ear piercing [1]. Frostbite may result in vesiculation, blisters and ischaemic necrosis of both skin and cartilage. Ears that have previously been damaged by cold may subsequently become calcified and even ossified [2,3].

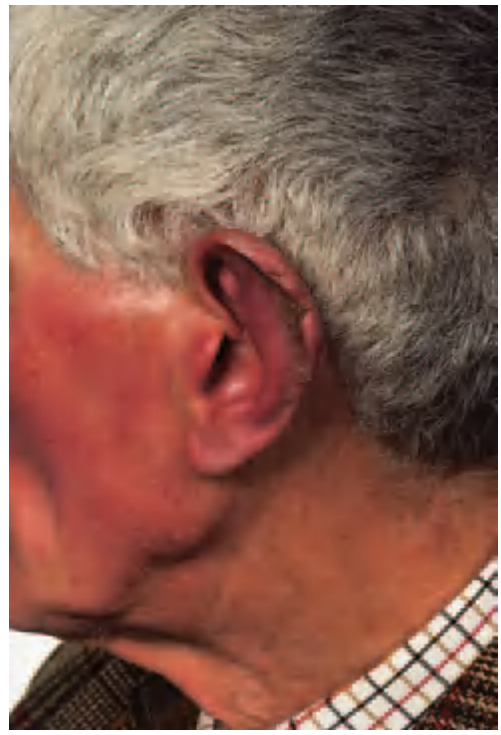

Fig. 65.7 Perniosis. Purple discoloration, soft-tissue loss and crusting due to acute-on-chronic cold injury.

Cold is also a provoking factor in many conditions that can affect the ear, for example chondrodermatitis nodularis helicis, chilblain lupus erythematosus and cryoglobulinaemia.

The ear subjected to frostbite should be thawed rapidly by the application of wet, sterile cotton pledgets warmed to 38–42°C for about 20 min [4] with adequate analgesic cover.

Emollients have traditionally been thought to protect against frostbite [5], at least in Finland. However, those who use them experience more frostbite, probably through conferring a false sense of safety, and only thermal protection from clothing can be expected to have protective value [6].

Fig. 65.8 Venous lakes on a sun-damaged pinna.

Solar damage

The external ear is often exposed to solar radiation and is therefore liable to acute and chronic sequelae. A significant hazard from severe sunburn is the development of perichondritis (see below). Many photosensitivity disorders will present on the ear, for example polymorphic light eruption, juvenile spring eruption, lupus erythematosus and porphyria (see Chapter 24).

The full gamut of chronic solar damage is frequently seen on the ears, including erythema, telangiectasia, atrophy, blotchy pigmentation, solar keratoses and cutaneous malignancies. As on the lower lip, venous lakes may be seen (Fig. 65.8). Solar elastosis is often evident, and distinctive elastotic nodules may be seen particularly on the anterior crus of the antihelix [1–3]. These lesions are usually bilateral and asymptomatic, and present as pale papules or nodules. Occasionally, they can occur on the helix and be painful, simulating chondrodermatitis nodularis. They differ from 'weathering' nodules (Fig. 65.9), which, like chondrodermatitis nodularis, occur on the helix of the ear [4].

For treatment of mild acute sunburn, cold compresses may be sufficient. More severe cases may benefit from a course of systemic corticosteroid, given for 5 days and then tapered. Preventive measures are discussed in Chapter 24.

Fig. 65.9 Several firm, white, 'weathering' nodules on the helical rim.

Altitude injury

A distinctive presentation of petechiae and haemorrhagic bullae in the skin of the external auditory canal and tympanic membrane has been described in air pilots descending from high altitudes or in pressure chambers while wearing well-sealed earplugs as noise protectors [1].

For treatment, a steroid–antibiotic ear drop has been advised, and if sizeable clots are present they can be gently dislodged by suction after the application of hydrogen peroxide. Preventive methods include the use of perforated earplugs on high-altitude descent.

Radiation injury

Therapeutic use of radiation may result in characteristic acute and chronic changes (see Chapter 76). The cartilage can be susceptible to destruction if inappropriate techniques are used. Post-radiation changes on the external auditory canal include thickening of the canal epithelium, subepithelial fibrosis and resorption of underlying bone, as well as ulceration of the epithelium and the development of cholesteatoma [1].

Foreign bodies

A variety of vegetable, animal and mineral substances may be encountered lodged in the external ear and external auditory canal, and are frequently unsuspected. Presenting symptoms include pain, hearing loss, inflammation and discharge.

Vegetable matter, such as beans, peas and cotton, tends to absorb water and swell, impacting in the ear canal. Arthropods are the commonest animal material. While alive, their motion within the ear can produce distinctive symptoms, even vertigo. Flies can deposit eggs in the external auditory canal and the resulting myiasis has produced severe complications [1]; larvae in the triangular fossa of the pinna can also cause marked inflammation [2]. Mineral materials include beads, sand and pebbles, fragments of plaster and metallic substances. Even batteries have been found lodged in the ear and can produce serious consequences [3–5]. Impacted cerumen can behave like a foreign body in the ear canal. Loose hairs in the ear canal have been reported as a cause of noise [6].

Retrieval of foreign bodies should only be undertaken if appropriate instrumentation and expertise is available. For children, with whom the problem is more common, general anaesthesia is required. Small foreign bodies can usually be extracted with a curette or alligator forceps. Live insects should first be killed by drowning, for example in 2% lidocaine (lignocaine) [7], ether, chloroform or spirit. If some vegetable materials have absorbed water and become impacted, it may be necessary to divide the foreign body *in situ* and remove the fragments. It may be necessary to control bleeding from the skin of the canal, for example with epinephrine (adrenaline)-soaked gauze, and the canal should then be packed with an antibiotic-impregnated dressing. In cases of a battery lodged in the ear canal, it is essential that an ENT surgeon is involved in the management, because of the likelihood of serious destructive change to the middle ear and beyond.

Chondrodermatitis nodularis

This painful condition usually involves the superior portion of the helix, but may appear on the antihelix, concha, tragus and antitragus. It has formerly been known as painful nodule of the ear [1].

Aetiology. The principal factors in its pathogenesis are pressure and a compromised local blood supply. It is much more common in patients who habitually sleep on one side at night but can be triggered off by other factors, including cold, and by other types of pressure (e.g. from headgear, earphones). Alteration of connective tissue by chronic sun exposure may also be a factor [2]. The age of onset is over 40 years in most cases and the condition is commoner in males than females. We have encountered chondrodermatitis nodularis in juveniles, but only when

there is an abnormality such as marked prominence of the antihelix or a history of injury (e.g. from contact sports). Chondrodermatitis nodularis has been reported in a series of patients with systemic sclerosis [3] and in childhood dermatomyositis [4].

Pathology [5,6]. A typical lesion of chondrodermatitis nodularis consists of a nodule of degenerate homogeneous collagen surrounded by vascular granulation tissue with an overlying acanthotic epidermis, and there may be a central ulcer through which the damaged collagen is extruded. In nearly all cases there is inflammation and fibrosis of the underlying perichondrium, and degenerative changes may be seen in the cartilage. Although many authors view the condition as an example of transepidermal elimination of altered connective tissue, it has been suggested that the infundibular portion of the hair follicle is primarily involved, with perforation of the follicular contents into the dermis [7,8].

Clinical features. The patient, usually a middle-aged to elderly man, seeks advice on account of pain. The more stoical may postpone consultation until the lesion interferes with sleep. The pain, which is sometimes severe, is initiated by pressure and occasionally by cold. It may be brief but can persist and throb for an hour or more. Occasionally, and particularly in women, there is little discomfort. The lesion is a globular or oval nodule, about 0.5–2 cm in diameter, raised above the often hyperaemic surrounding skin (Fig. 65.10). The surface is frequently scaly or crusted, concealing a small ulcer.

In men, nearly 90% of nodules are situated on the helix, usually at the upper pole and more frequently on the right, but may occur on the antihelix [9], tragus, concha and antitragus, in order of decreasing frequency [10]. Occasionally, there are multiple nodules or lesions, and they may occur bilaterally [11]. In women, the left and right ears are affected equally and the proportion of lesions on the antihelix and tragus is greater [12]. The nodules attain a maximum size in a few months and then remain unchanged indefinitely.

Diagnosis. Although the associated pain and tenderness are characteristic, the lesion is often misdiagnosed. Differential diagnosis includes basal and squamous cell carcinomas, solar keratosis, calcification of the pinna, elastotic nodules and 'weathering nodules' [13].

Treatment. For chondrodermatitis nodularis of the helix, excision with a narrow margin of normal skin has been recommended as standard treatment [14,15] and the approach can usefully be modified by the additional use of a curette, to define the extent of necrotic cartilage [16]. Cosmetic results are often poor and long-term recurrence rates rarely reported. Removal of cartilage only can provide excellent results and this technique can be applied to other sites such as the antihelix and tragus. The results are often cosmetically superior [17]; long-term cure rates in excess of 80% have been reported [18]. Other treatments include intralesional steroid therapy [19], liquid nitrogen cryotherapy and carbon dioxide laser [20,21]. In all patients, efforts must be made to reduce pressure or trauma to the helix. Where facilities exist for construction of individualized pressure-relieving devices, these can be useful [22].

Fig. 65.11 Pseudocyst. Asymptomatic fluctuant swellings on the upper pinna.

Pseudocyst of the ear

SYN. ENDOCHONDRIAL PSEUDOCYST; IDIOPATHIC CYSTIC CHONDROMALACIA

A non-inflammatory, fluid-filled cavity within the cartilage of the ear.

Aetiology. Although the cause is unknown in most cases, trauma is likely to be important at least in some, as in fracture in the ear cartilage [1], habit-twisting of the ears [2] and rubbing due to atopic eczema [3]. Most speculations about the pathogenesis include an underlying malformation of the cartilage [4] and degeneration due to release of lysosomal enzymes from chondrocytes. A role for cytokines has also been suggested [5].

Pathology. There is a cavity within the cartilage, the walls of which show the presence of eosinophilic amorphous material [6,7]. There may be focal fibrosis, especially in older lesions.

Clinical features. Most cases are young men, although the condition is seen over a wide age range [8] including infants [9]. Occasional cases have been recorded in females [4]. All races are affected [10]. There may be a predilection for Chinese, although this could be reporting bias [11,12]. The condition is usually unilateral and presents as an asymptomatic swelling, which is non-tender and fluctuant. Occasionally, there are signs of inflammation and some tenderness. The commonest location is on the upper half of the ear (Fig. 65.11), on the scapha, less commonly over the helix and antihelix. Sometimes, coalescent swellings are seen. Aspiration usually yields serous fluid, which soon reaccumulates.

Diagnosis. The differential diagnosis includes traumatic perichondritis, relapsing polychondritis (see Chapter 46), haematoma, dermoid cyst and epidermoid cyst, and various benign and malignant tumours; any of these can if necessary be excluded by histological examination.

Treatment. Needle aspiration followed by the introduction of a few drops of 1% tincture of iodine [10] or corticosteroid [13] and then application of a contour pressure bandage is often successful. Thermoplastic material as used for mobilizing extremities can be used to provide the pressure [14].

For recurrences, excision of the anterior wall of the cyst, suturing the skin flap back and use of a pressure dressing can produce a cosmetically satisfactory result in most cases [12].

Dermatoses and the external ear

Atopic dermatitis

A crusted eczematous fissure at the junction of the earlobe and the face is a common finding in atopics, and can be regarded as a reliable feature of atopy [1–3]. In the series of Tada *et al*. [3], 45 of their 46 patients with severe atopic dermatitis had infra-auricular fissures. In addition to involvement of the infra-auricular crease, the tragal notch and sometimes the whole of the pinna may be commonly involved. Treatment of eczema and the secondary infection that often accompanies it is discussed in Chapter 18.

Seborrhoeic dermatitis

In its mildest form, seborrhoeic dermatitis simply causes a little scaling and inflammation at the entrance to the external auditory meatus, in the concha or in the auricular folds. When severe, the whole pinna may be affected and there may be infective eczematoid dermatitis both in and around the ear or post-auricularly. The relationship between seborrhoeic dermatitis and otitis externa is discussed in Chapter 17.

Asteatotic eczema

The exposed position of the ear renders it vunerable to the climatic changes that can induce asteatotic eczema (see Chapter 17). This common cause of a dry itchy ear is mainly seen in the elderly. Aggravating factors include overzealous cleansing, cold, windy weather, low humidity indoors and air-conditioned air during the summer. There may be little to see other than slight scaling. Similar changes can occur in the ear canal, where additional factors include drying vehicles used in ear drops, for example alcohol and acetone. Management will include avoidance of provocative factors, and use of emollients.

Contact dermatitis

The external ear is commonly affected by both irritant and allergic contact dermatitis [4]. Causes of contact allergy may be grouped as follows.

1 Products used for the hair and scalp: hairspray, shampoos, hair dyes, hair nets, bathing caps.
2 Items worn or placed in or on the ear: jewellery, especially nickel alloys (see p. 65.8).
3 Plastic, rubber or metal ear appliances, for example hearing aids, spectacles, headphones, telephone receivers, earplugs, hair nets.
4 Objects used to clean or scratch the ear, for example hairpins, matches.
5 Cosmetics and toiletries: make-up, perfumes, soaps and creams.
6 Topical medicaments.
7 Others (transferred to the ear by fingers): nail varnish, plant resins (e.g. poison ivy, oak or sumac).

The role of occult allergic contact dermatitis in patients with otitis externa is discussed on p. 65.24.

Psoriasis

Both guttate and plaque psoriasis involve the external ear. Sometimes this is by extension from the scalp, face or neck. Like seborrhoeic dermatitis, psoriasis often involves the concha and distal part of the external auditory canal, but usually its colour, the nature of the scaling and the presence of psoriasis elsewhere allow it to be differentiated. Sometimes both conditions appear to coexist.

Acne

Comedones frequently involve the concha, and are occasionally found on the helix, tragus or earlobe. Inflammatory cysts may be found on the lobe, at the entrance to the external auditory canal, or in both the pre- and post-auricular areas. Pressure from spectacle frames, telephone receivers or headsets can aggravate acne lesions.

Darier's disease

Occasionally, Darier's disease can present with involvement of the external ear as the principal affected site, with erythema, oedema and crusting mimicking an eczematous reaction [5].

Transepithelial elimination disorders

The ear may occasionally be the site for lesions of Kyrle's

Fig. 65.12 Cutaneous lupus erythematosus. Acute erythema and erosions following sun exposure.

disease, elastosis perforans serpiginosa, perforating folliculitis and perforating papules of diabetic dialysis patients. These conditions are discussed in Chapter 46.

Lupus erythematosus (Fig. 65.12)

Although most parts of the pinna may be involved in lupus erythematosus, pits and scarring in the concha are distinctive features [6,7]. Atrophy often occurs, and even perforation of the pinna [8].

Mudi-chood

This distinctive dermatosis, which typically affects the nape of the neck and upper shoulders of girls and young women in the state of Kerala in South India, can occur on the ears. It is thought to be the result of the frictional and occlusive effects of moist oily hair in a hot and humid environment. Individual lesions are hyperpigmented papules with a thin surrounding rim of scale, occurring on the posterolateral aspects of the pinnae [9].

Lymphocytoma cutis

When the ear is involved, the lobe is characteristically affected, often with a large single nodule. Possible causative factors include *Borrelia burgdorferi* infection [10] and gold earrings [11,12].

Jessner's benign lymphocytic infiltration

This condition occasionally involves the ear and postauricular region, and sunlight may precipitate or worsen the eruption.

Granuloma annulare

Typical papular and annular dermal lesions of granuloma annulare may involve the pinna, sometimes in the absence of lesions elsewhere [13].

Primary cutaneous amyloidosis

Asymptomatic papules on the helix and concha of the ear have been described as the sole manifestation of cutaneous amyloidosis [14]; such lesions can also occur with more generalized papular amyloid [15] and with macular amyloid of the back [16].

Angiolymphoid hyperplasia with eosinophilia
SYN. PSEUDOPYOGENIC GRANULOMA; NODULAR ANGIOBLASTIC HYPERPLASIA WITH EOSINOPHILIA

This is a reactive proliferative disorder of blood vessels with a variable component of inflammatory cells [17]. Opinions vary as to whether it is identical with Kimura's disease, a condition mainly found in Eastern orientals (see Chapter 53). Angiolymphoid hyperplasia with eosinophilia occurs in both a dermal [18] and a subcutaneous [19] form, and is most commonly found on the head and neck. The two forms are regarded as variants of the same condition [20–22].

Aetiological factors include trauma, pregnancy and immunization procedures [23].

Histology. There are circumscribed collections of vessels whose endothelial cells are epithelioid, i.e. have abundant eosinophilic cytoplasm and large nuclei. These cells sometimes proliferate into the lumen, and may occur in solid clumps. The associated inflammatory infiltrate consists of lymphocytes, sometimes lymphoid follicles, and there are varying numbers of eosinophils. At least in some cases there may be an underlying associated arteriovenous malformation [24]. In typical Kimura's disease there is more prominent lymphoid hyperplasia.

Clinical features. The dermal form commonly affects the pinna, external auditory meatus (Fig. 65.13) and postauricular area. The lesions are red-brown papules or nodules. Occasionally, they itch and can be painful or pulsatile [23]. The condition mainly affects young to middle-aged adults, and in some series there is a female preponderance [25].

Kimura's disease has been reported as involving the

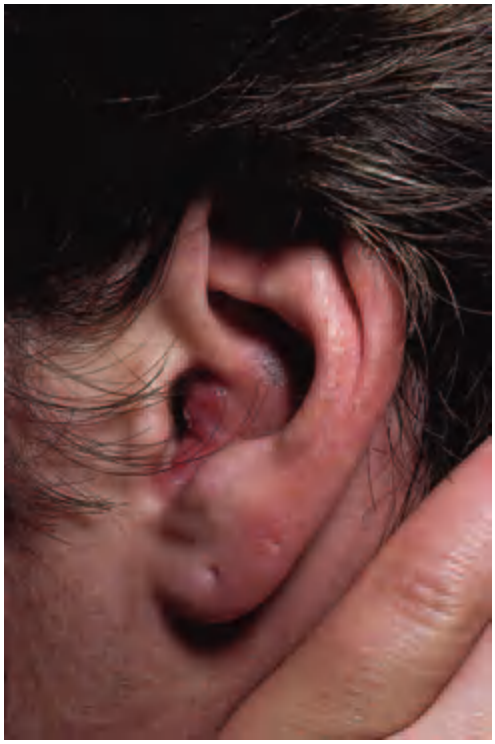

Fig. 65.13 Angiolymphoid hyperplasia with eosinophilia. Firm red-brown nodules at the entrance to the external auditory canal.

ears [26,27] but more commonly produces subcutaneous, lymph node and salivary gland-related masses in the head and neck.

Differential diagnosis includes pyogenic granuloma (rare at this site), bacillary angiomatosis and angiosarcoma.

Treatment. The treatment of choice is surgical excision, although there is often recurrence. Intralesional corticosteroids, pulsed dye laser [28], radiotherapy or oral immunosuppressive agents have been used in some cases with benefit.

Skin reactions to osseo-integrated implants

Restoration of the pinna following traumatic loss or congenital absence may be achieved using an osseo-integrated skin-penetrating titanium fixture. About 10% of such patients have skin reactions [29,30]. The reaction consists of erythema and crusting, sometimes with significant infection, which should be adequately treated.

Elephantiasis of the external ears

Chronically red swollen ears may occur for a number of reasons, including long-standing eczema, psoriasis [31] and chronic streptococcal infection. Long-standing head louse infection has also been reported as a cause [32].

Psychocutaneous disorders

Dermatitis artefacta and delusions of parasitosis (see Chapter 65) may occasionally result in self-induced lesions on the ears and even in the ear canals.

Granuloma faciale

The ear is an occasional site for this distinctive disorder [33].

Bullous diseases

Pemphigus, pemphigoid, dermatitis herpetiformis and epidermolysis bullosa aquisita may all involve the ear, and occasionally the auditory canal. Blistering of the pinna and stenosis of the canal can occur in dystrophic epidermolysis bullosa [34].

Verruciform xanthoma

This uncommon condition is typically found in the mouth but has been reported on the ear, where it can mimic squamous cell carcinoma [35].

Adult-onset xanthogranuloma

Symmetrical yellow-red nodular lesions with the same histology as juvenile xanthogranuloma have been described on the earlobes [36].

Systemic disease and the external ear

Many conditions described more fully elsewhere will occasionally present on the external ear with lesions of diagnostic value.

Granulomatous disorders

These include sarcoidosis [1,2], especially the lupus pernio variety. Metastatic Crohn's disease may rarely involve the ear [3]. Atypical facial necrobiosis may involve the ear, as well as the more typical location on the face and scalp. Wegener's granulomatosis can present with serous or suppurative otitis and conductive or sensorineural deafness [4,5]. A similar allergic granulomatosis affected both ears in a young black South African who died from glomerulonephritis [6]. Infective granulomatous diseases involve the ear, notably leprosy, in which the earlobe is a valuable site for taking smears [7]. Lupus vulgaris, other manifestations of tuberculosis, atypical mycobacterial infection (e.g. *Mycobacterium marinum* from swimming-pool injuries), deep fungal infections and even syphilis [8] can involve the ear.

Collagen vascular diseases

As well as discoid lupus, subacute cutaneous lupus erythematosus and systemic lupus erythematosus may also involve the ears. Scleroderma can produce pallor and telangiectasia of the auditory canal. Rheumatoid disease is characterized by nodules, which can occur on the ear, where they may ulcerate due to pressure from the pillow or spectacles. Redness, tenderness and swelling of the ear, but sparing the lobe, is characteristic of relapsing polychondritis (see Chapter 46).

Pyoderma gangrenosum

The ear is an occasional presenting site [9] for this primary ulcerative disorder, discussed in Chapter 49. Vasculitis and factitial disease may be mimicked.

Metabolic disorders

Xanthomas occasionally occur on the ears, presenting as yellow nodules. Gouty tophi frequently involve the pinna (Fig. 65.14), and may antedate the onset of joint disease or

Fig. 65.14 Gouty tophi. Yellowish dermal nodules.

Fig. 65.15 Porphyria cutanea tarda. Firm, whitish, sclerodermoid changes at the site of repeated blistering.

Fig. 65.16 Alkaptonuria. The auricular cartilage has a distinctive blue colour. (Courtesy of Dr P. Hollingworth, Southmead Hospital, Bristol, UK.)

appear decades after the initial attack. The helix and antihelix are typical sites. Histology is distinctive. Porphyria cutanea tarda (Fig. 65.15) may present with vesicles and bullae, often on a background of scarring, hyperpigmentation, milia, sclerodermoid plaques and hypertrichosis. Pseudocysts of the auricle and perichondritis may be simulated [10].

Diseases of connective tissue

Cutis laxa may result in distinctive pendulous earlobes [11].

Alkaptonuria

SYN. OCHRONOSIS

This is typically associated with a bluish discoloration of the auricular cartilage due to oxidation of bound homogentisic acid (Fig. 65.16). The cerumen in such patients may be very dark, a finding that can precede other clinical manifestations.

Calcium deposition

Calcium deposition may occur in many circumstances (see Chapter 57) and occasionally the ear is involved. The so-called petrified ear has been described in association with diabetes mellitus [12]. Usually, calcium deposits in the ear occur for local reasons, for example degenerative changes in the cartilage. In infants, congenital nodular calcification of Winer should be considered [13].

Endocrine disorders

In Addison's disease, the pigmentary changes may involve the ear, and ossification of the auricular cartilage may occur [14]. In acromegaly, there is usually enlargement of the auricular cartilage and coarsening of the overlying skin.

Paraneoplastic syndromes

Bazex's syndrome (acrokeratosis paraneoplastica) (see Chapter 59) commonly affects the ears and is an important marker for internal malignancy [15].

Drug-related effects

Purpura of the ears has been described in a series of children receiving levamisole for nephritic syndrome [16]. Both vasculitis and thrombotic changes occurred, and there was an association with circulating autoantibodies.

Hypertrophy of the retro-auricular folds may be seen as a consequence of phenytoin therapy [17]. Hypertrichosis of the ear canal due to minoxidil therapy can be a predisposing factor for external otitis [18].

Lymphoma

Systemic lymphoma can occasionally present as an isolated lesion on the ear [19].

Infection

The anatomy of the ear, with its many folds and the semi-occluded nature of the external auditory canal, make it particularly susceptible to intertriginous infection, especially with Gram-negative organisms. The close anatomical relationship between the middle and external ear means that infections can pass relatively easily from one to the other, and the eardrum should always be examined. The cartilaginous and bony structures close to the skin are particularly vulnerable to infection. Although chondritis and perichondritis may have other causes, they are included in this section.

Infections of the pinna

Staphylococcus aureus, alone or in association with group A β-haemolytic *Streptococcus*, may cause impetigo contagiosum of the ear. This is a relatively common site for infection in infants and young children. *Staphylococcus aureus* is also the most common causative organism of furuncles (boils) and carbuncles, which are more common in the external auditory canal than on the pinna. Cracks and fissures around the auricle are often the portal of entry for β-haemolytic streptococcal infection manifesting as erysipelas. This is more common in the elderly, the newborn and those suffering from malnutrition, disability, alcoholism, diabetes or immune deficiency states.

Erysipelas typically begins with high fever and constitutional upset, including malaise, vomiting and headache, and there is rapidly spreading erythema and oedema from the pinna on to the face. There is often lymphadenopathy. Recurrent attacks of cellulitis of the face may have the same predisposing factors as at other body sites. Recurrent attacks of cellulitis lead to fibrosis and lymphoedema. Treatment of erysipelas and cellulitis is discussed in Chapter 27.

Necrotizing fasciitis has rarely been described arising from an initial infection of the pinna [1].

The term *infective eczematoid dermatitis* is still used for an oozing, crusted, eczematous condition occurring on and often below the pinna in association with chronic discharge from the ear. Coagulase-positive staphylococci are the most frequently isolated bacteria. The ear canal is oedematous and erythematous, and purulent discharge may be seen coming from a perforated tympanic membrane. The condition should be differentiated from impetigo, secondarily infected contact dermatitis, seborrhoeic dermatitis and atopic dermatitis.

Treatment. Primary infection of the ear must be treated appropriately, usually with a systemic antibiotic; any associated chronic otitis media or mastoiditis is likely to be managed by an otologist. Involved skin can be cleansed with saline, 1 in 10 000 potassium permanganate or dilute aluminium acetate soaks and then treated with a topical steroid. Surgical intervention will be required for necrotizing fasciitis.

Perichondritis and chondritis

Inflammation of the cartilage itself (chondritis), or more commonly the vascularized lining (perichondritis), can be indistinguishable from infection of these structures, and infection is a common complication whatever the cause [2,3].

Aetiology. There are many causes, including physical trauma (Fig. 65.17), thermal and chemical burns, frostbite, pressure (e.g. from tight headphones and head-dresses [4]) and ear piercing (see p. 65.8) including acupuncture [5,6]. Perichondritis may occasionally follow superficial

Fig. 65.17 Pressure ulcer exposing cartilage, a potential cause of chondritis.

infections of the ear such as furunculosis or otitis externa. The most common infecting organism is *Ps. aeruginosa*, although other Gram-negative organisms or staphylococci may at times be responsible.

Clinical features. Chondritis and perichondritis are typically painful. The pinna becomes hot, painful and swollen, with loss of normal contour due to oedema, and there may be accumulation of pus in the subperichondrial layer. Constitutional symptoms are common. The inflammation can spread back to the adjoining face. The destruction of cartilage results in deformity of the ear, which may be severe. Necrotizing fasciitis can follow perichondritis of the pinna [1], and if suspected must be treated by urgent débridement.

Diagnosis. Perichondritis may be difficult to distinguish from cellulitis, although perichondritis is usually more painful and does not involve the lobule of the ear, which lacks cartilage. Relapsing polychondritis (see Chapter 46) usually also involves cartilage at other body sites, and is often recurrent.

Treatment. Treatment should be instituted promptly. If an abscess has developed, early drainage is necessary. Ciprofloxacin or other quinolones are probably the treatment of choice [7,8]. Necrotic cartilage may subsequently need to be excised, and fluid collections aspirated.

Other bacterial infections of the pinna

Mycobacterial infection can rarely involve the external ear. Lupus vulgaris can produce extensive destruction [1] and mimic other conditions [2]. Secondary involvement from underlying lymph-node disease (scrofuloderma) can present with hearing loss, tinnitus and peri-auricular lymphadenopathy, with only minimal secretion in the ear canal [3].

Atypical mycobacteria that may involve the ear include *M. marinum* acquired from swimming-pool injuries.

In leprosy, the ear is almost always involved in the lepromatous type, and there may be evident infiltration of the skin. The earlobe is often used for taking smears [4].

Syphilis may occasionally involve the ear, usually in the secondary stage [5].

Viral infections

Herpes simplex occasionally involves the ear. It is often transmitted during contact sports such as rugby and wrestling. Herpes zoster may present as an isolated herpetiform eruption of the external ear or may be associated with ipsilateral facial palsy and auditory symptoms (Ramsay–Hunt syndrome; geniculate herpes). The condition usually begins with pain and may initially be

mistaken for erysipelas. Vesicles usually appear on about the fifth day and involve the pinna, the external auditory meatus and, rarely, the tympanic membrane. There is usually malaise, pyrexia and lymphadenopathy. Facial palsy, when it occurs, is usually transient, but more severe and persistent cases do occur. Taste and lacrimation may also be affected. Compression damage to the VIIIth cranial nerve may lead to tinnitus, vertigo, nystagmus, nausea and deafness. Management of herpes zoster is discussed in Chapter 25. Orf affecting the ear has been described, presenting as an inflammatory nodule on the tragus [1].

Superficial and deep mycoses

Dermatophyte fungi may rarely involve the ear, and when present can simulate granulomatous disease [1] and chondritis [2].

Pityriasis versicolor may involve the ears, but is usually easy to diagnose.

In cases of ulcerative granulomatous disease of the ear, deep fungal infections, for example sporotrichosis [3], should be considered. Biopsy, examination of smears, cultures and serological studies should enable accurate diagnosis. Deep fungal infection may prompt an enquiry for underlying immune deficiency.

Otomycosis is discussed under otitis externa.

Infections of the external auditory canal and meatus

External otitis

SYN. OTITIS EXTERNA

Otitis externa [1] is a loose term that embraces more than one disease process. Aetiologically, it is rarely unifactorial [2]; constitutional, traumatic, environmental and microbial factors usually coexist. The condition is characterized by inflammation of the canal epithelium and by varying degrees of pain, itch, deafness and discharge. The term 'external otitis' sometimes includes furunculosis of the ear canal, and is then subclassified as acute localized external otitis; furunculosis is described separately below.

Pathogenesis. Otitis externa can be divided, for convenience, into two main groups [3]: (i) a *reactive* group consisting of patients suffering from eczema, psoriasis or seborrhoeic dermatitis; and (ii) a predominantly *infective* group in which either bacteria or fungi are involved. However, the two components often coexist. The cause in many cases is not apparent [4] but the following predisposing factors appear to be important.

Genetic and constitutional. There are significant racial and individual differences in susceptibility to otitis externa. This may be due to anatomical differences in the curvature of the external auditory canal or narrowing of the isthmus—natives of New Guinea with wide straight canals only rarely suffer from external otitis [5]—or, possibly, to differences in the type, amount or composition of cerumen, whose waxy consistency and low pH are protective against bacteria. *Pseudomonas aeruginosa*, the commonest bacterial pathogen in external otitis, binds to cells by a lectin-mediated process, and binding occurs more in individuals expressing blood group A on their epithelial cells [6].

Abundant tragal hair or plugs of wax and debris increase the relative humidity and reduce ventilation of the external auditory canal so that the canal epithelium becomes macerated and more susceptible to infection. Hypertrichosis of the canal due to minoxidil has been associated with external otitis [7]. Dental abnormalities and poor mastication [8] may also retard expulsion of wax and epithelial squames.

The atopic and seborrhoeic states predispose to external otitis not only by interfering with the integrity of the auricular epithelium but also by encouraging scratching and secondary infection. Both too much and too little cerumen and alterations in skin pH have at times been held responsible [9].

Environmental. Heat, humidity and moisture are undoubtedly important in 'hot-weather ear' or 'swimmer's ear' [10]. This condition is common, especially among white people in tropical and subtropical regions. High temperature, high relative humidity and swimming [11] all encourage maceration and secondary bacterial or fungal infections of the canal epithelium. Freshwater swimming appears to be a particular risk factor [12]. Failure to dry the ears completely after swimming, shampooing or showering may also be a factor in some cases [4].

Traumatic. Trauma, in the opinion of many investigators [2,11,13,14], is one of the prime factors in both the initiation and the persistence of many cases. In one series of 113 patients, 58 admitted using wool-tipped matches, two admitted using bare matches and seven used hairgrips to relieve itching [2]. Patients suffering from eczema or those with neurodermatitis tend to scratch, rub or

'fiddle' with their ears; other patients appear obsessed about cleaning their ears and by doing so excessively they interfere with the normal homeostatic and self-cleaning properties [15]. Impacted cerumen may cause irritation, which is often increased by inexpert attempts to remove it; pressure from hearing aids and transistor ear pieces may also cause irritation and, especially with the 'internal' hearing aid, a combination of pressure and occlusion often leads to the development of external otitis.

Bacterial and mycotic infection. The epidermis of the external auditory canal is normally fairly resistant to infection. The bacterial flora, although varying with race, geography and season, tends to resemble that of the skin but with a higher likelihood of finding *Ps. aeruginosa* [16]. In hot humid environments, however, and particularly among swimmers, whose ears are habitually wet, the incidence of *Ps. aeruginosa* and other Gram-negative infections rises substantially [17,18] as does the frequency with which *Aspergillus* or *Candida* species are isolated [13]. An outbreak of *Pseudomonas* otitis has been reported in association with contaminated pool water [19] but a source has rarely been found in other series, and it is assumed that *Pseudomonas* infections are of endogenous origin.

In more temperate climates, *S. aureus* is often isolated. This may be associated with evidence of skin disease elsewhere or with staphylococcal carriage. Certainly, patients with recurrent staphylococcal otitis externa should have nasal and perianal swabs sent for bacterial culture; occasionally it may be necessary to swab and 'destaph' the whole family. In other cases, there may be an underlying tympanic perforation or coexistent otitis media. The eardrums should therefore always be examined, especially in patients with unilateral or recurrent disease. Occasionally, infection spreads out from the ear canal and causes impetigo or infective eczema of the auricle and surrounding skin.

In the tropics, mycotic infections of the external ear canal are relatively common [20,21]. *Aspergillus*, *Candida*, *Penicillium* and *Mucor* spp. are the organisms most often incriminated, most cases being due to either *Aspergillus niger* or *Candida albicans*. There is some debate, however, as to whether these fungi are pathogenic, opportunistic, saprophytic or simply commensal [21–24].

Histopathology [1–4]. In most cases of external otitis, there is acanthosis, elongation of the rete ridges and an increase in orthokeratosis and parakeratosis. Spongiosis occurs in eczematous and seborrhoeic forms. The nature of the dermal infiltrate varies with both cause and chronicity. The histopathology is seldom diagnostic except when fungal mycelia are seen.

Clinical features. The condition can be acute, subacute or chronic. In patients seen at hospital, it tends to be severe, chronic or chronic relapsing, but in the community it is less severe and recalcitrant [5,6].

Mild attacks may present with pain or itching without discharge and with a minimally congested or swollen meatus. The degree of irritation or discomfort is often out of all proportion to the appearance. This stage probably represents early damage to the meatal skin [7]. Most cases of this type will resolve with simple therapeutic measures, but a minority, perhaps due to trauma, secondary infection or failure to keep the ear dry and clean, progress to more severe disease.

Fully developed acute external otitis (diffuse otitis externa) is characterized by a sudden onset of ear pain, itching, a sense of fullness or stuffiness if there is significant oedema, and a variable degree of hearing loss. The

otalgia is often exacerbated by jaw movements. With progression, there is usually drainage of malodorous pus, which tends to be bluish-green in colour if *Ps. aeruginosa* is the dominant infecting organism. Examination shows erythema and swelling, which may spread from the external auditory meatus to involve the concha or beyond. The external auditory canal shows erythema and oedema, and there is macerated debris and perhaps greenish pus present. In severe cases, inflammation can extend to involve the tympanic membrane. Hearing loss is due to oedema of the canal, and this may be sufficient to obscure vision of its full length. Traction on the pinna to examine the canal and pressure over the tragus characteristically elicit pain. There may be associated fever, malaise and regional lymphadenopathy.

It is important to gently remove debris in the process of a full examination, and to try to determine whether the disease is secondary to otitis media and whether or not the tympanic membrane is intact.

Bullous external otitis [8] is an uncommon variant in which there is a sudden onset of severe pain followed by discharge of blood from the ear canal. Bluish-red haemorrhagic bullae are visible on the osseous canal walls.

In granular external otitis the lining of the meatus and canal is replaced in part or whole by granulation tissue, which can project inwards as pedunculated masses. These are usually found near the tympanic membrane, arising from the osseous end of the canal. Granular external otitis is associated with a severe or neglected course [9,10].

The term 'chronic external otitis' is sometimes used for cases that have had persistent symptoms for more than 2 months [11]. Microbiological assessment has shown a significant organism in 82% in one series: *S. aureus* in one-third, *Pseudomonas* in one-third and various other Gram-negative and Gram-positive organisms in the remainder. In addition, 17 of the 99 patients had fungal disease alone [12]. There is often a dry canal due to lack of cerumen. It is likely that in most cases of chronic otitis externa, particularly when treatment has been used for the acute attack and symptoms have continued, concurrent dermatological disorders are present (Fig. 65.18). Patients in whom the disorder behaves in a recalcitrant manner may have an underlying systemic disease such as acquired immune deficiency syndrome (AIDS), malnutrition or uncontrolled diabetes mellitus; poor therapeutic response is also seen in patients treated with high-dose steroids or chemotherapeutic agents [13].

Seborrhoeic dermatitis, atopic dermatitis and psoriasis usually occur only at the meatus but may sometimes extend further into the canal. Seborrhoeic otitis externa is extremely common and has been regarded by some dermatologists as the basis for most cases of otitis externa. The symptoms and signs, however, are normally mild unless complicated by secondary factors and usually consist of no more than superficial scaling and a little discomfort or itching. Signs of pityriasis capitis or seborrhoeic dermatitis elsewhere are usually present. The condition may deteriorate at times of stress or fatigue. Secondary bacterial infection is common. In this 'reactive' group the appearance is often that of a dermatitis spreading into the ear, in contrast with those cases with a primarily 'infective' aetiology where infection and/or inflammation often appears to be spreading out from the ear and where the entire length of the canal is often affected. The clinical appearance, however, is often non-diagnostic.

Fig. 65.18 Chronic otitis externa in an atopic patient with a history of recurrent streptococcal infection and resultant lymphoedema contributing to narrowing of the canal.

In infective eczema there is usually intense pruritus associated with exudate. The condition may complicate both otitis media and otitis externa and is usually associated with some degree of otorrhoea. In others it appears to develop from seborrhoeic dermatitis that has become secondarily infected. The condition may affect the meatus, concha, lobe and peri-auricular skin and often spreads widely. The post-auricular fold is commonly affected. The symptoms and signs are those of eczema with an accompanying or preceding aural discharge. In seborrhoeic individuals, other areas may be involved at the same time. Fissures and cellulitis are common complications.

Contact dermatitis is often occult [14] and easily overlooked. Sensitivity to topically applied medicaments is common in chronic otitis externa. Occlusion, the recurrent nature of the disease and frequent use of antibiotics on an already damaged skin probably account for the high

incidence of contact dermatitis at this site. Other sensitivities include nickel from hair pins, metal implements, chromate and phosphorus sesquisulphide in matches, and nail varnish. It is characteristic that the degree of itching and burning is often markedly out of proportion to the amount of erythema and oedema present. Contact dermatitis may also rarely occur with ear moulds [15]. Clinically, it is often difficult to differentiate neurodermatitis from contact dermatitis.

Lichen simplex (neurodermatitis) may be localized to one area of the meatus or may occur more diffusely over the tragus, triangular fossa and adjoining skin. The condition is usually diagnosed by the history rather than the signs. Itching is intense, but often intermittent. The need to scratch or rub is compulsive, although often denied. Signs of inflammation are often minimal, but some degree of oedema and scaling is common. Complications from trauma, infection and sensitization are frequent. Intermittent itching of the external auditory canal (non-specific external otitis [2]) can also occur, irregularly and over a long period, without any obvious cause and with minimal signs of disease.

Whatever the primary aetiology, with the passage of time chronic external otitis becomes an increasingly complex diagnostic and therapeutic problem.

Differential diagnosis. The part played by trauma, environment, infection, sensitization and altered physiology and anatomy must be assessed and evaluated as accurately as possible. Difficulties often arise in the interpretation of bacteriological and mycological findings. 'Hearing-aid dermatitis' is more often due to traumatic and physical factors than to allergic sensitivity. Sensitivity to topical antibiotics may be occult, especially when they are prescribed in combination with corticosteroids, and are one cause of chronicity. Contact hypersensitivity to aural treatments (see below) may produce eczema that extends onto facial skin anterior to, or below, the ear. The importance of perineal and nasal transfer of infection should not be underestimated, and mechanical interference with the external auditory canal in patients with otitis externa tends to be the rule rather than the exception.

External otitis is unlikely to be confused with any other condition except perhaps psoriasis and eczema, and these, of course, may coexist. Middle-ear disease, past and present, should always be excluded.

Swabs should be taken for bacteriological culture and epithelial debris examined and sent for mycological culture. Potassium hydroxide preparations showing evidence of epithelial invasion with hyphae are probably more important in this respect than a positive culture, which may simply indicate commensal or saprophytic infection.

In any long-standing or resistant case, patch testing with a special 'ear battery' [1] should be undertaken to rule out unsuspected contact dermatitis. If there is excess granulation, middle-ear disease should be ruled out, and if the patient is diabetic, debilitated, very young, elderly or immunosuppressed, malignant otitis externa must also be excluded.

Another condition that may need to be considered is *bullous myringitis*, an uncommon condition probably due to upper respiratory tract viral infection (e.g. influenza), which presents with single or multiple bullae on the tympanic membrane and adjacent canal wall. It can resemble bullous external otitis, which is usually due to *Pseudomonas*. Sudden severe pain is a feature, but this resolves rapidly after rupture of the bullae. Furuncles of the external auditory canal are described below. Other bacteria may be a rare cause, for example gonococcal otitis externa [2].

Complications. Recurrent otitis externa may also develop into hypertrophic otitis externa or localized elephantiasis nostra [3] of the ears as a result of the effects of chronic lymphatic obstruction. The resultant narrowing of the external acoustic canal coupled with the underlying lymphoedema makes recurrent and repeated infections even more likely.

Secondary trauma. Once an irritable focus occurs in the canal, energetic attempts to remove wax or debris or to satisfy the urge to rub or scratch the infected area often intensify the inflammation. Cotton buds, although frequently regarded as safe, are a common cause of tympanic perforation [4].

Secondary sensitization. This is usually a consequence of treatment or a reaction to objects placed in the ear to

alleviate itching. Therapeutic agents may therefore enhance and perpetuate the condition for which they were prescribed. Penicillin, neomycin, framycetin (Soframycin) and chloramphenicol are all well-known topical sensitizers, but even gentamicin, Vioform (chinoform), polymyxin and bacitracin may sensitize at times [1]; allergy to topical corticosteroids used in the ear may also occur [5]. Allergy to topical medicaments is found in as many as 40% of patients with chronic or treatment-resistant otitis externa [1,6]. In only about 20% of cases is there improvement after discontinuing topical agents to which patients have been shown to be allergic [5].

Sensitivity to nail varnish may be misconstrued as lichen simplex and, in women who are nickel sensitive, otitis externa may be aggravated by using metal objects to alleviate itching or to clear the ear. Otoscopes themselves may release nickel. Another source of contact dermatitis is chromate [7] or phosphorus sesquisulphide in match heads, which some people use to scratch their ears.

Benign non-necrotizing otitis externa. This usually presents as chronic, non-painful otorrhoea with an ulcer present in the floor of the external canal. Surgery may be a better alternative than long-term medical management [8].

Allergic and 'ide' reactions [9,10]. A few well-documented cases have been reported in which recurrent pruritus, oedema and scaling of the ear canal have occurred in response to fungal infection at a distant body site, or associated with food or drug allergies. Some such cases also have an 'ide' reaction affecting the hands or other areas.

Treatment [1]. The general principles of treatment of otitis externa are to relieve pain, reduce itching, prevent trauma and avoid known or potential sensitizers. Significant infective organisms should be identified and treated appropriately.

Many mild cases of otitis externa will respond to simple aural toilet, optimally with careful suction and under direct vision, followed by the use of an acidifying and drying agent. Moderately severe cases are likely to require antibiotic or antiseptic drops.

When there is coexistent eczema, combined steroid–antiseptic or steroid–antibiotic drops or wicks can be used. It should be noted, however, that many of the common infecting organisms are frequently antibiotic resistant; swabs for culture and sensitivity should therefore be taken before prescribing topical or systemic antibiotics. When *S. aureus* is the infecting organism, this is increasingly likely to be methicillin-resistant *S. aureus* (MRSA), especially when there has been recent hospital exposure [2]. In chronic cases, a great variety of treatments will already have been given and medicament contact dermatitis will therefore be more likely. Because this is often occult, patch testing should be done in all patients with chronic disease.

Pain is often severe, especially with acute staphylococcal infections, and strong analgesics may be required. Local heat also often helps. Bed rest and daily wicks or dressing may be needed in the more severe case.

If there is significant pyrexia (> 38.3°C), lymphadenopathy or failure to improve with topical therapy, an oral antibiotic should be used, for example a cephalosporin or fluoroquinolone. If pain is very severe, granulations are present in the canal or the patient is diabetic or immunocompromised, there should be suspicion for invasive (necrotizing) otitis (see p. 65.27).

Topical treatment. This is the essential part of therapy and the most difficult to carry out satisfactorily. Ear drops are of less value than regular cleaning of the ear, and this initially needs to be done daily by a doctor or an experienced nurse. Less severe cases may be treated once a week. Having cleaned the ear of debris and wax, preferably by suction under direct vision, a wick may be inserted or the patient instructed to apply ear drops regularly. When the cartilaginous portion of the canal alone is involved, the patient can be shown how to apply the prescribed medicament by holding a loose wool-tipped orange stick 2.5 cm from its end and inserting this until the fingers touch the tragus.

If wax is impacted, this can be softened with oil, glycerine or sodium bicarbonate eardrops and then removed either manually or by syringing, as long as the drum can be visualized and there is no perforation. Obstinate cases should be referred to an otologist. Some proprietary cerumenolytics are irritant and should be left in the ear for only 15–30 min before syringing.

In most chronic or complicated cases, treatment must be continued regularly for some weeks after apparent cure. Care must be taken to prevent cross-infection from other body sites, especially from the anterior vestibule of the

nose or the perineum, and the ear should be kept as dry and as clean as possible.

A very large number of medicaments have been used in the treatment of otitis externa. Alcohol 70–85% (isopropyl alcohol), 1–2% acetic acid, aluminium subacetate solution and 2% salicylic acid in 60% spirit are all safe and effective, aluminium acetate solution being especially useful against the expected pathogens [3]. If acidic ear drops cause a burning sensation, ophthalmic hydrogen peroxide drops are a practical substitute. Wicks with 8–13% aluminium acetate, 0.25–0.5% silver nitrate, or glycerine and ichthyol are used to treat hypertrophic otitis externa. Although the use of corticosteroids with or without antimicrobials is a common practice, the evidence to support their use is controversial [4]. Neomycin, framycetin (Soframycin), gentamicin and polymyxin are probably acceptable as short-term treatments for acute otitis externa but the risk of sensitization and cross-sensitization increases with more protracted usage. The combination of neomycin and polymyxin will cover both *S. aureus* and *Ps. aeruginosa*. Topical ofloxacin is as effective and only has to be used twice daily [5]. For patients with chronic or chronic relapsing otitis externa, iodochlorhydroxyquinoline (Vioform, chinoform) can be used alone or in combination with corticosteroids.

The imidazoles have largely replaced nystatin and amphotericin as antifungal agents, as they are active against *Aspergillus* as well as *Candida*, although acetic acid, boric acid and 25% *m*-cresyl acetate may still at times be useful; 2% salicylic acid in spirit is useful for prophylaxis. Several ear-drops, for example the aminoglycosides, chlorhexidine, polymyxin and chloramphenicol, are potentially ototoxic [6,7] and should be avoided in the presence of tympanic perforation.

In all cases of external otitis, treatment should be prolonged beyond the time of apparent recovery and patients should be advised how best to avoid recurrence and about the dangers of indiscriminate or prolonged self-medication.

Surgical treatments. Occasionally, chronic otitis externa is due to narrowing of the external auditory meatus. Surgical enlargement of the meatus can then bring about resolution [8,9].

Invasive external otitis [1,2]

SYN. MALIGNANT EXTERNAL OTITIS; NECROTIZING EXTERNAL OTITIS

This is an infection of the skin of the external ear canal that spreads to deeper structures and causes necrosis.

Aetiology. In most cases, the infecting organism is *Ps. aeruginosa*, although occasionally other organisms have been involved: *S. aureus* [3], *S. epidermidis* [4], *Klebsiella oxytoca* [5], *Aspergillus* [6–10], *Malassezia sympodialis* [11], *Scedosporium apiospermum* [12] and *Actinomycetes*. The condition characteristically occurs in elderly diabetics [13–16] but is also seen with some frequency in the immunocompromised, including patients with HIV infection [1,16,17]; it has also been reported in association with diabetes insipidus [18]. Cases have been reported in children [19–21] in whom chronic illness or immunosuppression are usually present. In diabetics, microangiopathy may be important in the pathogenesis [1]. It is possible that abnormalities of cellular immunity and polymorphonuclear function are important in some cases [22,23], but in many instances the pathogenesis is poorly understood.

Pathology. In most cases, there is evidence of osteomyelitis [5]. An early event is acellular necrosis of cartilage [24].

Clinical features. Quite often there is a preceding history of irrigation of the ear. The commonest presenting symptom is pain, which is usually very severe and persistent. It may spread from the region of the ear to the vertex, temporal or occipital areas, and there may be temporomandibular joint pain. Pain progresses more quickly in children than adults. The second most common symptom is discharge from the ear. In up to 50% there is some degree of hearing loss. Systemic symptoms, including fever, are uncommon [1]. There may be symptoms due to involvement of cranial nerves, particularly dysphagia.

On examination the external auditory canal is always abnormal, with varying degrees of oedema and erythema, and extensive granulation tissue formation is evident. This is particularly seen on the posterior and inferior aspect of the wall and at the junction between the bony and cartilaginous segments of the canal. There may be swelling of the soft tissues around the ear. The tympanic membrane is frequently necrotic in children but characteristically spared in adults [21]. Cranial neuropathies may be found in up to 40% of patients [1,17]. Facial palsy is the most common finding but involvement of cranial nerves

IV, VI, VIII, IX, X and XII may be variably present. When such nerve involvement is found, the disease is more extensive.

Investigations usually show elevation of the erythrocyte sedimentation rate, but the white-cell count is often normal.

Diagnosis. Invasive external otitis is usually diagnosed on clinical suspicion. It is essential to obtain material for culture to determine the infective cause, and samples should be taken from the ear canal, granulations, soft tissue and bone, depending on the case. Blood cultures may also be valuable.

Imaging techniques can be helpful, particularly in diagnosing bony involvement and following progress of the disease, and should enable granular external otitis to be distinguished from the much more serious invasive external otitis. Plain films, computed tomography (CT), bone scans and magnetic resonance imaging (MRI) have all been used. MRI with or without gadolinium enhancement is probably the best technique for imaging soft-tissue involvement, and for evaluation of the meninges and changes within the osseous medullary cavity, although CT is preferred for the initial diagnosis and recognition of cortical bone erosion [25,26].

Complications. Spread of the disease can produce parotitis, mastoiditis or osteomyelitis of the base of the skull and thence spread to the contralateral side. Meningitis can occur, and is an important cause of death. Cranial nerve paralysis may result in aspiration pneumonia. A rare complication is destructive osteomyelitis of the temporomandibular joint [27]. Overall, there is a mortality of 10–20%; in the presence of cranial neuropathies the mortality is 70% [1,17].

Treatment. Because of the range of possible infections, it is essential to base treatment on the result of culture. For *Pseudomonas*, the traditional approach has been to use an extended-spectrum antipseudomonal penicillin for 4–8 weeks and an aminoglycoside for 4–6 weeks [1]. Ciprofloxacin [28,29] can be successful if used early in the course of disease. When there is evidence of extensive bone destruction, removal of necrotic material is necessary. Some cases fail to respond to antibiotic therapy and, if the facility is available, hyperbaric oxygen can improve the outlook [30]. Ascorbic acid has also been recorded as an adjuvant therapy [22].

When the infective cause is bacteria other than *Pseudomonas* or is a fungus, advice on the choice of antimicrobial agent should be taken from a microbiologist.

Furunculosis

SYN. ACUTE LOCALIZED EXTERNAL OTITIS

A furuncle is a staphylococcal infection of a hair follicle [1]. A common site is between the junction of the tragus

and the anterior crus of the helix. Furuncles also may occur in the skin of the external auditory canal at the junction with the concha. Coalescence of adjacent infected follicles results in a carbuncle.

The patient presents with pain, which can be aggravated by chewing if there is involvement of the anterior wall of the canal. There may be sufficient swelling to obstruct the entrance to the canal. There is often regional lymphadenopathy and sometimes fever.

Furunculosis can usually be distinguished from external otitis by the normal appearance of the canal epithelium and an absence of discharge; the two conditions can, however, coexist. If possible the tympanic membrane should be examined, in order to exclude otitis media and mastoiditis.

Localized lesions associated with mild swelling usually respond to an oral antistaphylococcal antibiotic [1]. If an abscess or carbuncle is present, incision and drainage is usually necessary. The latter can be achieved with a wick. Any draining material should be sent for culture and antibacterial sensitivities.

Otomycosis

Otomycosis is an inflammatory process due to a variety of yeast and fungal organisms as the primary aetiological agent. The same range of fungi may be found in patients with multifactorial or bacterial external otitis (see above).

Aetiology. The species of fungus and yeast involved vary somewhat depending on ambient climate. In most tropical regions of the world *Aspergillus* species account for the majority of isolates, whereas in temperate areas *Candida albicans* is the most frequent [1]. Others include phycomycetes, *Rhizopus*, *Actinomyces* and *Penicillium*. The fact that these organisms can be pathogenic as well as saprophytic has been confirmed in a number of studies [2–5].

The factors that convert organisms that are normally saprophytic into pathogens are similar to those that apply to bacterial external otitis. Heat and humidity are foremost, and account for the frequency of otomycosis in the tropics and in those using hearing aids or occlusive ear moulds. Diabetes mellitus, immunosuppression, systemic and topical antibiotics, and steroids are also important.

Clinical features. The principal symptom is usually itching, which can have a quality of being deep inside the ear. This is often accompanied by a sensation of fullness. Pain is uncommon, in contrast to bacterial external otitis. Discharge, if any, is usually slight. There may be hearing loss of a conductive type. Because of the irritation, patients are liable to traumatize the canal and may then initiate the symptoms and signs of bacterial external otitis. The most important complication is perforation of the eardrum [6].

On examination the dominant feature is the presence of wispy filamentous masses, which may be isolated or diffusely present in the canal. These masses are white, grey or stippled black if *Aspergillus* is present. Inflammation of the canal epithelium is usually mild. There may be some epithelial debris, which may be either moist or dry.

Diagnosis. The clinical appearance is usually distinctive. As always with external canal disorders it is important to check for other pathology. Material can be taken for mycological examination and culture.

Treatment [7]. Careful cleaning followed by drying is a prerequisite to successful management. The canal can then be wiped out, for example with *m*-cresyl acetate or 1% thymol in 70% alcohol, and the specific treatment applied on a wick. Treatment should be changed daily until a satisfactory result has been achieved. Many agents have been advocated for otomycosis, but there is little evidence to promote one above the others. They include aluminium acetate, acetic acid, *m*-cresyl acetate, thiomersal, gentian violet, clioquinol, nystatin, amphotericin and the imidazoles.

In rare situations, usually in immunosuppressed patients, there may be cellulitis of the surrounding soft tissues directly due to fungal infection. In such cases, itraconazole is likely to be the treatment of choice. Oral terbinafine has also been used when other treatments have failed [8].

AIDS and the external ear

The consequences of HIV infection will at times be seen on the pinna and in the external auditory canal [1]. The ear is a relatively common site for manifestation of Kaposi's sarcoma. Florid seborrhoeic dermatitis is often a presenting feature of AIDS. The occurrence of molluscum contagiosum lesions in an adult should prompt a suspicion of immunodeficiency; on the ear the lesions can resemble

basal cell carcinoma. Bacillary angiomatosis may produce vascular papules and nodules on the ear. Herpes simplex and zoster can be more florid in patients with AIDS. Polyps in the external auditory canal due to *Pneumocystis carinii* have been described [2] and can invade the middle ear and middle cranial fossa [3]. Invasive external otitis (see p. 65.27) is a well-recognized consequence of HIV-related immunosuppression [4]. Excessive growth of ear hair has been noted [5].

Tumours of the pinna and external auditory canal [1]

Benign tumours

On the pinna, these will present as papules or nodules, sometimes with distinctive morphology. In the external auditory canal, benign tumours tend to present with hearing loss and may predispose to infection [2].

Benign tumours found on the pinna include melanocytic naevus, seborrhoeic keratosis (Fig. 65.19), squamous cell papilloma, pilomatrixoma [3,4], trichoepithelioma [5], trichofolliculoma [6,7], Winer's dilated pore [8], myoma, chondroma, osteoma, fibroma [9], neurofibroma [10], neurilemmoma [11], granular cell tumour, haemangioma (Fig. 65.20) and lymphangioma [12]. Benign glandular tumours may occur on the pinna, but are more common in the canal, especially sebaceous adenoma. Occasional unique lesions have been described [13].

Benign mass lesions in the canal include exostosis and osteoma, fibrous dysplasia both monostotic and polyostotic (Albright's syndrome), eosinophilic granuloma, cholesteatoma and keratosis obturans (see p. 65.36), benign ceruminous gland tumours (see p. 65.31) and temporomandibular joint herniation [14].

Papillomatosis of the external auditory canal presents with multiple rounded papules; it has been associated with human papillomavirus (HPV) 6 [15].

Extra-adrenal paraganglioma (glomus jugulare tumour) of the temporal bone can manifest in the external ear canal as a friable haemorrhagic neoplasm and can cause conductive hearing loss [1]. This tumour can be locally aggressive, and there are rare instances of metastasis.

Fig. 65.19 Seborrhoeic keratosis (basal cell papilloma) of the pinna.

Fig. 65.20 Lobulated capillary haemangioma (pyogenic granuloma). A bright-red nodule with a surrounding collarette of keratin.

Various conditions can mimic benign tumours. On the pinna, these include cysts of various types, viral warts and molluscum contagiosum, chondrodermatitis, elastotic and weathering nodules, keloids, congenital malformations such as accessory tragi, nodular calcinosis [16], gouty tophi, deposits of amyloid, angiolymphoid hyperplasia with eosinophilia and 'pseudolymphoma', inflammatory polyps, hamartomas [17], choristomas [18] and congenital cysts of branchial arch origin in the external auditory

canal. Cholesteatoma (see p. 65.36) may also occur in the external canal.

Exostosis and osteoma

Exostoses of the external auditory canal are usually bilateral, symmetrical, multiple, diffuse, broadly based growths of bone arising from the tympanic bone in the external auditory canal [1,2]. Frequent exposure to cold water is an aetiological factor in nearly all cases [3]. Exostoses are very common in surfers, especially those who have surfed for more than 10 years [4,5].

Osteomas can usually be differentiated by their solitary and unilateral distribution, although they may be similar to exostoses histologically [6]. They are often attached by a narrow pedicle to the tympanosquamous or tympanomastoid suture line [1].

Occasionally other fibro-osseous lesions are found which are neither exostosis nor osteoma [7,8].

Osteomas and exostoses are normally asymptomatic unless they enlarge sufficiently to block the external auditory canal [9]. Surgical removal may be indicated [10].

Glandular tumours

Tumours of the ceruminous glands are rare. It is often difficult to distinguish between adenoma and carcinoma on histological grounds [1–3] and the term 'ceruminoma' [4] is probably best avoided. The tumours comprise benign and pleomorphic adenomas, adenocarcinomas, adenoid cystic carcinomas and perhaps others including mucoepidermoid carcinomas. Tumours of the cerumen glands have been reported in association with other sweat gland tumours elsewhere [5].

Isolated cases of syringocystadenoma papilliferum, apocrine cystadenoma, benign eccrine cylindroma, hidradenoma papilliferum and carcinomas of eccrine and sebaceous origin have also been reported [6,7].

Extramammary Paget's disease of the external ear and/or canal resembles Bowen's disease or a dermatosis [8].

Benign tumours produce symptoms of obstruction and hearing loss. Pain is the usual presenting feature of the more malignant tumours. They are usually seen as polypoid masses in the canal. Other symptoms include bleeding, otorrhoea and, with spread of the neoplasm, nerve palsies.

Treatment is the province of the otorhinolaryngologist. Because of the potential for malignant behaviour, all ceruminous gland tumours should be fully excised with an adequate margin of normal tissue [9].

Premalignant epithelial neoplasms of the auricle

Because of its high level of exposure to UV radiation [1], especially in men, the auricle is a common site for premalignant and malignant lesions of epidermal origin. Other predisposing factors include prior ionizing radiation, a chronic dermatosis such as lupus vulgaris, and genetic factors such as xeroderma pigmentosum and Gorlin's syndrome.

The commonest premalignant lesion is the solar keratosis, which can occur on all sun-exposed aspects of the auricle, but is especially common on the upper surface of the helix [2,3]. The clinical presentations include an erythematous telangiectatic patch, a focal area of scaling or hyperkeratosis, or a cutaneous horn. Solar keratoses on the auricle are often multiple. Solar elastosis may be evident in the surrounding skin. On the auricle, progression to squamous carcinoma from solar keratosis may occur more readily than at other sites [4].

Other premalignant lesions include Bowen's disease, radiation and tar keratoses and, rarely, keratoacanthoma [5,6].

Treatment. Several forms of treatment can eradicate premalignant lesions from the auricle, but there are no adequate data to compare them. They include excision, curettage, electrosurgery, cryotherapy, 5-fluorouracil and photodynamic therapy. The choice will depend on a number of factors, including the need for a tissue diagnosis, size and location of the lesion, likely cosmetic outcome and the available facilities. Follow-up is important for detection of recurrences and the appearance of new lesions. Lesions closely resembling squamous carcinoma, such as keratoacanthoma, should probably be totally excised to ensure accurate diagnosis [6].

Squamous cell carcinoma of the auricle

Although the ratio of basal cell carcinoma (BCC) to squamous cell carcinoma (SCC) is about 4 : 1 on the head and neck generally, on the ear SCC is relatively more common (BCC : SCC, 1.3 : 1) [1].

In most instances, SCC evolves from a premalignant lesion, usually a solar keratosis, and occurs predominantly in elderly white men, although at a younger age in the immunosuppressed. The most common site is the helix [2]. Early SCC may be suspected when there is induration of the base of a scaly papule, nodule or cutaneous horn. With progression, SCC usually ulcerates and with invasion of cartilage can become grossly destructive (Fig. 65.21). Local spread along perichondrial, periosteal and neurovascular planes can make SCC of the auricle very difficult to control. With the exception of the lip, auricular SCC is more likely to metastasize than is SCC at any other sun-exposed site (11% compared with 2%) [3]. There is a small but significant mortality [2,4,5]. Adverse prognostic factors for both local recurrence and metastasis of SCC include size (> 2 cm), depth of invasion (> 4 mm, Clark levels 4 and 5), perineural involvement and poor differentiation of the tumour [6]. The pre-auricular site

Fig. 65.21 Squamous carcinoma of the auricle. An advanced tumour with extensive destruction of the ear cartilage. (Courtesy of Mr D. Baldwin, Southmead Hospital, Bristol, UK.)

may also confer a poor prognosis [7]. It is not clear, however, to what extent these are independent variables; shallow lesions with large surface area (i.e. > 2 cm diameter) do not seem to have a poor prognosis. If SCC recurs after primary treatment, there is a much greater risk for further recurrence and metastasis [6].

Treatment. It is important to achieve control of the disease with the initial treatment for SCC. For small, minimally invasive lesions, simple excision, cryotherapy or curettage with cautery/electrodesiccation may be adequate. Excellent results have been reported from the combination of curettage and cryotherapy for carefully selected cases [8]. For larger lesions, and especially for those with adverse prognostic factors, the choice is likely to be between wide margin excision, Mohs micrographic surgery and radiation therapy.

The surgical procedure used will depend on the location and extent of the tumour. Smaller lesions can often be removed by wedge excision with primary repair by advancement flaps. Larger and ill-defined lesions are best closed by temporary grafts pending a histopathological assessment of the margins before definitive repair is carried out. Partial or total amputation may be needed for large tumours. If there is spread beyond the pinna, resection of the parotid, temporal bone, temporomandibular joint or mandibular ramus may be be required, with appropriate repair.

Several authors have recommended minimal resection margins, for example 1 cm [9], 6 mm with frozen section control [10], 8 mm for 1-cm-diameter tumours and 1.5 cm for 3-cm-diameter tumours [11], all with removal of the underlying cartilage. Overall, there is an incidence of 18.7% recurrence during follow-up for 5 years or more with non-Mohs modalities compared with 5.3% for Mohs micrographic surgery, suggesting that the latter is the treatment of choice [6,12].

SCCs in the tragal and pretragal location appear to have a greater tendency to spread along embryonic fusion planes and may only be curable by radical surgery, for example parotidectomy in association with removal of the tumour [7,13].

Various techniques are needed to reconstruct the ear after curative surgery [14–19].

Radiotherapy can be successful as a primary treatment for SCC of the auricle [20], with megavoltage electron-beam therapy having therapeutic and cosmetic advantages over conventional orthovoltage X-ray treatment [21]. There may, however, be a higher recurrence rate [22,23] compared with surgery, particularly for large tumours [2,24,25]. Radiation therapy can be complicated by damage to the cartilage and associated chronic infection; deformity of the pinna is another long-term consequence. Radiotherapy may improve the outlook for cases with extensive local spread requiring radical surgery.

The management of SCC with metastasis to regional lymph nodes and beyond is outside the scope of the dermatologist.

Basal cell carcinoma of the auricle

BCC of the auricle is somewhat less common than SCC (Fig. 65.22). It is also mainly due to the effects of solar

Fig. 65.22 Basal cell carcinoma. Translucent ulcerated nodules in the retro-auricular fold.

radiation, but is much less liable to metastasize [1,2]. Presentation is generally as for BCC elsewhere, although could be missed when resembling a cleft earlobe [3].

The approach to treatment is essentially similar to that outlined for SCC. Mohs micrographic surgery is the most likely modality to achieve cure with lesions that are extensive, deeply invasive or recurrent, or which have a morphoeic growth pattern.

Squamous and basal cell carcinoma of the external auditory canal

Non-glandular carcinomas of the external auditory canal are uncommon. Most are squamous in type (Fig. 65.23). They affect a younger age group (50–65 years) and, in contrast to SCC of the auricle, there is much less of a male preponderance. A preceding history of chronic otitis is common [1,2]. Pseudo-epitheliomatous hyperplasia secondary to chronic infection or inflammation can sometimes be difficult to distinguish from SCC [3].

Fig. 65.23 Squamous carcinoma of the external auditory canal. Purulent discharge, inflammation and destruction of the meatus. (Courtesy of Mr D. Baldwin, Southmead Hospital, Bristol, UK.)

Most squamous carcinoma of the canal has an infiltrative growth pattern. It tends to grow along the canal, escaping anteriorly through Santorini's fissures in the cartilaginous segment and Huschke's foramen in the bony portion, into the temporomandibular joint and parotid. Spread also occurs posteriorly into the mastoid, and through the tympanic membrane into the middle ear and thence to the carotid canal, apex of the petrous temple bone, the internal auditory canal, base of the skull and the dura. Metastasis to lymph nodes and distantly is common.

Overall, there is a much poorer prognosis than for SCC of the pinna, with 5-year survival rates of about 40% [4]. Adverse factors are a large lesion, invasion of cartilage or bone, facial nerve palsy, spread to the middle ear and beyond, and lymph node metastasis. The extent of the disease can be determined accurately by CT [5]. Staging using clinical and imaging data is important for assessing prognosis and the likelihood of benefit from adjuvant radiotherapy [6,7].

Fig. 65.24 Basal cell carcinoma of the external auditory canal. An erythematous tumour presenting as obstruction at the entrance of the canal. (Courtesy of Mr M. Birchill, Southmead Hospital, Bristol, UK.)

Verrucous carcinoma of the external auditory canal is an uncommon variant that can appear cytologically banal but nevertheless invade bone, by a pushing rather than an infiltrative growth pattern [8,9].

BCC of the external auditory canal can be locally destructive (Fig. 65.24), but does not metastasize and has a much better prognosis than SCC [10].

The most common symptoms of invasive SCC of the canal are purulent and bloody discharge from the ear, followed by pain, hearing loss and facial paralysis. Examination reveals a friable tumour, partially or completely obstructing the external auditory canal.

Treatment. Surgery has been regarded as the treatment of choice, the extent determined by an assessment of the limits of tumour growth. However, radiotherapy alone may be as effective if the disease is limited to the site of origin, i.e. there is no evidence of nerve or bone involvement [11]. Post-operative radiotherapy improves the outlook [6,7,12–15], but for lesions that have spread deeply or have metastasized cure is most unlikely.

Malignant melanoma

Malignant melanoma of the external ear is relatively uncommon, constituting about 1% of all cutaneous melanomas [1]. It accounted for 4.8% of all auricular malignancies in one series [2] and represented 7% of all melanomas in another series [3]. Melanomas at this site are about three times more common in males than females [3,4]. Melanoma is found in a similar frequency distribution on the ear as SCC and its precursors, i.e. about half occur on the helix and one-quarter on the antihelix [3], but they are rarely found in the external auditory canal [5,6]. Most melanomas on the ear are of superficial spreading or nodular type, the latter being relatively more common than at other head and neck sites [7,8]. The major determinant for prognosis is Breslow thickness [4].

Treatment is in principle no different from malignant melanoma elsewhere (see Chapter 38), and relatively conservative excision followed by reconstruction can be safe [9]. Sentinel lymph node mapping may be valuable for accurate staging, particularly for melanoma of the ear, since its lymphatic drainage is notoriously unpredictable [10].

Other malignant tumours

Other malignant tumours involving the external ear or the external auditory canal are all rare. The pathology is reviewed in Friedman and Arnold's monograph [1]. The dermatologist may encounter sebaceous carcinoma [2], atypical fibroxanthoma, trichilemmal carcinoma [3], Merkel cell tumour [4], Kaposi's sarcoma [5,6] or rhabdomyosarcoma (mainly in children) [7–9]. Angiosarcoma of the pinna has the same gloomy outlook as it does on the scalp [10]. Other sarcomas have been recorded but are exceptionally rare. Lymphomas may occur on the external ear [11], particularly mycosis fungoides [12]. Perichondritis can be mimicked by non-Hodgkin's lymphoma [13,14], and both lymphoma [15,16] and myeloma [17] can present with an external auditory canal tumour. The ear may be involved by direct extension from tumours nearby, for example the parotid, and also by metastases from distant sites [18].

Miscellaneous conditions

Cholesteatoma of the external auditory canal

Cholesteatoma of the middle ear space is accumulation of keratinous debris within a sac-like squamous epithelial lining. It can grow at the expense of normal structures and if it ruptures, the associated foreign body-type inflammatory reaction can produce serious damage.

A similar condition occurs rarely in the external auditory canal, although its status as a true cholesteatoma is disputed [1,2]. The accumulation of stratum corneum occurs within a cyst-like penetration of the bony portion of the canal wall by the epithelial lining. There is localized ulceration of the skin of the floor of the canal, with underlying osteitis and sometimes necrosis of bone. A necrotic sequestrum may become incorporated into the cholesteatoma. The cause is unknown, although trauma, for example from hard wax and manipulation of the canal, seems important in some cases [3].

Cholesteatoma usually occurs in patients over the age of 40 years. Symptoms are a dull pain in one ear and otorrhoea. Examination shows a white cystic mass protruding into the canal. The main differential diagnosis is from neoplasms and keratosis obturans [4,5]. External auditory canal cholesteatoma can occasionally behave aggressively, and may erode into the mastoid cavity, middle ear, temporomandibular joint and adjacent soft tissue. CT can be useful to assess the extent of the disease. Treatment is within the province of the otorhinolaryngologist.

Keratosis obturans

In this uncommon condition there is a localized accumulation of desquamated keratin in the ear canal. It may be due to a defect in the normal epithelial migration [6]. It is usually bilateral and typically occurs in younger patients than those presenting with external auditory canal cholesteatoma, which it can resemble. There is conductive hearing loss, sometimes with otalgia. Keratosis obturans can be associated with paranasal sinus disease and bronchitis; it has also been described in association with the yellow nail syndrome [7]. Treatment consists of careful removal of the accumulated keratin. Irrigation with water should be avoided [4,5].

Referred pain

Due to the complicated nerve supply to the ear, referred pain is commoner than pain due to lesions in the ear itself [1]. Non-otological causes of such pain include the otomandibular syndrome [2] due to dysfunction of the temporomandibular joint, cervical arthritis with involvement of the cervical nerves, tonsillitis and carcinoma of the pharynx. Hair in the ear canal is an occasional cause [3]. Psychogenic otalgia has also been reported [4].

Chapter 66

The Oral Cavity and Lips

Crispian Scully CBE

Introduction

Oral lesions are usually the result of local disease but may be the early signs of systemic disease, including dermatological disorders, and in some instances may cause the main symptoms. This chapter mainly discusses disorders of the dental, periodontal and mucosal tissues that may be related to skin disease and that may present at a dermatology clinic. It should be borne in mind that the professionals most competent in diagnosing and treating oral diseases are dentally qualified; few without this formal training and education are in a position to understand the full complexities of the region.

The chapter is an overview only and is divided into a brief discussion of the biology of the mouth, an overview of the more common signs and symptoms affecting specific oral tissues, discussion of the disorders of the oral mucosa of most relevance to dermatology and a tabulated review of oral manifestations of systemic diseases. Diseases affecting the jaws or temporomandibular joint are not discussed in any depth.

Only the more classic oral lesions are illustrated. About 20 of the colour illustrations are from the *Colour Atlas of Oral and Maxillofacial Disease*, 1996 (reproduced by kind permission of C. Scully, S. Flint, S.R. Porter and K. Moos, and publishers Martin Dunitz, London). More detail of histology is available elsewhere [1].

Biology of the mouth

Oral epithelium

The oral epithelium consists of a *functional compartment* —the progenitor cells (basal and parabasal cells)—which is the site of cell division; a *maturation compartment* (spinous and granular cells) where the cells become more terminally differentiated; and a superficial *cornified compartment* of squames and areas of keratinization, either orthokeratotic or parakeratotic. In the non-keratinized regions such as the buccal (cheek) and floor-of-mouth mucosae, overt keratinization and granular cells are absent and the surface cells are flattened, with elongated nuclei [2].

Lips

The lips extend from the lower end of the nose to the upper end of the chin. They mainly consist of bundles of striated muscle, particularly the *orbicularis oris* muscle, with skin on the external surface and mucous membrane on the inner surface, which has a profusion of minor salivary glands.

The vermilion zone, the transitional zone between the glabrous skin and the mucous membrane, is found only in humans. The vermilion zone contains no hair or sweat glands but does contain sebaceous glands (Fordyce spots, see below). The epithelium of the vermilion is distinctive, with a prominent stratum lucidum and a very thin stratum corneum. The dermal papillae are numerous at this site, with a rich capillary supply, which produces the reddish-pink colour of the lips in white people. Melanocytes are abundant in the basal layer of the vermilion of pigmented skin, but are infrequent in white skin.

The *oral commissures* are the angles where the upper and lower lip meet. The upper lip includes the *philtrum*, a midline depression, extending from the columella of the nose to the superior edge of the vermilion zone [3].

Oral mucosa

The mucosa is divided into masticatory, lining and specialized types. *Masticatory mucosa* (hard palate, gingiva) is adapted to the forces of pressure and friction and is keratinized, with numerous tall rete ridges and connective tissue papillae and little submucosa. *Lining mucosa* (buccal, labial and alveolar mucosa, floor of mouth, ventral surface of tongue, soft palate, lips) is non-keratinized, with broad rete ridges and connective tissue papillae and abundant elastic fibres in the lamina propria [4,5].

Specialized mucosa on the dorsum of the tongue, adapted for taste and mastication, is keratinized, with numerous rete ridges and connective tissue papillae, abundant elastic and collagen fibres in the lamina propria and no submucosa. The tongue is divided by a V-shaped groove, the *sulcus terminalis*, into an anterior two-thirds and a posterior third. Various papillae on the dorsum include the *filiform papillae*, which cover the entire anterior surface and form an abrasive surface to control the food bolus as it is pressed against the palate, and the *fungiform papillae*. The latter are mushroom-shaped, red structures covered by non-keratinized epithelium. They are scattered between the filiform papillae and have taste buds on their surface. Adjacent and anterior to the sulcus terminalis are eight to 12 large *circumvallate papillae*, each surrounded by a deep groove into which open the ducts of serous minor salivary glands. The lateral walls of these papillae contain taste buds.

The *foliate papillae* consist of four to 11 parallel ridges, alternating with deep grooves in the mucosa, on the lateral margins on the posterior part of the tongue. There are taste buds on their lateral walls. The *lingual tonsils* are round or oval prominences with intervening lingual crypts lined by non-keratinized epithelium. They are part of *Waldeyer's oropharyngeal ring* of lymphoid tissue. The lingual tonsil is a mass of lymphoid tissue in the posterior third of the tongue, between the epiglottis posteriorly and the circumvallate papillae anteriorly. It is usually divided in the midline by a ligament.

Teeth

The teeth develop from neuroectoderm [6]. Tooth development begins in the fetus, at about 28 days *in utero*. Indeed, all the deciduous and some of the permanent dentitions commence development in the fetus. At around the sixth week of intrauterine life the oral epithelium proliferates over the maxillary and mandibular ridge areas to form primary epithelial bands that project into the mesoderm, and produce a dental lamina in which discrete swellings appear—the enamel organs of developing teeth. Each enamel organ eventually produces tooth enamel, and the mesenchyme, which condenses beneath the enamel organ (actually neuroectoderm), forms a dental papilla that produces the dentine and pulp of the tooth. The enamel organ together with the dental papilla constitute the tooth germ, and this becomes surrounded by a mesenchymal dental follicle, from which the periodontium forms, ultimately to anchor the tooth in its bony socket. Mineralization of the primary dentition commences at about 14 weeks *in utero* and all primary teeth are mineralizing by birth. Permanent incisor and first molar teeth begin to mineralize at, or close to, the time of birth, mineralization of other permanent teeth starting later. Tooth eruption occurs after crown formation and mineralization is largely complete but before the roots are fully formed.

Teeth comprise a crown of insensitive enamel, surrounding sensitive dentine, and a root which has no enamel covering (Fig. 66.1). Teeth contain a vital pulp (nerve) and are supported by the periodontal ligament via which roots are attached into sockets in the alveolar process of the jaws (maxilla and mandible). The fibres of the periodontal ligament attach through cementum to the dentine surface. The alveolus is covered by the gingivae, or gum, which in health are pink, stippled and tightly bound down, and form a close-fitting cuff, with a small sulcus (gingival crevice), round the neck of each tooth.

The first or primary (deciduous or milk) dentition comprises two incisors, a canine and two molars in each of the four mouth quadrants (total 20 teeth). There are 10 deciduous (primary or milk) teeth in each jaw: all are fully

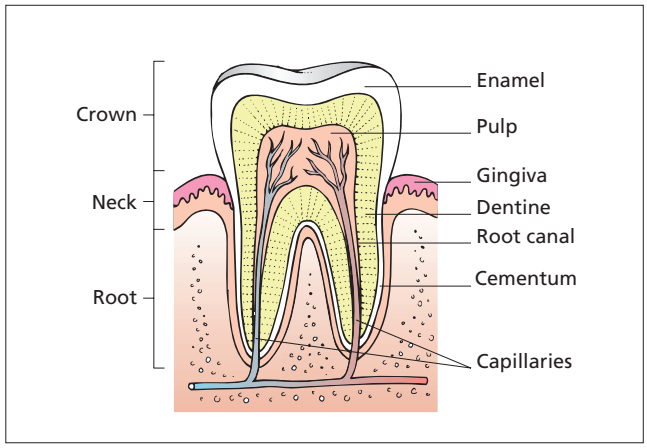

Fig. 66.1 Tooth structure.

Table 66.1 Tooth eruption timings (average timings; there is a wide range).

	Upper	Lower
Deciduous (primary) teeth		
A Central incisors	8–13 months	6–10 months
B Lateral incisors	8–13 months	10–16 months
C Canines (cuspids)	16–23 months	16–23 months
D First molars	13–19 months	13–19 months
E Second molars	25–33 months	23–31 months
Permanent teeth		
1 Central incisors	7–8 years	6–7 years
2 Lateral incisors	8–9 years	7–8 years
3 Canines (cuspids)	11–12 years	9–10 years
4 First premolars (bicuspids)	10–11 years	10–12 years
5 Second premolars (bicuspids)	10–12 years	11–12 years
6 First molars	6–7 years	6–7 years
7 Second molars	12–13 years	11–13 years
8 Third molars	17–21 years	17–21 years

erupted by the age of about 3 years (Fig. 66.2; Table 66.1). The secondary or permanent teeth begin to erupt at about the age of 6–7 years and the deciduous teeth begin to be slowly lost by normal root resorption.

The normal permanent (adult) dentition comprises two incisors, a canine, two premolars and three molars in each quadrant (total 32 teeth). The full permanent dentition consists of 16 teeth in each jaw: normally most have erupted by about 12–14 years of age. However, some milk teeth may still be present at the age of 12–13 years. The last molars (third molars or wisdom teeth), if present, often erupt later or may impact and never appear in the mouth.

Junction of the mucosa with the teeth

The dentogingival junction represents a unique anatomical feature concerned with the attachment of the gingival

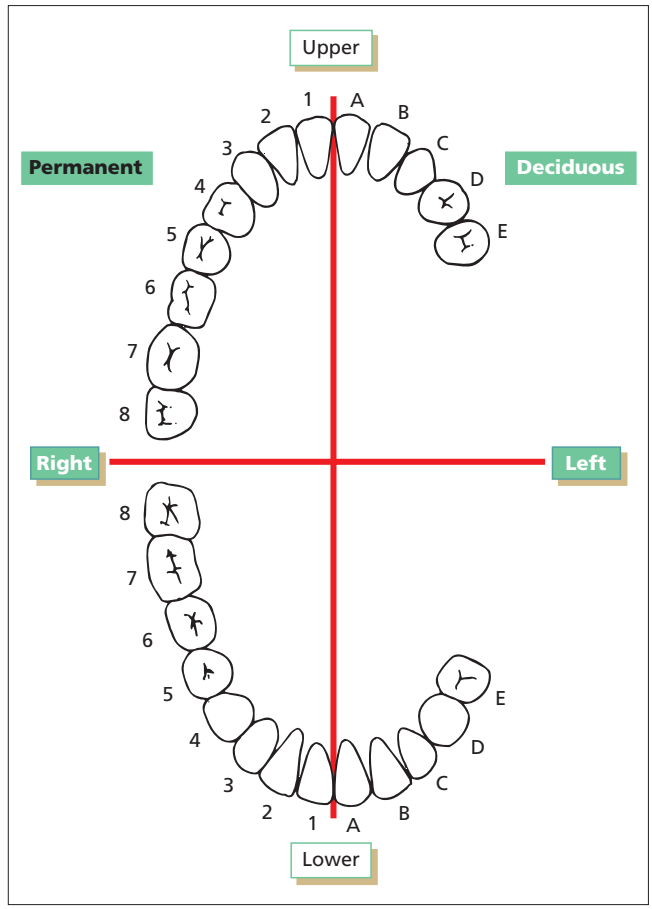

Fig. 66.2 Tooth notations.

(gum) mucosa to the tooth. Non-keratinized gingival epithelium forms a cuff surrounding the tooth, and at its lowest point on the tooth is adherent to the enamel or cement. This 'junctional' epithelium is unique in being bounded both on its tooth and lamina propria aspects by basement membranes. Above this is a shallow sulcus or crevice (up to 2 mm deep), the gingival sulcus or crevice. Neutrophils continually migrate into the gingival crevice, and there is also a slow exudate of plasma (crevicular fluid).

Immunity in the oral cavity

Movement of the soft tissues during speech and swallowing, and salivation, ensures that much foreign material is swallowed. The need for this cleaning mechanism is clearly apparent in patients with facial paralysis, or in those with xerostomia, in whom there is accumulation of oral debris and subsequent infection.

Saliva also aggregates bacteria and deters their attachment to surfaces. Salivary lysozyme, thiocyanate, peroxides and various mucins and other components may be

antimicrobial and saliva is inhibitory to various microbial agents including, for example, human immunodeficiency virus (HIV).

Salivary tissue derives its B cells from the gut-associated lymphoid tissue (GALT) system [7]. Salivary acinar cells produce secretory component (transport piece) needed for transport of IgA into the saliva and its stability in the presence of salivary or gastric proteolytic enzymes. Although the exact contribution to oral defence made by salivary IgA antibodies is difficult to assess, some patients who have IgA deficiency suffer from oral infections, and in animals it is possible to induce protective salivary IgA antibodies to caries-producing organisms such as *Streptococcus mutans*.

Neutrophils and other leukocytes are particularly essential for oral health as shown by the fact that patients with HIV infection, neutropenia, agranulocytopenia, leukaemia or chronic granulomatous disease are predisposed to severe gingivitis and rapid periodontal breakdown, as well as mouth ulceration and infections.

Examination of the mouth and perioral region

Examination includes inspection and palpation of the lymph nodes, temporomandibular joints, jaws, salivary glands and oral cavity.

Lymph nodes (Table 66.2)

Lymph from the superficial tissue of the head and neck generally drains first to groups of superficially placed lymph nodes, then to the deep cervical lymph nodes.

- Systematically, each region needs to be examined lightly with the pulps of the fingers, trying to roll the lymph nodes against harder underlying structures.
- Parotid, mastoid and occipital lymph nodes can be palpated simultaneously using both hands.
- Superficial cervical lymph nodes are examined with lighter palpation as they can only be compressed against the softer sternomastoid muscle.
- Submental lymph nodes are examined by tipping the patient's head forward and rolling the lymph nodes against the inner aspect of the mandible.

Table 66.2 Drainage areas of cervical lymph nodes.

Area	Draining lymph nodes
Scalp, temporal region	Superficial parotid
Scalp, posterior	Occipital
Scalp, parietal region	Mastoid
Ear, external	Superficial cervical over upper part of sternomastoid muscle
Ear, middle	Parotid
Over angle of mandible	Superficial cervical over upper part of sternomastoid muscle
Medial part of frontal region, medial eyelids, skin of nose	Submandibular
Lateral part of frontal region and lateral part of eyelids	Parotid
Cheek	Submandibular
Upper lip	Submandibular
Lower lip	Submental
Lower lip, lateral part	Submandibular
Mandibular gingivae	Submandibular
Maxillary teeth	Deep cervical
Maxillary gingivae	Deep cervical
Tongue tip	Submental; remainder drains to submandibular nodes
Tongue, anterior two-thirds	Submandibular; some midline cross-over of lymphatic drainage
Tongue, posterior third	Deep cervical
Tongue, ventrum	Deep cervical
Floor of mouth	Submandibular
Palate, hard	Deep cervical
Palate, soft	Retropharyngeal and deep cervical
Tonsil	Jugulodigastric

• Submandibular lymph nodes are examined in the same way with the patient's head tipped to the side being examined. Differentiation needs to be made between the submandibular salivary gland and submandibular lymph glands. Bimanual examination with one finger in the floor of the mouth may help.
• The deep cervical lymph nodes which project anterior or posterior to the sternomastoid muscle can be palpated. The jugulodigastric lymph node should be specifically examined, as this is the most common lymph node involved in tonsillar infections.
• The supraclavicular region should be examined at the same time as the rest of the neck; lymph nodes here may extend up into the posterior triangle of the neck on the scalene muscles, behind the sternomastoid.
• Parapharyngeal and tracheal lymph nodes can be compressed lightly against the trachea.
• Some information can be gained by the texture and nature of the lymphadenopathy.
• Tenderness and swelling should be documented. Lymph nodes that are tender may be inflammatory (lymphadenitis). Consistency should be noted. Nodes that are increasing in size and are hard or fixed to adjacent tissues may be malignant.
• Both anterior and posterior cervical nodes should be examined as well as other nodes, liver and spleen if systemic disease is a possibility.

Temporomandibular joints and muscles of mastication

Although disorders that affect the temporomandibular joint often appear to be unilateral, the joint should not be viewed in isolation but always considered together with its opposite joint, as part of the stomatognathic system. The area should be examined as follows.

Inspection

• Facial symmetry.
• Evidence of enlarged masseter muscles (masseteric hypertrophy) suggestive of clenching or bruxism.
• Mandibular opening and closing paths.
• Mandibular opening extent: (i) measure the interincisal distance at maximum mouth opening; (ii) measure the amount of lateral excursions achievable; (iii) listen for joint noises (a stethoscope placed over the joint can help).

Palpation

• Both condyles: via the external auditory meatus to detect tenderness posteriorly, and by using a single finger placed over the joints in front of the ears to detect pain, abnormal movements or clicking within the joint.
• Masticatory muscles on both sides.

Masseters: by intraoral/extraoral compression between finger and thumb. Palpate the masseter bimanually by placing a finger of one hand intraorally and the index and middle fingers of the other hand on the cheek over the masseter over the lower mandibular ramus.
Temporalis: by direct palpation of the temporal region. Palpate the temporal origin of the temporalis muscle by asking the patient to clench the teeth. Palpate the insertion of the temporalis tendon intraorally along the anterior border of the ascending mandibular ramus.
Lateral pterygoid (lower head): by placing a little finger up behind the maxillary tuberosity (the 'pterygoid sign'). Examine the lateral pterygoid muscle, which cannot readily be palpated, indirectly by asking the patient to open the jaw against resistance and to move the jaw to one side while a gentle resistance force is applied.
Medial pterygoid muscle intraorally lingually to the mandibular ramus.

Some palpate using a pressure algometer to standardize the force used, and undertake range-of-movement measurements.
• Examination of the dentition and occlusion: this may require monitoring of study models on a semi-adjustable or fully adjustable articulator. Note particularly missing premolars or molars, and attrition.
• Examination of the mucosa: note particularly occlusal lines and scalloping of the tongue margins, which may indicate bruxism and tongue pressure.

Jaws

There is wide normal individual variation in morphology of the face. Most individuals have facial asymmetry but of a degree that cannot be regarded as abnormal.
• Maxillary, mandibular or zygomatic deformities or lumps may be more reliably confirmed by inspection from above (maxillae/zygomas) or behind (mandible). The jaws should be palpated to detect swelling or tenderness.
• Maxillary air sinuses can be examined by palpation for tenderness over the maxillary antrum, which may indicate sinus infection. Transillumination or endoscopy can be helpful.

Salivary glands

Inspect and palpate the major salivary glands (parotid and submandibular) for:
• symmetry;
• evidence of enlarged glands;
• evidence of salivary flow from salivary ducts;
• appearance of saliva.

Parotid glands. Palpate by placing fingers over the preauricular glands, to detect pain or swelling. Early enlargement of the parotid gland is characterized by outward

deflection of the lower part of the earlobe, which is best observed by looking at the patient from behind. This simple sign may allow distinction from simple obesity. Swelling of the parotid sometimes causes trismus. Swellings may affect the whole or part of a gland or tenderness may be elicited. The parotid duct (Stensen's duct) is most readily palpated with the jaws clenched firmly since it runs horizontally across the upper masseter where it can be gently rolled; the duct opens at a papilla on the buccal mucosa opposite the upper molars.

Submandibular glands. Bimanually palpate using fingers inside the mouth and extraorally. The submandibular gland is best palpated with a finger of one hand in the floor of the mouth lingual to the lower molar teeth, and a finger of the other hand placed over the submandibular triangle. The submandibular duct (Wharton's duct) runs anteromedially across the floor of the mouth to open at the side of the lingual fraenum.

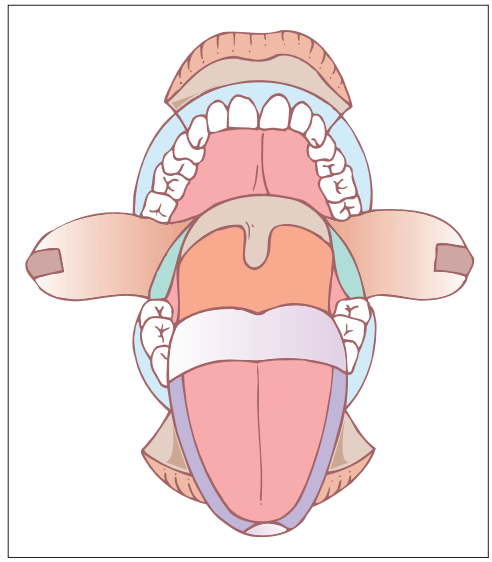

Fig. 66.3 Diagram of oral cavity.

Intraoral examination

The examination should be conducted in a systematic fashion to ensure that all areas are included. If the patient wears any removable prostheses or appliances, these should be removed in the first instance, although it may be necessary later to replace the appliance to assess fit, function and relationship to any lesion.

Complete visualization with a good source of light is essential. All mucosal surfaces should be examined, starting away from the location of any known lesions or the focus of complaint. The lips should be inspected first. The labial mucosa, buccal (cheek) mucosae, floor of mouth and ventrum of tongue, dorsal surface of the tongue, hard and soft palates, gingivae and teeth should then be examined in sequence and lesions noted on a diagram of the oral cavity (Fig. 66.3).

Lips. Features such as cyanosis are seen mainly in the lips in cardiac or respiratory disease; angular cheilitis (stomatitis) is seen mainly in oral candidiasis or in iron, vitamin or immune deficiencies. Examination is facilitated if the mouth is gently closed at this stage, so that the lips can then be everted to examine the mucosa.

Labial mucosa. Normally appears moist with a fairly prominent vascular arcade. In the lower lip, the many minor salivary glands which are often exuding mucus are easily visible. The lips therefore feel slightly nodular and the labial arteries are readily felt. Many adults have a few yellowish pinhead-sized papules in the vermilion border (particularly of the upper lip) and at the commissures; these are usually ectopic sebaceous glands (Fordyce spots), and may be numerous especially as age advances.

Cheek (buccal) mucosa. This is readily inspected if the mouth is held half open. The vascular pattern and minor salivary glands so prominent in the labial mucosa are not obvious in the buccal mucosa but Fordyce spots may be conspicuous, particularly near the commissures and retromolar regions in adults. Place the surface of a dental mirror against the buccal mucosa. The mirror should lift off easily; if it adheres to the mucosa, then xerostomia is present.

Floor of mouth and ventrum of tongue. These are best examined by asking the patient to push the tongue first into the palate then into each cheek in turn. This raises for inspection the floor of the mouth, an area where tumours may start (the 'coffin' or 'graveyard' area of the mouth). Its posterior part is the most difficult area to examine well and one where lesions are most easily missed. Lingual veins are prominent and, in the elderly, may be conspicuous (lingual varices). Bony lumps on the alveolar ridge lingual to the premolars are most often tori (torus mandibularis). During this part of the examination the quantity and consistency of saliva should be assessed. Examine for the normal pooling of saliva in the floor of the mouth; normally there is a pool of saliva in the floor of the mouth.

Dorsum of tongue. This is best inspected by protrusion, when it can be held with gauze. The anterior two-thirds is embryologically and anatomically distinct from the posterior third, and separated by a dozen or so large circumvallate papillae. The anterior two-thirds is coated with many filiform but relatively few fungiform papillae. Behind the

circumvallate papillae, the tongue contains several large lymphoid masses (lingual tonsil) and the foliate papillae lie on the lateral borders posteriorly. These are often mistaken for tumours. The tongue may be fissured (scrotal) but this is usually regarded as a developmental anomaly. A healthy child's tongue is rarely coated but a mild coating is not uncommon in healthy adults. The voluntary tongue movements and sense of taste should be formally tested. Abnormalities of tongue movement (neurological or muscular disease) may be obvious from dysarthria or involuntary movements and any fibrillation or wasting noted. Hypoglossal palsy may lead to deviation of the tongue towards the affected side on protrusion. Taste sensation can be tested by placing the tongue across the terminals of a pocket torch battery when a metallic taste may be obvious. Formal testing with salt, sweet, sour and bitter should be carried out by applying solutions of salt, sugar, dilute acetic acid and 5% citric acid to the tongue on a cotton swab or cotton bud.

Palate and fauces. These consist of an anterior hard and posterior soft palate, and the tonsillar area and oropharynx. The mucosa of the hard palate is firmly bound down as a mucoperiosteum (similar to the gingivae) and with no obvious vascular arcades. Rugae are present anteriorly on either side of the incisive papilla that overlies the incisive foramen. Bony lumps in the posterior centre of the vault of the hard palate are usually tori (torus palatinus). Patients may complain of lumps distal to the upper molars that they think are unerupted teeth but the pterygoid hamulus or tuberosity is usually responsible for this complaint. The soft palate and fauces may show a faint vascular arcade. Just posterior to the junction with the hard palate is a conglomeration of minor salivary glands. This region is often also yellowish. The palate should be inspected and movements examined when the patient says 'Aah'. Using a mirror, this also permits inspection of the posterior tongue, tonsils, oropharynx, and can even offer a glimpse of the larynx. Glossopharyngeal palsy may lead to uvula deviation to the contralateral side.

Gingivae. In health they are firm, pale pink, with a stippled surface, and have sharp gingival papillae reaching up between the adjacent teeth to the tooth contact point. Look for gingival redness, swelling or bleeding on gently probing the gingival margin. The 'keratinized' attached gingivae (pale pink) are normally clearly demarcated from the non-keratinized alveolar mucosa (vascular) that runs into the vestibule or sulcus. Bands of tissue which may contain muscle attachments run centrally from the labial mucosa onto the alveolar mucosa and from the buccal mucosa in the premolar region onto the alveolar mucosa (fraena).

Fig. 66.4 Torus palatinus.

Teeth. The dentition should be checked to make sure that the expected complement of teeth is present for the patient's age. Extra teeth (supernumerary teeth) or deficiency of teeth (partial loss or hypodontia; oligodontia; complete loss or anodontia) can be features of many syndromes but teeth are far more frequently missing because they are unerupted, or lost as a result of caries or periodontal disease. The teeth should be fully examined for signs of disease, either malformations such as hypoplasia or abnormal colour, or acquired disorders such as dental caries, erosion or abrasion. The occlusion of the teeth should also be checked; it may show attrition or may be disturbed, as in some jaw fractures or dislocation of the mandibular condyles.

Anatomical variants

Patients sometimes become concerned after noticing various anatomical variants in the mouth. These include tori and exostoses [1,2], which are developmental bony lumps seen especially in Mongoloid and Negroid races. Most common is torus palatinus, a slow-growing, asymptomatic, benign bony lump in the midline of the palate (Fig. 66.4). Torus mandibularis are bilateral, asymptomatic, benign bony lumps lingual to the premolars.

The diagnosis is confirmed by radiography. Surgery is rarely indicated. These are excised or reduced only if causing severe difficulties with dentures.

Disorders affecting the teeth

Disorders of tooth eruption

Teething

'Teething' in infancy is a poorly understood condition and the soreness and fever is often due to infection such as herpes simplex stomatitis. Nevertheless, there may be a very minor degree of pyrexia around the time of tooth eruption [1].

REFERENCE

1 Jaber L, Cohen IJ, Mor A. Fever associated with teething. *Arch Dis Child* 1992; **67**: 233–4.

Premature eruption of teeth [1–4]

Erupted teeth, particularly in the mandibular central incisor region, may be present at birth (natal teeth) or appear within the first few days or weeks of life (neonatal teeth). This rare event (about 0.1% of live births) occasionally has a familial basis or is associated with some other developmental anomaly. Such teeth occasionally cause ulceration of the infant's tongue or mother's nipple but usually they can be safely left *in situ*.

Retarded eruption of teeth

Congenital hypopituitarism, congenital hypothyroidism (cretinism), Down's syndrome, cleidocranial dysplasia, cytotoxic drugs and radiotherapy may cause retarded eruption of teeth, but most cases are of local aetiology (e.g. impactions).

Extra teeth

Extra (supernumerary) teeth are uncommon and usually of an unknown cause. They are generally found in the premaxilla. Supernumerary teeth are common in cleidocranial dysplasia.

Missing teeth

It is important to remember that teeth may be apparently missing simply because they are unerupted.

Dental aplasia

SYN. HYPODONTIA; ANODONTIA

Wisdom teeth (third molars), second premolars and upper lateral incisors are sometimes absent in otherwise normal individuals, probably because of some unidentified genetic trait. Up to 25% of white people lack a third molar. Absence of several teeth may indicate systemic disease such as cleidocranial dysplasia, incontinentia pigmenti or ectodermal dysplasia.

Hypodontia is often associated with microdontia and is often bilaterally symmetrical.

Loosening and early loss of teeth (Table 66.3)

Early loss of teeth is usually caused by trauma, dental caries or destructive periodontal disease, as discussed below [1,2]. Congenital disorders that may predispose to periodontal breakdown include Down's syndrome, Papillon–Lefèvre syndrome, neutropenia and other immune defects. Acquired disorders such as diabetes mellitus or immune defects also predispose to periodontal breakdown. Teeth are also lost early in other rare systemic disorders, for example eosinophilic granuloma or hypophosphatasia.

Acrodynia
Neoplasms
Eosinophilic granuloma

Table 66.4 Causes of discoloration of teeth.

Extrinsic
Poor oral hygiene
Smoking
Beverages/food
Drugs, e.g. iron, chlorhexidine, sweetened medication
Stains, e.g. from betel chewing
Intrinsic
Trauma
Caries
Restorative materials, e.g. amalgam
Pink spot (internal resorption)
Drugs: mainly tetracyclines
Fluorosis
Dentinogenesis imperfecta
Amelogenesis imperfecta
Porphyria
Kernicterus (severe neonatal jaundice)

Malformed and discoloured teeth (Table 66.4)

There is a wide range of normal variation in tooth morphology and colour, especially between races.

Most dental discoloration is caused by smoking, foods and beverages (such as tea), medicines such as iron or chlorhexidine, or poor oral hygiene. The regular use of sweetened medication at night (e.g. trimeprazine syrup in a child with eczema) can cause discoloration due to dental caries. Erosion of teeth may occur because of the repeated use of acidic drinks or sucking citrus fruits, or as a feature of gastric regurgitation in bulimia, anorexia nervosa or alcoholism.

Teeth may be malformed for genetic reasons. Peg-shaped teeth may be normal variants (Fig. 66.5) or may be found in some ectodermal dysplasias (see p. 66.11). Taurodontism (see below) can be found in a range of dermatological disorders [1]. Genetic defects that may cause tooth discoloration include dentinogenesis imperfecta (Fig. 66.6), which may be seen in some patients with osteogenesis imperfecta, and amelogenesis imperfecta (Fig. 66.7) [2,3].

Fig. 66.5 A peg-shaped maxillary lateral incisor, a fairly common variant.

Fig. 66.6 Dentinogenesis imperfecta: staining and severe attrition.

Fig. 66.7 Amelogenesis imperfecta: one variant showing longitudinal ridging of teeth.

Teeth may be damaged during their development. Local infection or trauma, or unknown factors, may cause malformation of a single tooth (or a few). The lower premolars are usually affected because there is caries and periapical infection related to their deciduous predecessors; such hypoplastic teeth are termed *Turner's teeth*. The upper permanent incisors may be malformed if there is trauma to the deciduous incisors. Radiotherapy or cytotoxic therapy may cause hypoplasia, as may congenital rubella or cytomegalovirus infection. However, classical *Hutchinsonian* (*screwdriver-shaped*) *incisors* and *Moon's* (*or mulberry*) *molars* of congenital syphilis are extremely rare.

Hypoplasia is relatively common in apparently healthy persons [4–7] and is also seen in early-onset malabsorption syndromes, many severe childhood illnesses (Fig. 66.8) and organ transplantation [8–10] and in some forms of epidermolysis bullosa (see below). Neonatal jaundice can produce greenish teeth.

Fig. 66.8 Hypoplasia of teeth related to severe childhood respiratory infection.

Fig. 66.9 Pronounced intrinsic tooth discoloration from use of tetracyclines in childhood.

Fluoride, at the concentrations present in water supplies in Western countries or given prophylactically, may occasionally produce inconsequential minute white flecks; however, concentrations over 2 ppm may produce significant fluorosis. Tetracyclines given to a pregnant or lactating mother may discolour the child's teeth and, if given to a child, particularly one under the age of 12 years, may cause significant brown intrinsic tooth staining (Fig. 66.9).

Taurodontism

Taurodont teeth have an enlarged pulp chamber and a more inferiorly placed root furcation in premolars and molars. They are not readily detectable on clinical examination and are therefore most easily diagnosed on radiographs (Fig. 66.10). However, on clinical examination, lack of constriction of the tooth at the neck may be suggestive of taurodontism. Taurodontism is generally most obvious in molars of both deciduous and permanent dentitions, and may be found in single or several teeth, with or without evidence of other disorders.

Most studies have shown an overall prevalence of the order of 2% with no sex predilection, but oriental people and some other racial groups are especially affected [1–3]. XXY and other syndromes with additional X chromosomes may be affected [4–6] as may other chromosomal anomalies [7–9]. Dermatological conditions with which taurodontism may be associated are shown in Table 66.5 [10].

Ectodermal dysplasia

Ectodermal dysplasia is typically characterized by developmental abnormalities in at least two different ectodermally derived systems. Oral abnormalities are common, especially missing teeth and abnormally shaped teeth (Fig. 66.11). There are many variations, as discussed in the following sections and in Chapter 12.

X-linked hypohidrotic ectodermal dysplasia [1–3]

Hypodontia is common in X-linked hypohidrotic ectodermal dysplasia. Some anterior teeth are usually present but their crowns are typically conical or peg-shaped. The posterior teeth, when present, are smaller but otherwise normal. Overclosure of the jaws, together with maxillary hypoplasia and frontal bossing, give a characteristic facial appearance. There may be a degree of impaired salivary gland function.

Female carriers of this syndrome may have hypodontia and/or microdontia.

Fig. 66.11 Hypodontia and malformed teeth are common in ectodermal dysplasia.

Autosomal recessive ectodermal dysplasia [1,4]

Dental and oral anomalies in this condition are identical to those in the X-linked form of ectodermal dysplasia, although relatives may have a normal dentition.

Hypodontia, taurodontism and sparse hair [5]

There are a few reports of a variant of ectodermal dysplasia where there is taurodontism, and somewhat lesser hypodontia than in the more classic forms of ectodermal dysplasia.

Autosomal dominant hypodontia with nail dysgenesis [6]

Hypodontia, conical deciduous and permanent teeth, and dysplastic nails characterize this variant of ectodermal dysplasia.

Incontinentia pigmenti [7]

SYN. BLOCH–SULZBERGER SYNDROME

Hypodontia and retarded eruption affect both dentitions and the anterior teeth are small. The teeth tend also to be conical, often with accessory cusps.

Chondroectodermal dysplasia [8–10]

SYN. ELLIS–VAN CREVELD SYNDROME

Ellis–van Creveld syndrome, also called chondroectodermal dysplasia, is a rare autosomal recessive condition that manifests with chondrodysplasia of tubular bones resulting in disproportionate dwarfism, polydactyly and syndactyly of hands and feet, severe dystrophic nails, anomalous teeth, bilateral partial clefts of the alveolar bone and malocclusion. Half of the cases have cardiac malformations.

The most obvious oral anomalies are the multiple fraena extending from the lips and buccal mucosae to the alveolar ridges of both jaws. Natal teeth, mild hypodontia or hyperdontia, malformed or small teeth and accessory cusps are common.

Cranioectodermal dysplasia [11]

Deciduous teeth are small and may have dysplastic enamel, although the condition is so rare that the permanent teeth have not been clearly described. There may be hypodontia or taurodontism. Dolicocephaly, hair anomalies and shortened arms, fingers and toes are associated.

Nance–Horan syndrome [12]

X-linked congenital cataracts with supernumerary teeth constitute the Nance–Horan syndrome. The incisor teeth may also be morphologically abnormal and can resemble Hutchinson's incisors of congenital syphilis.

Trichodental syndrome [13,14]

The trichodental syndrome is a rare dominantly inherited condition in which there is fine short hair, thinning of the lateral ends of the eyebrows, hypodontia and/or conical teeth.

Trichodento-osseous syndrome [15–18]

Tight curly hair, sclerotic cortical bone and oral anomalies (especially thin enamel) are found in this autosomal dominant condition. The hypoplasia–hypomaturation type of amelogenesis imperfecta, enamel hypoplasia, unerupted teeth and taurodontism may be associated.

Trichonychodental syndrome [19]

This autosomal dominant trait of fine curly hair and thin dysplastic nails may be associated with taurodontism and enamel or dentinal developmental defects.

Curry–Hall syndrome [20]

Deciduous teeth are small and conical, and the incisors are often retained since their permanent successors may be congenitally absent. The remaining permanent teeth do erupt but are small. Other features include short limbs, polydactyly and nail dysplasia.

Otodental dysplasia [21–23]

Globe-shaped posterior teeth (globodontia) in both dentitions are the most common oral feature of this autosomal dominant condition, which is associated with sensorineural hearing loss. The incisors are not affected and the patients are otherwise well.

Other oral anomalies may include taurodontism, microdontia and hypodontia.

Clouston syndrome [24] (see Chapter 12)

Palmoplantar hyperkeratosis, hair defects, nail dysplasia and oral white lesions characterize this autosomal dominant form of hidrotic ectodermal dysplasia. There may be diffuse white lesions in the buccal mucosa, palate, tongue and elsewhere but reports of malignancy are rare.

Disorders affecting the periodontium

Gingival disorders affecting the periodontium

Bleeding

Bleeding from the gingival margins is common, usually a consequence of inadequate oral hygiene leading to the accumulation of dental bacterial plaque and thus gingivitis (Table 66.7). The tendency to gingivitis is slightly increased in patients taking oral contraceptives and in some pregnant women (especially during the second trimester).

Table 66.7 Causes of gingival bleeding.

Local
Chronic gingivitis
Chronic periodontitis
Acute necrotizing gingivitis
Systemic
Any condition causing exacerbation of gingivitis (e.g. pregnancy)
Leukaemia
Human immunodeficiency virus infection
Other causes of purpura
Clotting defects
Drugs, e.g. anticoagulants
Scurvy

Gingival haemorrhage may, however, also be an early feature in some vascular or platelet disorders and is commonly a problem, for example, in leukaemic patients.

Swelling

Localized gingival swellings (epulides) may be of local aetiology or can be manifestations of pregnancy, a neoplasm or systemic disease (Table 66.8).

Gingival swelling affecting many areas is most commonly seen in chronic gingivitis, may be produced by drugs such as phenytoin, ciclosporin (cyclosporin) and calcium channel blockers (Fig. 66.12), and is occasionally hereditary. Gingival swelling is seen with hypertrichosis in both drug-induced hyperplasias and hereditary gingival fibromatosis.

A degree of gingival swelling may also be seen in herpetic stomatitis, pregnancy, leukaemia, Crohn's disease,

Table 66.8 Causes of gingival swelling.

	Generalized swelling	Localized swelling
Local	Chronic gingivitis Hyperplastic gingivitis due to mouth breathing	Abscesses Cysts Pyogenic granuloma Neoplasms and warts (various)
Systemic	Hereditary gingival fibromatosis and associated syndromes Drugs (phenytoin, ciclosporin, nifedipine, diltiazem) Pregnancy Sarcoidosis Crohn's disease Leukaemia Wegener's granulomatosis Scurvy Amyloidosis Mucopolysaccharidoses Mucolipidosis Lipoid proteinosis Juvenile hyaline fibromatosis Hypoplasminogenaemia	Pregnancy Sarcoidosis Orofacial granulomatosis Crohn's disease Wegener's granulomatosis Amyloidosis Neoplasms (various)

Fig. 66.12 Gingival hyperplasia in phenytoin therapy. Concomitant folate deficiency in this patient also caused mouth ulcers, seen in the maxillary buccal vestibule.

scurvy, Wegener's granulomatosis, sarcoidosis, amyloidosis, lipoid proteinosis, hypoplasminogenaemia, mucopolysaccharidoses and other disorders.

Redness

Chronic marginal gingivitis is the usual cause of gingival redness, and then is usually restricted to the gingival margins and interdental papillae.

More widespread erythema, particularly if associated with soreness, is usually caused by primary herpes simplex stomatitis, desquamative gingivitis (usually due to lichen planus or mucous membrane pemphigoid), rarely by pemphigus or other dermatoses, or occasionally by allergic responses.

Telangiectasia may be a manifestation of hereditary haemorrhagic telangiectasia, primary biliary cirrhosis or systemic sclerosis, or may follow radiotherapy. Haemangiomas are usually isolated but may occasionally extend deeply and rarely involve the ipsilateral meninges, producing a facial angioma and epilepsy, sometimes with learning disability (Sturge–Weber syndrome). Intraoral haemangiomas may be seen in Maffucci's syndrome.

Localized red areas may represent erythroplasia, carcinoma, candidiasis, lichen planus or lupus erythematosus. Kaposi's sarcoma may present as a red, purple, brown or bluish macule or nodule as may epithelioid angiomatosis. Hereditary mucoepithelial dysplasia is a rare cause of oral erythema. Irradiation-induced mucositis is a further cause of a red sore mouth.

White patches (Table 66.9)

Thrush (acute candidiasis) is a 'disease of the diseased' and produces oral white patches.

Leukoplakia is often associated with friction or smoking, occasionally with syphilis, candidiasis or chronic renal failure, but most cases are idiopathic. Lichen planus and lupus erythematosus may present as white lesions. Rarely, lichenoid lesions are associated with various drugs, liver disease or graft-versus-host disease (GVHD). Carcinoma may present as a white lesion.

Inherited causes of white patches, such as white sponge naevus and dyskeratosis congenita, are rare [1,2].

Pigmentation

Gingival pigmentation is usually seen in dark-skinned races (but may be seen even in white people) (Fig. 66.13).

Table 66.9 Main causes of oral white lesions.

Local
Frictional keratosis
Smoker's keratosis
Idiopathic keratosis
Carcinoma
Burns
Skin grafts
Systemic
Candidiasis
Lichen planus
Lupus erythematosus
Papillomas (some)
Hairy leukoplakia (mainly human immunodeficiency virus disease)
Syphilitic keratosis
Chronic renal failure
Inherited lesions (e.g. white-sponge naevus)

Fig. 66.13 Gingival hyperpigmentation of racial origin. The white lesion is due to accumulated oral debris—oral hygiene is very poor.

Other common causes include amalgam tattoo and melanotic macules.

Addison's disease, Kaposi's sarcoma and melanoma are the most important acquired causes of pigmented lesions but drugs such as hydroxychloroquine and minocycline may also cause hyperpigmentation.

Ulcers

Gingival ulcers are sometimes self-induced (artefactual) [1,2]. Herpesviruses can cause gingival ulceration, often with ulcers elsewhere in the mouth. Acute ulcerative (necrotizing) gingivitis causes ulceration of the interdental papillae and though usually a consequence of poor oral hygiene, it or a similar disorder is a rare complication of HIV infection, neutropenia or leukaemia, and in the malnourished or some immunosuppressed patients may spread to the cheek (*noma*, or *cancrum oris*). Other bacterial infections (e.g. syphilis, tuberculosis) and mycoses (deep mycoses) are uncommon causes of ulceration. Aphthae (sometimes) and other causes of mouth ulcers (rarely) involve the gingiva (Table 66.10).

Table 66.10 Main causes of mouth ulcers associated with systemic disease.

Microbial disease
Herpetic stomatitis
Chickenpox
Herpes zoster
Hand, foot and mouth disease
Herpangina
Infectious mononucleosis

Sweet's syndrome
Reiter's disease
Drugs
Cytotoxic, NSAIDs, nicorandil, alendronate and other agents
Acrodynia
Radiotherapy
Disorders of uncertain pathogenesis
Angina bullosa haemorrhagica
Hypereosinophilic syndrome
Eosinophilic ulcer
Necrotizing sialometaplasia

Blisters

Blisters may be seen as a result of burns or mucoceles, but the most important vesiculobullous disorders affecting the gingivae are pemphigoid (including cicatricial pemphigoid) and pemphigus and the typical presentation is of desquamative gingivitis. Vesicles may be seen in viral infections, especially in herpes simplex stomatitis,

chickenpox, herpangina and hand, foot and mouth disease [3–6].

Genetic disorders affecting the periodontium

Hereditary gingival fibromatosis

Aetiology. An autosomal dominant condition due to chromosome 2 or 5 anomalies, resulting in transforming growth factor (TGF)-β1 autocrine stimulation of fibroblast proliferation with alteration in expression of matrix metalloproteinases (MMP)-1 and MMP-2 [1–14].

Pathology. The gingival connective tissue is mainly composed of thick interlacing collagen fibres forming a dense, almost avascular, mass in which many fibrocytes have dark shrunken nuclei. Mucoid material and some giant cells may be found.

Clinical features. There is generalized gingival enlargement, especially obvious over the anterior maxilla and during the transition from deciduous to permanent dentitions [1]. If the enlargement is gross, it may move or cover the teeth and even protrude from the mouth. The changes initially involve the gingival papillae and later the attached gingiva. The affected gingiva is usually of normal colour but firm in consistency, and the surface becomes coarsely stippled. Patients may also be hirsute, as may patients with drug-induced gingival hyperplasia. The prognosis is good, but gingival surgery is often indicated.

Although most patients have only gingival fibromatosis, there are occasional associations with supernumerary teeth [15] or with Zimmermann–Laband, Rutherford's, Cowden's and Cross's syndromes [16–18].

Juvenile hyaline fibromatosis (see Chapter 46)

SYN. MURRAY–PURETIC–DRESCHER SYNDROME

Gingival enlargement may be seen in juvenile hyaline fibromatosis. It may precede tooth eruption or may present only in the first decade. It increases with age. Histology shows dilated capillaries in a hyaline PAS (periodic acid–Schiff)-positive matrix with pseudocartilaginous cells [1–5].

Leukocyte adhesion deficiency

Defects in cell-surface receptors on neutrophils and other leukocytes result in a range of disorders, especially recurrent cutaneous, respiratory and middle-ear infection, as well as periodontal destruction in both dentitions.

Local efforts to preserve the dentition, using débridement together with antimicrobials have been of little value [1–4].

Papillon–Lefèvre syndrome (see Chapter 34)

This is a rare, autosomal recessive condition of palmoplantar hyperkeratosis with periodontal breakdown (periodontosis or periodontoclasia) that manifests from childhood [1–3] and is related to a defect in cathepsin C [4] with defective polymorphonuclear leukocyte function [5].

The major oral feature of Papillon–Lefèvre syndrome is premature periodontal breakdown. The teeth develop and erupt normally in both the deciduous and permanent dentitions but the gingiva become red, swollen and bleed easily with the formation of periodontal pockets, loss of alveolar bone, loosening and loss of the teeth. The teeth are involved roughly in the order they erupt. The deciduous teeth are often lost by the age of 5 years and the permanent teeth are almost invariably lost by the age of 16 years. There are no obvious abnormalities in either the tooth cementum or dentine.

Hyperkeratosis of the palms and particularly the soles appears at about the age of 3–5 years, concurrent with periodontal breakdown of the deciduous dentition. Similar plaques may also be seen on the lips, cheeks and eyelids. The affected skin shows diffuse hyperkeratosis, hypergranulosis and acanthosis. There may also be calcification of the dura and some patients have recurrent pyogenic infections [6].

Similar syndromes include Haim–Munk syndrome [7], late-onset Papillon–Lefèvre syndrome [8], a condition including arachnodactyly and acro-osteolysis [9], and Unna–Thost syndrome (see below).

Diagnosis is on clinical and radiographic grounds. Intensive dental care is needed. Retinoids may be useful in suppressing oral and cutaneous lesions and minimizing the pyogenic infections [6,10,11] and it is possible to retain the dentition for some years [12].

Congenital epulis

SYN. GRANULAR CELL TUMOUR OR MYOBLASTOMA

Epulis is the term applied to a swelling on the gingiva. Congenital epulis is a rare, benign, pedunculated, firm pink swelling on the maxillary alveolus, seen in an infant [1,2]. It can be a prenatal ultrasonographic diagnosis [3,4]. There is an 8 : 1 female predominance.

It is probably a reactive mesenchymal lesion and is usually treated by excision. Histology shows large polygonal cells with a fine granular eosinophilic cytoplasm.

Epstein's pearls

SYN. GINGIVAL CYSTS OF THE NEWBORN

Epstein's pearls are superficial, white, keratin-containing cysts seen on the palatal or alveolar mucosa of about 80% of neonates. They are symptomless and inconsequential, usually being shed within a few weeks, sometimes found with cleft lip and palate [1–3].

Acquired disorders affecting the periodontium

Chronic gingivitis

This is an extremely common condition. Over 90% of dentate adults exhibit some degree of gingivitis. The accumulation of dental bacterial plaque because of inadequate oral hygiene produces non-specific chronic inflammation. It is painless but may manifest with bleeding from the gingival crevice. The gingival margins are red and slightly swollen [1].

Dental advice on improved oral hygiene is needed. If untreated it may progress to periodontitis and tooth loss.

REFERENCE

1 Page RC. Gingivitis. *J Clin Periodontol* 1986; **13**: 345–59.

Chronic periodontitis

Chronic periodontitis (inflammation of the gingiva and periodontal membrane) may be a sequel of chronic gingivitis usually because of plaque accumulation and calculus (tartar) [1]. Smoking is a risk factor. The gingiva

Fig. 66.14 Periodontitis.

detaches from the tooth neck, the periodontal membrane and alveolar bone are damaged, and an abnormal gap (pocket) develops between the tooth and gum. The tooth may slowly loosen and eventually be lost (Fig. 66.14).

Diagnosis. Chronic periodontitis is typically seen in adults. It is painless but may be associated with bleeding, halitosis and a foul taste. Debris and pus may be expressed from the pockets (pyorrhoea), and there may be increasing tooth mobility.

Management. Although periodontal disease has a bacterial component, systemic antibiotics have no place in routine treatment. Management comprises improvement in oral hygiene, although in this case plaque accumulates below the gumline, within periodontal pockets. Toothbrushing and mouthwashes have effect only above, or very slightly below, the gum level and are therefore ineffective in the treatment of periodontitis. Surgical removal of the pocket wall and removal of diseased tissue may be needed to facilitate future cleansing, or attempts to regenerate lost periodontal tissue (such as guided tissue regeneration) may be indicated. Periodontal attention is therefore required.

REFERENCE

Early-onset periodontitis

Periodontal breakdown (periodontitis) is usually a consequence of inflammatory destruction as a result of poor oral hygiene and the subsequent accumulation of dental bacterial plaque [1] and is seen mainly in adults. The host response and periodontal microbiota can both be implicated in a heterogeneous group of causes of early-onset periodontitis [2–10]. If present in children or adolescents, it can be a manifestation of severely neglected oral hygiene, such as seen in some patients with learning disability, or may be a feature of an immunocompromised host.

That host defences are extremely important in maintaining periodontal health is demonstrated well in the periodontal breakdown that may accompany leukaemias, leukocyte defects, diabetes and HIV infection. Periodontal breakdown is also a feature of Down's syndrome, Ehlers–Danlos syndrome type VIII and Papillon–Lefèvre syndrome.

Periodontal breakdown in a child or adolescent who is capable of maintaining good oral hygiene almost invariably suggests an immune or other systemic defect.

HIV infection

HIV disease can be complicated by necrotizing ulcerative gingivitis (see p. 66.74), periodontitis, candidiasis, herpetic ulceration, Kaposi's sarcoma, lymphomas and other gingival lesions [1].

Fig. 66.15 Desquamative gingivitis.

REFERENCE

1 Laskaris G, Scully C, eds. *Periodontal Manifestations of Local and Systemic Disease*. Berlin: Springer, 2003.

Desquamative gingivitis

In this fairly common condition, the labial gingiva are persistently glazed, red and sometimes sore but the gingival margins may be spared, differentiating desquamative gingivitis from chronic marginal gingivitis (Fig. 66.15).

Desquamative gingivitis typically affects middle-aged or elderly women and is usually a manifestation of mucous membrane pemphigoid or lichen planus [1–5]. Rarely, it may be seen in pemphigus, dermatitis herpetiformis, linear IgA disease, chronic ulcerative stomatitis with epithelial antinuclear antibodies or other dermatoses [4,5].

Desquamative gingivitis tends to be chronic and recalcitrant. The underlying condition should be treated where possible. Improved oral hygiene and topical corticosteroids in a nocturnally worn polythene splint may help. Dapsone or topical ciclosporin or tacrolimus may be beneficial in severe cases.

Allergic gingivostomatitis

SYN. ATYPICAL OR PLASMA-CELL GINGIVOSTOMATITIS

Diffusely red, swollen gingivae with or without oral ulceration may occasionally follow exposure to various allergens and other substances. Such reactions have followed the use of certain chewing gums, confectionery such as mints, and dentifrices [1–7] and dental materials [8], particularly 'tartar control' dentifrices containing cinnamon or cinnamaldehyde [2].

Biopsy is usually not indicated and is fairly non-specific with epithelial atrophy, oedema and a variable cellular infiltrate in the lamina propria which, in the earlier reported cases due to chewing gum, was often predominantly plasmacytic [1,3,5–7]. The lesions resolve on withdrawal of the causal agent and reappear on rechallenge. Patch testing may be of value in diagnosis.

Idiopathic plasmacytosis (see also Plasma-cell balanitis, Chapter 68)

This term refers to red, velvety gingival lesions associated with a plasmacytic infiltrate. Most cases are restricted to the gingiva (atypical gingivostomatitis, plasmacyte gingivitis, allergic gingivostomatitis) [1], while a few have supraglottic laryngeal lesions [2]. Corticosteroids are the main treatment but irradiation may be required [3].

Fibroepithelial polyp

SYN. FIBROUS LUMP

Fibrous lumps are common in the mouth and are seen

mainly in adults. They appear to be purely reparative in nature. They may attain their full size (which rarely exceeds 2.5 cm diameter) quite rapidly, and then stop growing. Fibrous lumps should not be confused with the true fibroma, a benign neoplasm derived from fibroblasts, which is rare in the mouth (see below).

The variable inflammatory changes account for the different clinical presentations of fibrous lumps from red, shiny, soft lumps to those which are pale, stippled and firm [1]. Commonly, they are round pedunculated swellings arising from the marginal or papillary gingiva (epulides), sometimes adjacent to sites of irritation (e.g. a carious cavity). They are usually painless. They may reach quite a large size, but the prognosis is good.

Fibrous epulides should be removed down to the periosteum, which should be curetted thoroughly.

Fibroma [1]

The true fibroma, a benign neoplasm of fibroblastic origin, is rare in the oral cavity and many lesions in the past called fibromas were probably fibroepithelial polyps.

Histology shows marked proliferation of fibroblasts, with nuclei of uniform shape, size and staining characteristics.

The true fibroma is a continuously enlarging new growth, not necessarily arising at a site of potential trauma. It is a pedunculated growth with a smooth, non-ulcerated, pink surface.

Removal should be total, deep and wide.

REFERENCE

1 Lee KW. The fibrous epulis and related lesions. *Periodontics* 1986; **6**: 277–99.

Pyogenic granuloma (see Chapter 53)

Pyogenic granuloma commonly affects the gingiva, the lip or the tongue [1]. In these sites, the lesion should be excised completely. It will readily recur if excision is not adequate.

REFERENCE

1 Vilmann A, Vilmann P, Vilmann H. Pyogenic granuloma: evaluation of oral conditions. *Br J Oral Surg* 1986; **24**: 376–82.

Giant cell epulis

SYN. PERIPHERAL GIANT CELL GRANULOMA

The giant cell epulis probably arises because chronic irritation triggers a reactionary hyperplasia of muco-periosteum and excessive production of granulation tissue. Giant cell granulomas are occasionally a feature of hyperparathyroidism.

The giant cell epulis characteristically arises interdentally, adjacent to permanent teeth that have had deciduous predecessors [1], i.e. not the permanent molars. Classically, the most notable feature is the deep-red colour, although older lesions tend to be paler.

This is a benign lesion which is cured by excision.

Pregnancy gingivitis and epulis

There can be an exaggerated inflammatory reaction to dental bacterial plaque in pregnancy, and chronic gingivitis may therefore be aggravated giving rise to 'pregnancy gingivitis' [1,2] and, occasionally, a pyogenic granuloma (pregnancy epulis).

Pregnancy gingivitis is characterized by soft reddish enlargements, usually of the gingival papillae, varying from small smooth enlargements to more extensive, ragged, granular lumps resembling the surface of a strawberry. Changes of pregnancy gingivitis usually appear about the second month of pregnancy, and reach a peak at the eighth month. Poor oral hygiene predisposes to these changes. A similar appearance may occur with oral contraceptives.

Sometimes there is a localized epulis (pregnancy epulis) that, although unsightly, is usually painless. Occasionally it ulcerates or interferes with eating. Despite the vascularity, the immaturity of the vessels may lead to superficial ischaemia and ulceration. Larger lesions are prone to trauma, which may contribute to the ulceration.

Oral hygiene should be improved. Most lesions tend to resolve on parturition. There is one report of a beneficial effect of folic acid on pregnancy gingivitis [3]. An epulis requires excision only if it is being traumatized or is grossly unaesthetic [2].

Drug-induced gingival swelling

Gingival swelling is a recognized adverse effect of medication, especially following use of phenytoin, calcium-channel blockers and ciclosporin.

Phenytoin

Phenytoin induces gingival swelling presumably by an effect on fibroblast activity. There is no correlation between the extent of overgrowth and the dose of phenytoin, its serum level, or the age and sex of the patient. Rather, the hyperplasia is aggravated by poor oral hygiene.

Phenytoin can produce a variable degree of gingival enlargement, which characteristically affects the interdental papillae first but which may later involve the marginal and even attached gingiva. The palatal and lingual gingivae are usually involved less than the buccal and labial gingivae [1–4].

The enlargement is characteristically firm, pale and tough, with coarse stippling, although these features may take several years to develop, and earlier lesions may be softer and redder (see Fig. 66.12).

The patient's level of plaque control should be improved [5] and a 0.2% aqueous chlorhexidine mouthwash may be helpful. Excision of the enlarged tissue may be indicated but the swelling unfortunately readily recurs, although this is less likely with meticulous oral hygiene, particularly if the phenytoin can be stopped. Folic acid may improve the condition and systemic isotretinoin may be of some value [2].

Calcium-channel blockers

Nifedipine can cause gingival swelling, typically affecting the papillae in a similar fashion to phenytoin [3,6]. Several other calcium-channel blockers have a similar effect [7].

Improved oral hygiene may reduce the hyperplasia [8]. Excision of the enlarged tissue may be followed by recurrence, and patients should be warned accordingly. If possible the medication should be changed.

Ciclosporin

Ciclosporin also causes gingival hyperplasia, initially of papillae [3,9]. Only about one-third of patients are affected, more commonly children, and this change may be lessened by meticulous removal of plaque before the drug is introduced.

Scurvy (see Chapter 57)

Scurvy (vitamin C deficiency) causes gingival swelling, bleeding and oral purpura, but is now rare in the West.

Disorders affecting the oral mucosa or lips

Swellings

Mucosal swelling may be seen after trauma and in angio-oedema, Crohn's disease, orofacial granulomatosis, sarcoidosis, Wegener's granulomatosis, amyloidosis and other disorders. Localized swellings may be of local aetiology or can be manifestations of neoplasia or systemic disease.

Pigmentation

Mucosal pigmentation is usually seen in dark-skinned races (but may be seen even in white people) (see Fig. 66.13). Other common causes include amalgam tattoo and melanotic macules.

Addison's disease, Kaposi's sarcoma, melanoma, Laugier–Hunziker syndrome, pigmentary incontinence and other causes must be excluded. Peutz–Jeghers disease is the association of circumoral and sometimes intraoral melanosis with small-intestinal polyposis (see Chapter 59). Oral petechiae are usually caused by trauma or suction. More widespread purpura is most frequently a manifestation of a bleeding tendency caused by thrombocytopenia and may also be seen in infectious mononucleosis, rubella, HIV infection, leukaemia or scurvy. Petechiae may also occur in amyloidosis.

Redness

Red lesions may be inflammatory, or represent erythroplasia, haemangiomas or neoplasms such as carcinoma, Wegener's granulomatosis or Kaposi's sarcoma [1,2].

Candidiasis is a common cause of red lesions, which may be sore. Widespread erythema, particularly if associated with soreness, is usually caused by primary herpes simplex stomatitis or a mucocutaneous disorder such as lichen planus or mucous membrane pemphigoid, rarely by pemphigus or other dermatoses and occasionally by allergic responses.

Localized red areas may represent erythroplasia, carci-

noma, candidiasis, lichen planus or lupus erythematosus. Kaposi's sarcoma may present as a red, purple, brown or bluish macule or nodule as may epithelioid angiomatosis. Hereditary mucoepithelial dysplasia is a rare cause of oral erythema.

Telangiectasia may be a manifestation of hereditary haemorrhagic telangiectasia, primary biliary cirrhosis or systemic sclerosis, or may follow radiotherapy. Haemangiomas are usually isolated but may occasionally extend deeply and rarely involve the ipsilateral meninges, producing a facial angioma and epilepsy, sometimes with learning disability (Sturge–Weber syndrome). Intraoral haemangiomas may be seen in Maffucci's syndrome.

Lingual depapillation in deficiencies of iron, folate or vitamin B_{12} may produce the red tongue termed 'glossitis'. Geographical tongue may also produce red patches.

Mucositis can readily be induced by irradiation or chemotherapy.

Ulcers

Oral ulcers are often caused by trauma or recurrent aphthae (see p. 66.43). Malignant neoplasms may present as ulcers. Various infections or systemic disorders, particularly those of blood, gastrointestinal tract or skin, also produce mouth ulcers, as may drugs and irradiation (see Table 66.10).

Blisters

Blisters may be seen as a result of burns but the most important vesiculobullous disorders affecting the oral mucosa are pemphigoid (including cicatricial pemphigoid) and pemphigus (see Table 66.10). The bullae of mucous membrane pemphigoid may or may not be blood-filled and, in the former case, a bleeding tendency must be excluded. Blood-filled blisters may also be caused by localized oral purpura (angina bullosa haemorrhagica) or amyloidosis. The bullae of pemphigus are rarely seen as they break down rapidly to produce ulcers. Epidermolysis bullosa and erythema multiforme may present with oral bullae or vesicles, although ulcers are more common. Vesicles may be seen in viral infections, especially in herpes simplex stomatitis, chickenpox, herpangina and hand, foot and mouth disease.

Mucoceles, caused by extravasation of mucus from minor salivary glands, produce isolated blisters, typically in the lower labial mucosa.

White patches (see Table 66.9)

Thrush (acute candidiasis) is a 'disease of the diseased' and produces oral white patches.

HIV infection causes hairy leukoplakia, a white lesion on the tongue (see p. 66.89).

Leukoplakia is often associated with friction or smoking, occasionally with syphilis, candidiasis or chronic renal failure, but most cases are idiopathic. Lichen planus and lupus erythematosus may present as white lesions. Rarely, lichenoid lesions are associated with various drugs, liver disease or GVHD. Carcinoma may present as a white lesion.

Inherited causes of white patches, such as white sponge naevus and dyskeratosis congenita, are rare [1–5].

Genetic disorders affecting the oral mucosa or lips

This section discusses the main congenital causes of white or whitish lesions, pigmented lesions, red lesions, vesiculoerosive lesions, lumps and swellings, and some orocutaneous disorders.

White or whitish lesions

Sebaceous glands

Fordyce spots

SYN. FORDYCE'S GRANULES

Fordyce spots are yellowish small grains seen beneath the buccal or labial mucosa. Fordyce spots are sebaceous glands containing neutral lipids similar to those found in skin sebaceous glands [1] but are not associated with hair follicles.

Fordyce spots are extremely common: probably 80% of the population have them. They are usually seen in the buccal mucosa, particularly inside the commissures (Fig. 66.16), and sometimes in the retromolar regions and upper lip [1–5]. Fordyce spots are often not noticeable in children until after puberty (although they are present histologically), and they seem to be more obvious in males, patients with greasy skin and the elderly, and they may be increased in some rheumatic disorders [6].

Fordyce spots are totally benign, although the occasional patient or physician becomes concerned about them or misdiagnoses them as thrush or lichen planus. Occasionally they may be mistaken for leukoplakia [7].

No treatment is indicated, other than reassurance. The spots may become less prominent if isotretinoin is given [8].

Fig. 66.16 Fordyce spots: sebaceous glands in the buccal mucosa.

Sebaceous adenoma

Sebaceous adenomas are exceedingly rare in the mouth, except in association with salivary glands but have been described in the buccal mucosa [1–5].

Nevus sebaceus of Jadassohn

SYN. LINEAR NAEVUS SYNDROME

Oral manifestations may rarely occur as fibroepitheliomatous nodules in patients with a sebaceous naevus of the skin but are extremely rarely seen in isolation [1–3].

REFERENCES

Epithelium

Leukoedema

Leukoedema is not a mucosal disease but simply the name given to the faint whitish lines seen in some normal buccal mucosae, often prominent in black people. The whitish lines disappear if the mucosa is stretched—a diagnostic test [1–3]. Confusion with lichen planus should thereby be avoided.

Clouston syndrome (see above)

See also Chapter 12.

White-sponge naevus

SYN. CANNON'S DISEASE; PACHYDERMIA ORALIS; WHITE FOLDED GINGIVOSTOMATOSIS

Aetiology. A rare familial disorder usually first seen in childhood and inherited as an autosomal dominant trait [1,2]; there appear to be defects in keratins 4 and 13 with abnormal tonofilament aggregation [3–6].

Pathology. There is hyperplastic acanthotic epithelium in which gross oedema causes a basket-weave appearance. The superficial epithelium has a 'washed-out' appearance as it stains only very lightly.

Clinical features. The oral mucosa is almost invariably involved in white-sponge naevus. Painless shaggy or folded white lesions typically affect the buccal mucosa bilaterally but may also involve other areas, although rarely the gingival margins.

Similar lesions may also affect the upper respiratory tract, genitalia and anus [1,2].

Diagnosis. The family history and clinical examination are usually adequate to differentiate this from other more

common causes of white lesions such as cheek biting, burns, lichen planus and candidiasis.

Treatment. This is a benign condition with an excellent prognosis. Reassurance is all that is required, although some have suggested that tetracyclines clear the lesions [7,8].

Dyskeratosis congenita (see Chapter 12)

SYN. ZINSSER–ENGMAN–COLE SYNDROME

Dyskeratosis congenita usually presents with oral lesions between the ages of 5 and 10 years, when the tongue and sometimes the buccal mucosa and palate develop diffuse white lesions with a malignant potential [1,2]. The lesions resemble leukoplakia or lichen planus and show non-specific hyperkeratosis, a prominent granular cell layer and mild acanthosis [1–5].

Other manifestations include lesions of other mucosae, skin and appendages, and bone marrow dysfunction. Other rare oral features include taurodont or hypocalcified teeth and mucosal hyperpigmentation.

Pachyonychia congenita (see Chapter 62)

SYN. JADASSOHN–LEWANDOWSKY SYNDROME

Pachyonychia congenita is a benign disorder associated with mutations in keratin 16 [1,2]. About 60% of patients have oral keratosis, 16% have natal or neonatal teeth, and 10% have angular stomatitis. Some patients also develop chronic intraoral candidiasis [3–5].

The keratosis requires no treatment. Dental advice should be sought regarding natal or neonatal teeth.

Tylosis [1–4] (see Chapter 34)

Tylosis is an autosomal dominant syndrome of palmoplantar hyperkeratosis that may predispose to oesophageal carcinoma but although oral white lesions have also been described, there is little evidence that these are premalignant.

Focal palmoplantar and oral hyperkeratosis syndrome (keratosis palmaris et plantaris)

Focal hyperkeratosis at weight-bearing areas of the palms and soles, with hyperkeratosis of the attached gingiva and occasionally other sites, is an autosomal dominant trait [1–3].

Hereditary benign intraepithelial dyskeratosis [1–3]

SYN. WITKOP–VON SALLMANN SYNDROME

Aetiology. Hereditary benign intraepithelial dyskeratosis is a rare, benign, autosomal dominant condition associated with chromosome 4 anomalies, seen mainly in some groups of mixed ethnic origin, predominantly in North Carolina, USA.

Pathology. There is pronounced epithelial acanthosis, vacuolization in the stratum spinosum and eosinophilic cells apparently engulfed by normal squamous cells ('tobacco cells').

Clinical features. Oral milky white, smooth, somewhat translucent plaques appear in childhood and become more obvious by adolescence. These lesions affect predominantly the buccal mucosae, lips and ventrum of the tongue.

Ocular lesions include conjunctivitis with gelatinous conjunctival plaques, which become evident in infancy. There may be photophobia and eventual corneal involvement.

Oral biopsy is usually indicated for diagnosis.

Treatment. No treatment is required.

Darier's disease (see Chapter 40)

Oral lesions are seen in up to 50% of patients with skin lesions of Darier's disease. The oral changes are most marked in patients with the most severe skin changes and are typically flattish, coalescing, red plaques that eventually turn white and affect the keratinized mucosa of the dorsum of the tongue, palate and gingiva (Fig. 66.17) and then may resemble nicotinic stomatitis clinically [1–3].

Fig. 66.17 Darier's disease: oral white lesions resemble those of nicotinic stomatitis.

Salivary duct anomalies, including dilatations with periodic strictures and indentations, may affect the main ducts [4,5].

Warty dyskeratoma [1–4] (see Chapter 34)

SYN. FOCAL ACANTHOLYTIC DYSKERATOSIS

Warty dyskeratoma, oral warty dyskeratoma or focal acantholytic dyskeratosis is rare in the oral cavity but typically presents as a nodule or papule on the gingiva, palate or alveolar ridge. The histology is similar to that of Darier's disease and transient acantholytic dermatosis, with suprabasal epithelial splits and corps ronds.

Keratitis, ichthyosis and deafness syndrome (see Chapter 34)

SYN. KID SYNDROME

Dental dysplasia, persistent oral ulceration, chronic mucocutaneous candidiasis and occasional carcinoma may be seen in the KID syndrome of keratitis, ichthyosiform dermatosis and deafness [1,2].

REFERENCES

1 Baden HP, Alper JC. Ichthyosiform dermatosis, keratitis and deafness. *Arch Dermatol* 1977; **113**: 1701–4.

Chronic mucocutaneous candidiasis (see Chapter 31)

Chronic mucocutaneous candidiasis includes a range of congenital disorders characterized by chronic candidiasis involving mouth, nails and other sites. Persistent adherent white lesions are seen in the mouth, often with angular stomatitis [1–4]; in candidiasis–endocrinopathy syndrome, there may also be enamel hypoplasia [5,6] and, rarely, oral carcinoma [7].

Pigmented lesions

Most oral hyperpigmentation is racial in origin (see Fig. 66.13). Seen mainly in blacks and Asians it can also be noted in patients of Mediterranean descent, sometimes even in some fairly light-skinned people. It is most obvious in the anterior labial gingivae and palatal mucosa and pigmentation is usually symmetrically distributed. Patches may be seen elsewhere. Pigmentation may be first noted by the patient in adult life and then incorrectly assumed to be acquired rather than congenital in origin.

Melanotic macule

The melanotic macule is an acquired, small, flat, brown to brown-black, asymptomatic, benign lesion, unchanging in character [1,2]. Oral melanotic macule is similar to the ephelis and lentigo.

Melanotic macules may be seen in up to 3% of normal persons, at any age. Melanotic macules are usually solitary, discrete, pigmented brown collections of melanin-containing cells. The macules are less than 2 cm in diameter, seen especially on the vermilion of the lips, gingiva, buccal mucosa or palate. Most on the lips are seen near the midline, on the lower lip vermilion. Most are solitary and seen in white adults and their colour ranges from brown to black [1,3,4]. Occasional cases are seen in HIV infection [5].

Clinically, the melanotic macule may resemble other lesions such as early melanoma and ephelides, although the latter tend to fade in winter and darken in summer. Histopathologically, the mucosal epithelium is normal apart from increased pigmentation of the basal layer, accentuated at the tips of rete ridges. There are no naevus cells or elongated rete ridges [3]. There is melanin in the epithelial basal layer and/or upper lamina propria. Occasionally they are seen along with melanonychia striata (Laugier–Hunziker syndrome, see below).

Melanotic macules can be excised to exclude melanoma or for cosmetic reasons, or hidden by lipstick.

Peutz–Jeghers syndrome (see Chapter 39)

Peutz–Jeghers syndrome is as an autosomal dominant trait characterized by hamartomatous intestinal polyposis and mucocutaneous melanotic pigmentation, especially circumorally. Those affected have discrete, brown to bluish black macules mainly around the oral, nasal and ocular orifices. The lips, especially the lower, have pigmented macules in about 98% of patients (Fig. 66.18). Oral brown or black macules, unlike the circumoral lesions, do not

Fig. 66.18 Peutz–Jeghers syndrome.

fade after puberty. Mucosal and facial hyperpigmentation may also be seen in relatives [1–3].

Intestinal polyps are found mainly in the small intestine in Peutz–Jeghers syndrome. They rarely undergo malignant change but if they produce intussusception, surgical intervention is required. There is a slightly increased risk of gastrointestinal carcinoma and carcinomas of the pancreas, breast and reproductive organs [4–7].

Ruby and argon lasers have been used to treat the pigmentation of the lips and oral mucosa [8] (see Chapter 77).

Laugier–Hunziker syndrome

SYN. LAUGIER–HUNZIKER–BARAN SYNDROME
[1–4]

Laugier–Hunziker syndrome presents with labial, oral mucosal and nail hyperpigmentation. A possible variant of this or Peutz–Jeghers syndrome has been termed *idiopathic lenticular pigmentation* [5], in which there are oral, labial, perianal and digital hyperpigmented lenticular macules. Similar patients have been reported previously [6–8].

Pseudoxanthoma elasticum

See Chapter 46.

Lentiginoses

The lentiginoses (or lentigenoses) include Peutz–Jeghers syndrome (Chapter 39) and the LEOPARD syndrome, which comprises:

- *l*entigines (multiple);
- *e*lectrocardiographic conduction abnormalities;
- *o*cular hypertelorism;
- *p*ulmonary stenosis;
- *a*bnormalities of genitalia;
- *r*etardation of growth; and
- *d*eafness.

The lentiginoses also include the syndrome of arterial dissections with lentiginosis, Laugier–Hunziker syndrome, Cowden disease, Ruvalcaba–Myhre–Smith (Bannayan–Zonana) syndrome, and the centrofacial, benign patterned and segmental lentiginoses, all of which can be associated with a variety of developmental defects.

Centrofacial lentiginosis syndrome

SYN. TOURAINE'S CENTROFACIAL LENTIGINOSIS

Centrofacial lentiginosis [1] is associated with bone abnormalities, malformations due to dysraphia, endocrine dysfunctions and neurological diseases.

REFERENCE

1 Dociu I, Galaction-Nitelea O, Sirjita N, Murgu V. Centrofacial lentiginosis. A survey of 40 cases. *Br J Dermatol* 1976; **94**: 39–43.

Complex of myxomas, spotty pigmentation and endocrine overactivity

SYN. CARNEY'S SYNDROME; CARNEY COMPLEX

This autosomal dominant trait causes cardiac and cutaneous myxomas, with mammary myxoid fibroadenomas, spotty cutaneous hyperpigmentation, primary pigmented nodular adrenocortical disease, testicular Sertoli cell tumours and growth hormone-secreting pituitary adenoma. It may present with oral hyperpigmentation and myxomas [1–4]. The hyperpigmentation in Carney complex is facial and occurs on the vermilion of the lips in about 35%, although about 8% have pigmented lesions on the oral mucosa and about 2% have oral myxomas, usually on the palate or tongue [2]. Carney complex differs clinically from Peutz–Jeghers syndrome in that hyperpigmentation is less common intraorally but more common on the conjunctiva, and other manifestations are also present.

Cases previously described as NAME syndrome (*n*aevi, *a*trial myxoma, *m*yxoid neurofibromas, *e*phelides) and LAMB syndrome (*l*entigines, *a*trial myxoma, *m*ucocutaneous myxoma, *b*lue naevi) may represent this complex, which also has close similarities to LEOPARD syndrome and the syndrome of arterial dissections with lentiginosis (see Chapter 39).

Inherited patterned lentiginosis in black people

This autosomal dominant condition is characterized by small, discrete, hyperpigmented macules on the face, lips, extremities, buttocks and palmoplantar areas [1]. No patients have been reported with oral mucosal lesions or internal organ system abnormalities.

This condition can resemble other lentiginosis syndromes, especially Peutz–Jeghers syndrome, centrofacial lentiginosis syndrome and Carney complex.

Naevi

Pigmented naevi are much less common in the oral mucosa than in skin. Approximately half of naevi are histologically of the intradermal (intramucosal) type; one-third are blue naevi, many others are compound naevi and some are junctional naevi.

Pathology. They are formed from increased melanin-containing cells, are flat or raised, do not change rapidly in size or colour, are painless and are seen particularly on the palate. The intramucosal type of naevus is most common (about 60%), while another 25% are blue naevi. Compound and junctional naevi and combined naevi are rare in the mouth. The intramucosal naevus consists of a collection of melanocytic cells in the lamina propria without involvement of the epithelium. The blue naevus consists of spindle cells at any level in the lamina propria. The junctional naevus consists of clusters of benign naevus cells at the epithelio-mesenchymal junction and the lamina propria is otherwise not involved.

Clinical features. Pigmented naevi are seen particularly on the vermilion border of the lip and on the palate or buccal mucosa [1]. These lesions are usually brown, macular, do not change rapidly in size or colour and are painless. The prognosis is good.

Treatment. There is no evidence that most naevi, except junctional naevi, progress to melanoma. However, they may resemble melanomas. If early detection of oral melanomas is to be achieved, all pigmented oral cavity lesions should be viewed with suspicion. Therefore, excision biopsy is recommended to exclude malignancy, because of the premalignant potential of some, particularly the junctional naevus, and for cosmetic reasons (Table 66.11). This is particularly important if the lesions are raised or nodular [2].

Red lesions

Vascular anomalies

Hereditary haemorrhagic telangiectasia (see Chapter 51)

SYN. OSLER–RENDU–WEBER SYNDROME

This syndrome is characterized by multiple telangiectasia on the lips, perioral skin, oral and nasal mucosae [1,2] as

Table 66.11 Causes of mucosal pigmentation.

Localized
Amalgam tattoo
Ephelis (freckle)
Naevus
Malignant melanoma
Kaposi's sarcoma
Peutz–Jegher syndrome
Laugier–Hunziker syndrome
Melanotic macules
Complex of myxomas, spotty pigmentation and endocrine overactivity
Generalized
Racial
Localized irritation, e.g. smoking
Drugs, e.g. phenothiazines, antimalarials, minocycline, contraceptives, mephenytoin
Addison's disease
Nelson's syndrome
Ectopic adrenocorticotrophic hormone (e.g. bronchogenic carcinoma)
Heavy metals
Albright's syndrome
Other rare causes, e.g. haemochromatosis, generalized neurofibromatosis, incontinentia pigmenti
Malignant acanthosis nigricans

well as the gastrointestinal tract. Occasionally there are colonic or hepatic complications [3,4]. Oral haemorrhage can be controlled by cryotherapy, cautery, infrared coagulation or Nd-Yag laser [5,6].

Haemangioma

Haemangiomas are usually deep red or blue–purple, blanch on pressure, are fluctuant to palpation, and are level with the mucosa or have a lobulated or raised surface [2]. Most are small and of no consequence [1,2].

Most haemangiomas are seen in isolation but a few may be multiple and/or part of a wider syndrome such as Maffucci syndrome [3]. Large facial haemangiomas, which can involve the lips, may be associated with Sturge–Weber syndrome (Fig. 66.19) [3] or Dandy–Walker syndrome, or other posterior cranial fossa malformations [4].

Fig. 66.19 Haemangioma affecting the lip in Sturge–Weber syndrome.

Haemangiomas are at risk from trauma and prone to excessive bleeding if damaged (e.g. during tooth extraction). Occasionally, oral haemangiomas develop phlebolithiasis.

Oral lesions suspected of being haemangiomatous should not be routinely biopsied; aspiration is far safer. Kaposi's sarcoma and epithelioid angiomatosis should be excluded. After intravenous administration of contrast medium, enhancement is observed in haemangiomas in areas corresponding to those with high signal on T_2-weighted magnetic resonance imaging (MRI).

Oral haemangiomas are left alone unless causing symptoms, when they are best treated with cryosurgery or laser if small, or by ligation or embolization of feeding vessels if large.

Sturge–Weber–Krabbe syndrome [1–5] (see Chapter 15)

The haemangioma in the trigeminal area in Sturge–Weber syndrome is usually unilateral, may involve the mouth but fortunately rarely involves bone. It may be associated with hypertrophy of affected tissues and, if the patient is treated with phenytoin, with gingival hyperplasia [3].

Hereditary mucoepithelial dysplasia

Hereditary mucoepithelial dysplasia is an autosomal dominant dyskeratotic epithelial syndrome affecting oral, nasal, vaginal, urethral, anal, bladder and conjunctival mucosae, causing cataracts, follicular keratosis, nonscarring alopecia and terminal lung disease [1–4].

Pathology. The condition is probably a pan-epithelial cell defect of desmosomal and gap junction structure. Histochemically there is a lack of cornification and keratinization. Electron microscopy shows an abnormality in desmosomes and gap junctions, with a lack of keratohyalin granules, a paucity of desmosomes, intercellular accumulations, cytoplasmic vacuolization, and formation of bands and aggregates of filamentous fibres and structures in the cytoplasm resembling desmosomes and gap junctions. There is some acantholysis as well as benign dyskeratosis of individual cells [1,2]. Histologically the mucosal epithelium shows dyshesion, thinning of the epithelial layer and dyskeratosis. Mucosal Papanicolaou smears show lack of epithelial maturation, cytoplasmic vacuoles and inclusions, and individual cell dyskeratosis.

Clinical features. Red, periorificial mucosal lesions are typically noted during infancy and may persist throughout life. The oral lesions are painless red macules or maculopapules and are seen predominantly on the palate and gingiva.

Severe photophobia, tearing and nystagmus in infancy herald the development of keratitis, corneal vascularization and lens cataracts.

In addition there may be various cardiorespiratory complications, especially potentially lethal bullous lung disease—spontaneous pneumothorax and bullous emphysema, terminating in cor pulmonale. Chronic rhinorrhoea and repeated upper respiratory infections frequently progress to bilateral pneumonia. Loss of hair, diarrhoea, melaena, enuresis, pyuria and haematuria may also be seen.

Vesiculoerosive disorders

Acrodermatitis enteropathica

Acrodermatitis enteropathica is an inborn error of metabolism resulting in zinc malabsorption and severe zinc deficiency [1–4].

Clinical features. Diarrhoea, mood changes, anorexia and neurological disturbance are reported most frequently in infancy. Growth retardation, alopecia, weight loss and recurrent infections are prevalent in affected toddlers and schoolchildren. A vesiculobullous dermatitis with perioral involvement may be seen, often sparing the vermilion [2]. Zinc deficiency during growth periods results in growth failure and lack of gonadal development in males. Other effects of zinc deficiency include skin changes, poor appetite, mental lethargy, delayed wound healing, neurosensory disorders and cell-mediated immune disorders. Skin lesions and poor wound healing are observed in severe forms and the disorder can be lethal.

Diagnosis. Assays of zinc in granulocytes and lymphocytes provide better diagnostic criteria for marginal zinc deficiency than plasma zinc assays. In cases of doubt, zinc absorption tests using radioisotopes (^{65}Zn or ^{69m}Zn) may be performed. Levels of alkaline phosphatase are reduced.

Management. Management includes zinc sulphate 2 mg/kg daily, at least until adult life.

Epidermolysis bullosa (see Chapter 40)

Epidermolysis bullosa is characterized by blisters, sometimes preceded by white patches, which develop rapidly, particularly where there is trauma. Blisters rupture to produce ulcers, often with eventual scarring, particularly in the recessive dystrophic types [1–5]. Oral lesions are fairly common in dystrophic and lethal forms of epidermolysis bullosa but are rare in most simplex types except the superficial type, where they are found in 70% of patients [2,6–8]. Overall, oral mucosal lesions are found in about 30% of patients with epidermolysis bullosa [1–5]. There is a predisposition to oral squamous cell carcinoma, mainly in the Hallopeau–Siemens type.

Dental hypoplasia and other defects and delayed tooth eruption may also be a feature, especially in junctional epidermolysis bullosa (Table 66.12) and, with the difficulty in maintaining adequate oral hygiene, there is a predisposition to caries [4].

Patients with recessive dystrophic epidermolysis bullosa suffer from severe growth inhibition due to reduced food intake as a result of severe oropharyngeal and oesophageal blistering or scarring, with smaller maxillae and smaller mandibles than normal [9–11]. Treatment is improved with modalities such as implants [12–14].

The oral manifestations in the various inherited forms of this condition are summarized in Table 66.12 and epidermolysis bullosa acquisita is discussed in Chapter 41.

Lumps and swellings

Hereditary angio-oedema (C1 esterase inhibitor deficiency)

Hereditary angio-oedema mimics allergic angio-oedema (see Chapter 47), although it produces a more severe reaction, with oedema affecting the lips, mouth, face and neck region, the extremities and gastrointestinal tract after minor trauma [1,2].

Blunt injury is the most consistent precipitating event. The trauma of dental treatment is a potent trigger, and some attacks even follow emotional stress. Oedema may persist for many hours and even up to 4 days. Involvement of the airway is a constant threat. The mortality may be as high as 30% in some families but the disease is compatible with prolonged survival if emergencies are avoided or effectively treated.

Diagnosis. In 85% of cases plasma C1 esterase levels are reduced (type 1 hereditary angio-oedema) but in 15% the

enzyme is present but dysfunctional (type 2 hereditary angio-oedema). In both types, plasma C4 levels fall but C3 levels are normal.

Management. C1 esterase concentrates are available for treatment [3]. Plasminogen inhibitors such as tranexamic acid can be used to mitigate attacks [4], although more effective agents are the androgenic steroids danazol and stanozolol, which raise plasma C1 esterase inhibitor levels to normal [1,2].

Focal dermal hypoplasia (see Chapter 12)

SYN. GOLTZ–GORLIN SYNDROME

Focal dermal hypoplasia is a rare, presumably X-linked, genodermatosis [1] involving developmental anomalies of tissues and organs of mesoectodermal origin. Thus there are abnormalities of the eyes, skin, musculoskeletal system, central nervous system (CNS) and oral structures.

Papillomas, usually of the oral mucosae and lips, dental anomalies and occasional cleft lip and palate are the main oral features [2,3]. The dental anomalies, seen in about half of affected individuals, include hypodontia, enamel defects and taurodontism [4–6].

Acanthosis nigricans (see Chapter 34)

Oral papilliferous lesions may be a feature of both familial [1,2] and malignant [1,3–6] acanthosis nigricans. Between 30 and 50% of patients with acanthosis nigricans secondary to neoplasia (malignant acanthosis nigricans) have oral lesions, which involve the tongue and lips predominantly.

Lymphangioma (see Chapter 51)

Lymphangioma is uncommon in the mouth. At least some are hamartomas and many are of similar structure to haemangiomas and can clinically resemble them, with a 'frog-spawn' appearance, but they contain lymph rather than blood (Fig. 66.20).

Lymphangiomas are usually solitary and affect the tongue predominantly. They are occasionally associated with cystic hygroma [1–5].

Small lymphangiomas need no treatment. Larger lesions may require excision, although cryotherapy can be useful. Contrast-enhanced T_1-weighted MRI can be used to differentiate between lymphangiomas and deep haemangiomas [6]. One study has found blue, domed lymphangiomas on the alveolar ridges of about 4% of newborn black children [3]. These lesions, which were usually bilateral, often regressed spontaneously.

Fig. 66.20 Lymphangioma of the tongue: a common site.

Dermoid cyst (see Chapter 15)

Dermoid cyst is a hamartoma, a developmental lesion commonly arising in the midline of the neck, above the mylohyoid muscle, occasionally elsewhere, even in the tongue or antrum [1–4]. It usually becomes clinically obvious in the second decade of life and causes elevation of the tongue.

Occasionally dermoid cysts become infected and then painful. Treatment is by surgical excision.

Lingual tonsil

The lingual tonsil is a mass of lymphoid tissue in the posterior third of the tongue, between the epiglottis posteriorly and the circumvallate papillae anteriorly [1,2]. It is usually divided in the midline by a ligament (Fig. 66.21). Although usually small and asymptomatic, it may become enlarged, especially in atopic individuals, in patients taking phenytoin or in some infections. It may be so prominent that it fills the vallecula and impinges against the epiglottis. If the lingual tonsil is large, it may cause a globus sensation, alteration of the voice, obstructive sleep apnoea or airways obstruction [3–6]. It tends to involute with increasing age.

Occasionally, there may be lingual tonsillitis with a red, swollen, painful tongue, fever and neutrophilia [7].

The condition must be distinguished from benign and malignant tumours of the tongue, including lingual thyroid, but the symmetry of the lingual tonsil and its midline division are helpful diagnostic pointers.

Fig. 66.21 Lingual tonsil showing a well-demarcated midline groove. (Courtesy of Dr C.T.C. Kennedy, Bristol Royal Infirmary, Bristol, UK.)

Treatment may be required if the enlarged tonsil causes symptoms. Surgery may be hazardous because of the copious blood supply to the tongue base. Electrocautery and cryotherapy are generally regarded as the safer procedures [1].

Lingual thyroid

Ectopic thyroid tissue may rarely present in the mouth. Some 10% of cadaver tongues contain thyroid tissue, although clinical presentation is much less common. Typically, there is an asymptomatic smooth-surfaced lump in the midline of the base of the tongue, between the sulcus terminalis and epiglottis at the site of the foramen caecum [1–4]. Occasionally, a lingual thyroid may produce dysphagia, cough, pain or, rarely, airways obstruction [1–10].

Not all lingual thyroid tissue is functional, and function tends to decline with age. Where thyroid-stimulating hormone levels are high, thyroid hormone supplements are indicated [1]. Malignant change is rare in lingual thyroid,

although follicular carcinomas have been recorded. MRI and ^{99m}Tc pertechnetate scintiscanning is important to ensure the presence of normal thyroid tissue in the neck [11,12] before considering treatment of a lingual thyroid by surgery or radioiodine [1,2,13].

Multiple mucosal neuroma syndrome

The syndrome of multiple endocrine neoplasia (MEN) type 2b (also called type 3) is inherited as an autosomal dominant, although new cases often arise sporadically. The gene locus is on chromosome 10.

MEN2b is characterized by medullary carcinoma of the thyroid and phaeochromocytoma, in association with multiple mucosal neuromas and an abnormal phenotype—a striking facial appearance, with thick, slightly everted lips that usually have a slightly bumpy surface due to multiple neuromas [1,2]. These are actually mucosal and submucosal hamartomatous proliferations of nerve axons, Schwann cells and ganglion cells.

Lesions may also involve the tongue and commissures but are less frequent on the buccal mucosa, gingivae, palate, pharynx or larynx (Fig. 66.22). Ganglioneuromatosis may also occur throughout the gastrointestinal tract, and this may result in constipation or megacolon [3]. Ocular changes include yellowish masses on the conjunctivae, thickened corneal nerves and keratitis due to decreased tear production [4].

Most patients have an asthenic marfanoid habitus, with high arched palate, pectus excavatum, arachnodactyly and kyphoscoliosis, but the lens subluxation and cardiovascular abnormalities of Marfan's syndrome are not present [5–8].

Fig. 66.22 Multiple neuromas of the lips and tongue in a patient with multiple endocrine neoplasia syndrome (type 2). (Courtesy of Dr M. Hartog, Bristol Royal Infirmary, Bristol, UK.)

Other congenital anomalies

Ankyloglossia

Ankyloglossia, or tongue-tie, is an uncommon and typically isolated anomaly in which the lingual fraenum is tight and the tongue cannot be fully protruded [1].

There may be a family history and sometimes deviation of the epiglottis or larynx [2]. The association of cleft palate with ankyloglossia is inherited as a semi-dominant

X-linked disorder previously described in several large families of different ethnic origins and related to chromosome Xq21: the T-box transcription factor gene *TBX22* is mutated [3,4].

Speech is not usually affected in patients with ankyloglossia but the ability to suckle [5] and to cleanse the buccal sulcus with the tongue may be, and there can be effects on jaw development [6]. If necessary, surgery to the fraenum will relieve ankyloglossia [7,8].

Fissured tongue

Fissured tongue (plicated or scrotal tongue) is a common condition affecting more than 5% of the population [1]. The cause is unclear, but it is often accompanied by geographical tongue (Fig. 66.23).

Patients with Down's syndrome often have a fissured tongue and it is a feature of the rare Melkersson–Rosenthal syndrome.

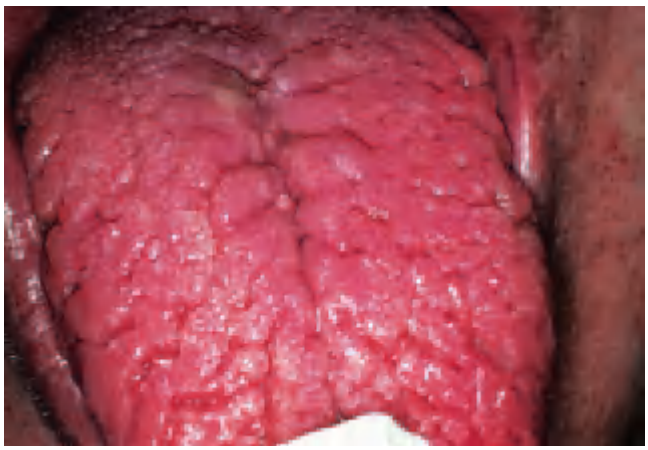

Fig. 66.23 Fissured or scrotal tongue.

Various orocutaneous syndromes

Cleft lip

Cleft lip and/or palate are the most common congenital craniofacial abnormalities. Cleft lip occurs in about 1 per 1000 white-skinned neonates. The prevalence is higher in oriental neonates (about 1.7 per 1000 births) and lower in black neonates (approximately 1 per 2500 births) and appears reduced if women take multivitamins containing folic acid early in pregnancy [1]. Clefts are often accompanied by impaired facial growth, dental anomalies, speech disorders, poor hearing and psychosocial problems [2]. Clefts can be seen in over 300 different syndromes [3].

Cleft lip is not always complete (i.e. extending into the nostril). A cleft may involve only the upper lip or may extend to involve the nostril and the hard and soft palates. In about 9% of the cases, the cleft is associated with skin bridges or Simonart's bands.

Isolated cleft lip may be unilateral or bilateral (approximately 20%). When unilateral, the cleft is more common on the left side (about 70%).

Lips are more frequently cleft bilaterally (approximately 25%) when combined with cleft palate. Cleft lip and palate is more common in men. Cleft lip and palate comprises about 50% of the cases, with cleft lip and isolated cleft palate each comprising about 25%. About 85% of bilateral cleft lips and 70% of unilateral cleft lips are associated with cleft palate. One subgroup have cleft lip and palate with median facial dysplasia and cerebrofacial malformations [4], others with laryngotracheal oesophageal clefts (Opitz–Firas or G syndrome) or cranial asymmetry (Opitz or B syndrome) [5].

Clefts in the middle of the upper lip may be true or false. True median clefts have been described in association with bifid nose and ocular hypertelorism. Other cases of true median labial cleft are associated with polydactyly or other digital anomalies, constituting an autosomal recessive trait called *orofaciodigital syndrome II*.

Pseudocleft of the middle of the upper lip may occur in *orofaciodigital syndrome I*. A somewhat similar central defect, but of mild degree, is seen in chondroectodermal dysplasia (Ellis–van Creveld syndrome). Clefts in the lower lip are rare and usually median but may involve the mandible and sometimes the tongue. Management of cleft lip is discussed elsewhere [6,7].

Cowden's syndrome (see Chapter 12)

SYN. MULTIPLE HAMARTOMA SYNDROME

Cowden's syndrome may be associated with the *PTEN* gene [1] and multiple hamartomas [2]. Oral mucosal lesions may be found in the presence or absence of cutaneous stigma [3–7]. The oral lesions are typically smooth, pink or whitish benign fibromas found especially on the palatal, gingival and labial mucosae. Oral squamous carcinoma is a rare complication [8]. There may be overlap with Bannayan–Riley–Ruvalcaba syndrome [9,10].

Treatment with acitretin may lead to regression of the hypertrophic lesions of the lip and mouth [11].

De Lange syndrome

SYN. AMSTERDAM DWARF

Classical Brachmann or Cornelia de Lange syndrome presents with a striking face, pronounced growth and learning disability, and variable limb deficiencies. Most cases are sporadic [1]. A long philtrum and crescent-shaped mouth with down-turned corners is typical [2,3].

The characteristic face of classical de Lange syndrome is present at birth and changes little throughout life, although there is some lengthening of the face with age and the jaw becomes squared.

Double lip

Double lip is a developmental anomaly usually involving the upper lip. A fold of redundant tissue is found on the inner aspect of the involved lip [1]. It is reported to be common among some groups of Africans [2].

Double lip may occur alone or in association with other anomalies. The association with blepharochalasis (laxity of the upper eyelid skin) and sometimes non-toxic thyroid enlargement is known as *Ascher's syndrome* [3] (see Chapter 46).

Double lip requires no treatment except for cosmetic purposes.

Down's syndrome

The incidence of angular cheilitis is increased in people with Down's syndrome, caused by an increased level of *Staphylococcus aureus* and *Candida albicans*, possibly because of the immune defects [1–3]. Lip fissures may appear intermittently over a period of years or be intractable and long-standing (see p. 66.120).

Erythropoietic protoporphyria

Erythropoietic protoporphyria is an autosomal dominant disorder of ferrochelatase, resulting in inhibition of the conversion of protoporphyrin to haem.

Shallow elliptical or linear scars around the lips and linear perioral furrowing (pseudorhagades) are subtle changes that are pathognomonic when observed in children [1,2].

Focal mucinosis

Oral focal mucinosis is an uncommon clinicopathological entity considered to be the oral counterpart of cutaneous focal mucinosis and/or cutaneous myxoid cyst. The nature of the lesion is unclear but may be the result of fibroblastic overproduction of hyaluronic acid. It comprises a clinically elevated mass with a histological picture of localized areas of myxomatous connective tissue. Most of the lesions affect the gingiva and alveolar mucosa [1–3].

All these diseases share distinct histological features. There is an increased number of fibroblast-like cells in early lesions, whereas these are diminished or predominantly at the margin in advanced ones. The myxomatous areas show slight to absent reticulum and elastic fibres, and collagen fibres are fragmented and replaced by variable amounts of mucin. Vimentin is consistently present and correlates with the number of fibroblast-like cells, these being negative for S-100 protein, Leu7, desmin and α-SMA [4].

Gardner's syndrome (see Chapter 12)

Multiple jaw osteomas are a feature of Gardner's syndrome of familial adenomatous polyposis coli [1,2]. Some 80% of patients with familial adenomatosis coli have osteomas and 30% have dental anomalies such as supernumerary or impacted teeth, or odontomes [3–9].

Gorlin's syndrome (naevoid basal cell carcinoma syndrome) (see Chapter 36)

Odontogenic keratocysts (primordial cysts) of the jaws are a prominent feature of Gorlin's syndrome [1–3]. The syndrome is caused by mutations in the Sonic Hedgehog *patched* gene, a tumour-suppressor gene [4]. A single point mutation in one *patched* allele may be responsible for the various malformations found in the syndrome [5–10]. Inactivation of both *patched* alleles results in the formation of tumours and cysts (basal cell carcinomas, odontogenic keratocysts and medulloblastomas) [4].

The keratocysts should be surgically removed but have a tendency to recur. There are also occasional reports of oral neoplasms, notably fibrosarcoma, ameloblastoma and squamous carcinoma [5–10].

Kindler syndrome

Kindler syndrome is characterized by bulla formation, which starts at birth on areas of the skin that receive pressure and may lead to bilateral incomplete syndactylies involving all web spaces [1].

Oral lesions may include atrophy of the buccal mucosa, trismus (an inability to fully open the mouth) and a form of desquamative gingivitis [2].

Histology shows classical features of poikiloderma, namely epidermal atrophy with flattening of the rete ridges, vacuolization of basal keratinocytes, pigmentary incontinence and mild dermal perivascularization. Ultrastructural studies demonstrate reduplication of the basal lamina with branching structures within the upper dermis and cleavage between the lamina densa and the cell membrane of the keratinocytes. Antibody against type VII collagen shows extensive broad bands with intermittently discontinuous and reticular staining at the dermal–epidermal junction.

Lip pits and sinuses

Dimples are common at the commissures. They should be distinguished from *commissural pits*, which are distinct definite pits ranging from 1 to 4 mm in diameter and depth [1,2] present from infancy, often showing a familial tendency and probably determined by a dominant gene

Fig. 66.24 Angular sinus (lip-pit), a congenital anomaly.

(Fig. 66.24). Their incidence is 1–20% in various population groups [2,3]; for example, in one series they were found in 12% of white people and 20% of black people [4]. Commissural pits are sometimes associated with aural sinuses or pits. Rarely, they may be infected and present as recurrent or refractory angular cheilitis.

Congenital lip pits or sinuses are small blind fistulae on the vermilion border [5]. They are usually bilateral and symmetrical, often just to one side of the philtrum. The pits may be up to 3–4 mm in diameter and up to 2 cm deep. They may communicate with underlying minor salivary glands. They may appear as isolated findings, but are often (67%) associated with cleft lip and/or palate (Van der Woude syndrome) [6–9]. This autosomal dominant syndrome [10,11] has a frequency of 1 in 75 000 to 1 in 100 000 in white populations (see Chapter 12).

Surgical removal may be indicated for cosmetic purposes.

Noonan's syndrome

SYN. ULLRICH–TURNER SYNDROME

Ullrich–Turner syndrome is caused by monosomy X or a structural abnormality of the second X chromosome. It is seen in females with a syndrome of short stature, sexual infantilism and a pattern of characteristic minor anomalies including pterygium colli. This syndrome was later called Noonan's syndrome, and it was shown that central giant cell lesions or cherubism of the jaws may be present [1–7]. Oral keratosis is sometimes seen [8].

Tuberous sclerosis (see Chapter 12)

SYN. EPILOIA; BOURNEVILLE DISEASE

Oral manifestations in tuberous sclerosis include pit-shaped enamel defects in both dentitions, and gingival fibromatosis [1–6] and rare instances of myxoma or desmoplastic fibroma [7,8].

Van der Woude syndrome

Van der Woude syndrome is a rare autosomal dominant syndrome [1] in which lower lip pits are associated with cleft lip and/or palate [2–5], sometimes seen with syndactyly or talipes equinovarus.

Von Recklinghausen's neurofibromatosis

Neurofibromatosis (NF) consists of distinct variants due to *NF* gene mutations [1]: type I (NF-I), often referred to as von Recklinghausen's disease or generalized neurofibromatosis; and type II (NF-II), a much less common disorder of bilateral acoustic schwannomas. The incidence of head and neck manifestations in patients with NF varies between 14 and 37%. Cosmetic lesions include pigmentary changes (café-au-lait spots) and prominent neurofibromas [2–6].

Neurofibromas may be seen mainly in NF-I. Neurofibromas may also be seen in NF-II, but bilateral acoustic neuromas are the hallmark of this disease and neurilemmomas and acoustic neuromas are this predominant neural tumours. Neurofibromas may also be part of the MEN syndrome (see Chapter 59).

Oral lesions are not uncommon in von Recklinghausen's generalized NF [7–14]. About two-thirds of patients have intraoral neurofibromas affecting predominantly the tongue, lips, buccal mucosa or palate. Neurofibroma represents a benign overgrowth of all elements of a peripheral nerve (axon cylinder, Schwann cells and fibrous connective tissue), arranged in a variety of patterns. Enlarged fungiform papillae are found in about 50% of patients. About 60% of patients have radiographic evidence of disease, especially enlargement of the inferior alveolar canal or foramen, or branching of the canal.

Neurofibromas may occur multiply as a feature of NF but only rarely undergo sarcomatous change [15]. Other rare malignant tumours include nerve sheath tumour [16], triton tumour [17] and Merkel cell carcinoma [18].

Xeroderma pigmentosum

Squamous cell carcinoma of the lip may arise in patients with xeroderma pigmentosum [1,2] and therefore it is crucial to institute sun protection. Oral retinoids such as etretinate or isotretinoin may be of prophylactic value [3,4]. Topical 5-fluorouracil or surgery may be used to treat potentially malignant lesions (see Actinic cheilitis, p. 66.115).

Mouth ulcers

The causes of mouth ulcers are diverse (Tables 66.10 & 66.13), partly because lesions such as vesicles rapidly break down in the mouth as a result of trauma, moisture and infection. Ulcers are usually caused by the following.

1 Local factors
2 Recurrent aphthous stomatitis
3 Neoplasms
4 Systemic conditions
  (a) Hematological
  (b) Gastroenterological
  (c) Dermatological
  (d) Infective
  (e) Vasculitis
  (f) Iatrogenic
  (g) Uncertain causes
5 Drugs.

Mouth ulcers of local aetiology

It is surprising that oral ulceration due to local factors is not more frequent. Accidental cheek biting or facial trauma may cause ulceration in any individual; the his-

Table 66.13 Causes of mouth ulcers (see also Table 66.10).

Local causes (e.g. trauma)
Recurrent aphthae (and Behçet's syndrome)
Malignant neoplasms
Ulcers associated with systemic disease
Drugs
Irradiation of the oral mucosa
Disorders of uncertain pathogenesis

tory is usually quite clear and a single ulcer of short duration (5–10 days) is present. Ulceration due to biting an anaesthetized lower lip or tongue following a dental local analgesic injection is a fairly common problem in young children.

Orthodontic appliances or, more commonly, dentures (especially if new) are responsible for many traumatic oral ulcers. These ulcers are usually clearly related to the appliance and have been a problem in the care of cleft-palate patients [1]. Chronic trauma may cause a well-defined ulcer with a whitish keratotic halo [2].

The possibility of some other aetiology for ulcers of apparently local cause should always be borne in mind. Child abuse may cause ulcers, especially over the upper labial fraena. Self-mutilation may be seen in some psychologically disturbed patients [3,4], patients with learning disability, individuals with sensory impairment, and in Lesch–Nyhan syndrome [5–9]. Oral purpura or ulceration may be seen on the lingual fraenum or palate due to cunnilingus or fellatio respectively [10]. Other local causes of ulceration include thermal burns, especially of the tongue and palate (e.g. 'pizza burn—now more common with microwave oven use'), chemical burns from the holding of medicaments or drugs (e.g. aspirin or cocaine) against the mucosa [11], and irradiation mucositis.

Prognosis. Most ulcers of local cause heal spontaneously within 7–14 days if the cause is removed.

Treatment. Maintenance of good oral hygiene and the use of hot saline mouthbaths and 0.2% aqueous chlorhexidine gluconate mouthwash aid healing. A 0.1% benzydamine mouthwash may help give relief. Occasionally, mechanical protection with a plastic guard may help [7].

Patients should be reviewed within 3 weeks to ensure healing has occurred. Any patient with a single ulcer lasting more than 2–3 weeks should be regarded with suspicion and investigated further, usually by biopsy—it may be a neoplasm or other serious disorder.

Eosinophilic ulcer [1–4]

SYN. TRAUMATIC EOSINOPHILIC GRANULOMA

Eosinophilic ulcer is a rare self-limiting disease that often appears on the tongue in older adults or children. Its aetiology remains obscure and may be associated with traumatic factors. Eosinophilic ulcers are unifocal, with a benign course. Pathological features show an extensive inflammatory cell infiltration, with predominantly eosinophilic cells throughout the submucosa. The peripheral blood eosinophil count is normal. Diagnosis and treatment is with either conservative excision or incisional biopsy.

Recurrent aphthous stomatitis

SYN. APHTHAE; CANKER SORES

Recurrent aphthous stomatitis (RAS) is characterized by recurring episodes of ulcers, typically from childhood or adolescence, each lasting from 1 to about 4 weeks before healing. Aphthae typically are multiple round or ovoid ulcers with a circumscribed margin, erythematous halo and a yellow or grey floor (Fig. 66.25). The term 'recurrent oral ulcer' is rather imprecise and should be avoided [1–4].

Aetiology. The aetiology of RAS is not clear. A positive family history is found with about one-third of patients and there is an increased frequency of human leukocyte antigens (HLA)-A2, HLA-A11, HLA-B12 and HLA-DR2, supporting a genetic basis for susceptibility in some patients [1–4].

There are identifiable predisposing factors in some patients (Table 66.14). A minority (about 10–20%) of patients attending outpatient clinics with RAS have an

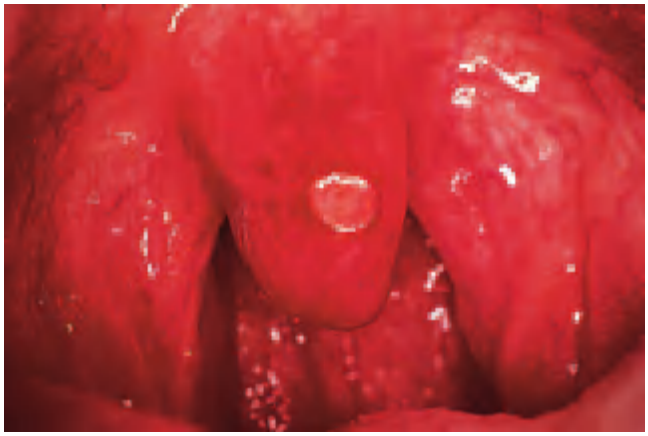

Fig. 66.25 Recurrent aphthae.

underlying haematological abnormality, usually a low serum iron or ferritin, or deficiency of folate or vitamin B_{12}. A few have multiple deficiencies [5,6]. Up to 3% of RAS patients have coeliac disease but in others a gluten-free diet is of no value [7]. Patients with deficiency states often, but not always, have gastrointestinal symptoms, and their RAS is often of recent onset. Other aetiological factors in RAS can include stress, trauma and cessation of tobacco smoking. Ulcers similar to aphthae are also seen in Behçet's syndrome; Sweet's syndrome; HIV infection, cyclic neutropenia and other immunodeficiencies; and, rarely, in children in association with fever and pharyngitis (periodic fever, aphthous stomatitis, pharyngitis and cervical adenitis; PFAPA) [8,9]. Orogenital ulceration with aphthae is probably a forme fruste of Behçet's syndrome.

There is no evidence that RAS is an autoimmune disease [1–4]. There is no known association with systemic autoimmune disorders, none of the common autoantibodies are found, and RAS tends to resolve or decrease spontaneously with increasing age. The serum immunoglobulin levels are usually normal, although IgA and IgG may be increased, and immune complexes may be found.

It now seems likely that there is a minor degree of immunological dysregulation underlying aphthae. Attempts to implicate a variety of viruses or bacteria in the aetiology of RAS have largely been unsuccessful, but there may be cross-reacting antigens between the oral mucosa and microorganisms such as *Streptococcus sanguis* or its L form, or heat-shock protein [10].

Cell-mediated immune mechanisms appear to be involved in the pathogenesis of RAS. In the lesions, helper T cells predominate early on, with some natural killer cells. Cytotoxic cells then appear and there is evidence for an antibody-dependent cellular cytotoxicity reaction [1–4].

Clinical features. RAS is a common disease that probably afflicts at least 20% of the population. There is a high prevalence in higher socio-economic classes.

There are three main clinical types of RAS. Most common are minor aphthous ulcers, which account for 80% of all RAS. Some 10% of patients with RAS have major aphthous ulcers, and a further 10% suffer from a herpetiform type of ulceration (Table 66.15).

Table 66.14 Systemic and other factors that may occasionally underlie or be associated with recurrent aphthous stomatitis (RAS).

	Comments
Behçet's syndrome	Association of RAS with ocular lesions, genital ulcers and multisystem disease
Sweet's syndrome	See Chapter 49
Haematinic deficiency	In some studies, 10–20% of patients with RAS have deficiencies of iron, folic acid or vitamin B_{12}
Gastrointestinal disease	Malabsorption states (pernicious anaemia, coeliac disease and Crohn's disease) may precipitate RAS in a small minority
Endocrine factors	In some women, RAS is clearly related to a fall in progestogens in the luteal phase of the menstrual cycle; hormone therapy may be beneficial
Immunodeficiency	A few patients with RAS have an immune defect such as human immunodeficiency virus disease
Other factors	Trauma, certain foods, stress and cessation of smoking may play a part

Table 66.15 Main features of recurrent aphthous stomatitis.

	Minor aphthae	Major aphthae	Herpetiform ulcers
Age of onset	Childhood or adolescence	Childhood or adolescence	Young adult
Ulcer size	2–4 mm	May be 10 mm or larger	Initially tiny but ulcers coalesce
Number of ulcers	Up to about 6	Up to about 6	10–100
Sites affected	Mainly vestibule, labial, buccal mucosa and floor of mouth; rarely dorsum of tongue, gingiva or palate	Any site	Any site but often on ventrum of tongue
Duration of each ulcer	Up to 10 days	Up to 1 month	Up to 1 month
Other comments	Most common type of aphthae	May heal with scarring	Affects females predominantly

Fig. 66.26 Major aphthous ulcers.

Minor aphthous ulcers (syn. Mikulicz ulcers). Minor RAS (MiRAS) occur mainly in the 10–40-year age group, and often cause minimal symptoms. MiRAS are usually 2–4 mm in diameter and found mainly on the non-keratinized mobile mucosa of the lips, cheeks and floor of the mouth, sulci or ventrum of the tongue. They are uncommon on the gingiva, palate or dorsum of the tongue. Only a few ulcers (one to six) appear at a time; they heal in 7–10 days and recur at variable intervals. MiRAS are usually round or ovoid, but are often more linear when in the buccal sulcus, a common site. The ulcer floor is initially yellowish but becomes greyish as epithelialization proceeds. There is an erythematous halo and some oedema but MiRAS heal with little or no evidence of scarring.

Major aphthous ulcers (syn. Sutton's ulcers). Previously known as periadenitis mucosa necrotica recurrens (PMNR), major RAS (MaRAS) are larger, recur more frequently, last longer and are more painful than MiRAS. They may reach a large size, even more than 1 cm in diameter. MaRAS are found on any area of the oral mucosa, including the dorsum of the tongue or palate. Usually only a few ulcers (one to six) occur at one time; they heal slowly over 10–40 days, and recur frequently. MaRAS are round or ovoid with an inflammatory halo, and may heal with scarring (Fig. 66.26). Occasionally, a raised erythrocyte sedimentation rate or plasma viscosity is found.

Herpetiform ulceration. Herpetiform ulceration (HU) is found in a slightly older age group and there is a female predominance. Herpetiform ulcers are often extremely painful and recur so frequently that ulceration may be virtually continuous. HU begins with vesiculation, which passes rapidly into multiple, minute (2 mm), discrete ulcers at any oral site. The ulcers increase in size and coalesce to leave large ragged ulcers that heal in 10 days or longer. Their similarity to herpetic stomatitis gives herpetiform ulcers their name, but there is no evidence that herpes simplex virus is involved.

Prognosis. RAS in most patients resolves or abates spontaneously with age. An underlying identifiable predisposing cause is particularly likely where RAS commences or worsens in adult life.

Diagnosis. Diagnosis is based on history and clinical features, since specific tests are unavailable. Biopsy is indicated only where some other cause of ulceration is suspected. To exclude relevant systemic predisposing factors it is often useful to perform:

- full blood count;
- haemoglobin assay;
- white cell count and differential;
- red cell indices;
- iron studies;
- red cell folate level;
- serum vitamin B_{12} measurements;
- serum antiendomysial antibodies.

The relevance of HLA studies for differentiating RAS from Behcet's syndrome is discussed on p. 66.46.

Management. Few patients have spontaneous remission until after several years and thus treatment is often indicated [11]. Fortunately, the natural history of RAS is one of eventual remission in most cases.

Predisposing factors should be corrected. If there is an obvious relationship to certain foods, the causal food should be excluded from the diet [12]. Good oral hygiene should be maintained: chlorhexidine or triclosan mouthwashes help achieve this and may help reduce ulcer duration [1–4].

Ulcer pain can usually be reduced, and the time to healing reduced, with hydrocortisone hemisuccinate pellets (Corlan) 2.5 mg or triamcinolone acetonide in carboxymethylcellulose paste (Adcortyl in Orabase) used four times daily; failing the success of these, a stronger topical corticosteroid (e.g. betamethasone, beclomethasone, fluticasone, mometasone) [13] or systemic corticosteroid (e.g. prednisolone) may be required (see Chapter 49).

Other therapies for RAS, such as sucralfate [14], colchicine and pentoxifylline (oxpentifylline), may have a role in individual cases but are not generally very effective or have adverse effects [3,15,16].

Thalidomide, in doses from 50 mg up to 300 mg daily, can frequently induce remission, especially in major aphthae, but its important teratogenic effects and the risk of neuropathy must be considered [17]. Topical tacrolimus may be effective but randomized trials are awaited.

There are multiple other therapies available for RAS, including carbenoxolone, benzydamine, dapsone, cromoglicate, levamisole and many others, but generally their

Behçet's syndrome

SYN. ADAMANTIADES SYNDROME

Definition. Behçet's syndrome (BS) is the association of RAS with genital ulceration and eye disease (especially iridocyclitis and retinal vasculitis) [1–5]. There may be a number of other systemic or cutaneous manifestations (Table 66.16).

Aetiology. The aetiology of BS is uncertain but it appears to be becoming more common. There is a genetic background and, as in RAS, there are occasional familial cases and associations with HLA types, in BS particularly with HLA-B5 (Bw51 split). HLA-B51 or its B101 allele is significantly associated with BS in Japan, Korea, Turkey and France, as well as with the ocular manifestations in Britain. The MICA6 allele, a member of the polymorphic MHC class I-related gene A (MICA) family, is thought to be in linkage disequilibrium with HLA-B51 and has been shown to be significantly associated with BS in Japan and France [6]. HLA-DR/DQ haplotypes are more important than individual HLA-DR and HLA-DQ phenotypes for the development of mucocutaneous type of BS and for disease shift from RAS to mucocutaneous type of BS [7].

The aetiopathogenesis of BS is still unclear [8,9]. It does not appear to be infectious, contagious or sexually transmitted. The disease is found worldwide but is most common in the eastern Mediterranean countries and eastern Asia, along the Silk Road taken by Marco Polo. In these countries, it is a leading cause of blindness though this is not the case in the Western world.

There are many immunological findings in BS:

- circulating autoantibodies against a number of components, including intermediate filaments found in mucous membranes, cardiolipin and neutrophil cytoplasm;

Table 66.17 Oculomucocutaneous syndromes.*

	Main lesions		
Disease	Oral and genital	Ocular	Skin
Behçet's syndrome	Aphthae	Uveitis	Erythema nodosum
Sweet's syndrome	Aphthae	Conjunctivitis, episcleritis	Inflamed papule or nodule
Erythema multiforme	Erosions	Erosions	Target lesions
Cicatricial pemphigoid	Bullae Erosions	Erosions Scarring	Occasional dome-shaped bullae
Pemphigus	Erosions	Erosions	Multiple, flaccid bullae
Reiter's syndrome	Ulcers	Conjunctivitis	Keratoderma blenorrhagica

* Ulcerative colitis, herpes simplex, syphilis, lupus erythematosus, mixed connective tissue disease and other disorders may also cause oral, cutaneous and ocular lesions.

• circulating immune complexes and changed levels of complement;
• immunoglobulins and complement deposition within and around blood vessel walls;
• decreased ratio of T-helper (CD4) cells to T-suppressor (CD8) cells.

These immunological changes mimic those seen in patients with RAS—various T-lymphocyte abnormalities (especially T-suppressor cell dysfunction), changes in serum complement and increased polymorphonuclear leukocyte motility. There is also evidence that mononuclear cells may initiate antibody-dependent cellular cytotoxicity to oral epithelial cells, and evidence of disturbance of natural killer cell activity.

The common denominator in all systems is vasculitis, usually leukocytoclastic vasculitis. Many of the features of BS (erythema nodosum, arthralgia, uveitis) are common to established immune complex disease and, indeed, immune complexes (usually antigen–antibody complexes) are found in the sera. The antigen responsible has not been reliably identified but may include herpes simplex virus or streptococcal antigens [10–12]. As in RAS, heat-shock proteins have been implicated.

Clinical features. BS is a chronic multisystem disorder, most patients being male, usually in their third or fourth decade.

Because BS is rare and symptoms of the disease overlap symptoms of other diseases, it can be very difficult to diagnose. Spontaneous remission is common for patients with BS; this can add to the difficulty in diagnosis.

BS is characterized mainly by a triad of RAS [13,14], genital ulcers [15,16] and ocular lesions. The CNS, heart and intestinal tract may be involved.

One variant of BS (MAGIC syndrome) is associated with *m*outh *a*nd *g*enital ulcers and *i*nflamed *c*artilage [17]. Other oculomucocutaneous syndromes (Table 66.17) may cause similar manifestations [18,19].

Diagnosis. BS is usually diagnosed on clinical grounds, although findings of HLA-B5101 and pathergy are supportive, as are antibodies to cardiolipin and neutrophil cytoplasm. Disease activity may be assessed by serum levels of acute phase proteins or antibodies to intermediate filaments, or by erythrocyte sedimentation rate; all are raised in active BS.

Differential diagnosis is mainly from the following.
• Sweet's syndrome: aphthae, conjunctivitis, episcleritis, inflamed tender papule or nodule.
• Erythema multiforme: erosions, target (iris) lesions.
• Pemphigoid: bullae, erosions.
• Pemphigus: erosions, multiple flaccid bullae.
• Reiter's syndrome: ulcers, conjunctivitis, keratoderma blenorrhagica.
• Ulcerative colitis.
• Herpes simplex.
• Syphilis.
• Lupus erythematosus.
• Mixed connective tissue disease.

The diagnosis is often made on the basis of RAS plus two or more of recurrent genital ulceration, eye lesions, skin lesions and pathergy [20,21].

Major criteria include:
1 RAS: in 90–100% of cases.
2 Recurrent painful genital ulcers that tend to heal with scars in 64–88% of cases. Genital ulcers are especially common in females with BS, and resemble RAS.
3 Ocular lesions: uveitis with conjunctivitis (early) and hypopyon (late), retinal vasculitis (posterior uveitis), iridocyclitis and optic atrophy. The most common ocular manifestation is relapsing iridocyclitis but uveitis, retinal vascular changes and optic atrophy may occur. Both eyes are eventually involved and blindness may result.
4 CNS lesions: meningoencephalitis, cerebral infarction, psychosis, cranial nerve palsies, cerebellar and spinal cord lesions, hemiparesis and quadriparesis.
5 Skin lesions: erythema nodosum, papulopustular lesions and acneform nodules. Venepuncture is, in some patients, followed by pustulation (pathergy).

Minor criteria are:

1 Arthralgia: large joint arthropathies that are subacute, non-migratory, self-limiting and non-deforming.
2 Superficial or deep migratory thrombophlebitis, especially of lower limbs.
3 Intestinal lesions: inflammatory bowel disease with discrete ulcerations.
4 Lung involvement: pneumonitis.
5 Haematuria and proteinuria.

However, very non-specific signs and symptoms, which may be recurrent, may precede the onset of the mucosal membrane ulceration by 6 months to 5 years. These include malaise, anorexia, weight loss, generalized weakness, headache, perspiration, decreased or elevated temperature, lymphadenopathy and pain in the substernal and temporal regions.

A history of repeated sore throats, tonsillitis, myalgias and migratory erythralgias without overt arthritis is also common.

Management. Unlike RAS, BS is not self-limiting. It causes morbidity (especially in terms of ocular and neurological disease) and mortality. Most patients present with oral and ocular disease but there follows a relapsing and remitting but variable course. CNS involvement, thromboses of major vessels and gastrointestinal perforation result in a poor prognosis. Few patients with BS have spontaneous remission and thus treatment is indicated [22,23].

Chronic morbidity is usual; the leading cause is ophthalmic involvement, which can result in blindness. The effects of the disease may be cumulative, especially with neurological, vascular and ocular involvement. Mortality is low but can occur from neurological involvement, vascular disease, bowel perforation, cardiopulmonary disease or as a complication of immunosuppressive therapy. In the face of the serious potential complications, patients with suspected BS should be referred early for specialist advice.

Topical treatment for RAS (see p. 66.45). Oral ulcers may respond to topical corticosteroids or 5-aminosalicylic acid [24]. Even nicotine patches may have some success [25].

Systemic treatment includes mainly colchicine 0.5–1.5 mg daily.

Other systemic treatments include corticosteroids, azathioprine, ciclosporin, chlorambucil, cyclophosphamide, dapsone, interferon-alpha, levamisole or thalidomide. Ocular lesions usually respond to ciclosporin, but tend to relapse when treatment is stopped. Thalidomide at a dose of up to 400 mg daily may be of value in recalcitrant orogenital ulceration, although it must be used with caution as it is teratogenic and carries a risk of neuropathy [26,27].

Sweet's syndrome (see Chapter 49)

Pustular lesions leading to aphthous-like ulcers may be

found in Sweet's syndrome and there are occasional associations with BS and Sjögren's syndrome, each of which has oral manifestations. About 5% of patients in the UK with Sweet's syndrome have oral aphthae, although up to 30% of Japanese patients suffer aphthae [1–3].

Malignant neoplasms

More than 90% of malignant neoplasms in the mouth are squamous cell carcinomas. Nearly 30% of all squamous cell carcinomas affect the lip; some 25% affect the tongue, the most common intraoral site [1–5]. Most intraoral cancers involve the posterolateral border of the tongue and/or the floor of the mouth (the 'graveyard' area).

Oral cancer is a significant world health problem, being overall the sixth most common malignant neoplasm. In parts of South-East Asia for example, particularly India, some 40% of all malignancy is oral cancer. High levels are also seen in other parts of the developing world such as Brazil, but also in parts of Europe such as areas of northern France and eastern Europe.

Oral squamous cell carcinoma

Cancer of the oral cavity is classified according to site:
- lip (International Classification of Diseases [ICD] 140);
- tongue (ICD 141);
- gum (ICD 143);
- floor of the mouth (ICD 144); and
- unspecified parts of the mouth (ICD 145).

Carcinoma of the lip

Squamous carcinoma is the commonest malignancy to affect the vermilion zone and, as with squamous carcinoma of the glabrous skin, it is usually due to actinic damage [1]. Like actinic cheilitis it is most common on the lower lip of fair-skinned, outdoor workers in sunny climates, and is relatively rare in pigmented skin [2–4]. Lip cancer is common in certain population groups in the UK, Romania, Hungary, Poland, Spain, Finland, Israel, Canada, the USA and Australia, but in most areas reported the incidence is falling [4–7].

Lip cancer generally occurs in men who are employed in outdoor activities such as farming and fishing [8]. Squamous cell carcinomas occur on the lower lip in 89%, with 3% on the upper lip and 8% at the commissures [9]. Although sunlight is accepted as the major aetiological factor, some studies have shown a poor correlation between the incidence of lip cancer and the rate of annual solar radiation [10]. *Actinic radiation* may predispose to lip cancer. Facts that support such a relationship include the following.
- Lip cancer involves the more exposed lower lip, rather than the upper lip.
- There is a higher incidence of lip cancer in outdoor workers and rural populations than in office workers or urban populations.
- Fair-skinned more than dark-skinned people tend to develop lip cancer (as well as skin cancer and melanoma) in sunny climates.

Other risk factors may include low social class, tobacco smoking, syphilis, poor dentition, infection with herpes simplex virus [3,5,8] and immune suppression [11]; for example lip cancer is increased in immunosuppressed renal transplant recipients.

The initial features are a keratinous growth or swelling of the lip (Fig. 66.27), soreness and ulceration. Most lesions are amenable to surgical excision, with more than 70% surviving for 5 years.

Intraoral carcinoma

Most intraoral carcinoma is squamous cell carcinoma [1–3]. In many countries there is evidence for an increase in oral squamous cell carcinoma (OSCC) over recent years [4–7], especially in young persons. There is marked inter-country variation in both the incidence of, and mortality from, OSCC [8]. In addition, there is also growing evidence of intra-country ethnic differences in incidence and mortality, especially in the UK and USA.

In the developing world, particularly South-East Asia and Brazil, the incidence of OSCC varies widely in different areas and there are ethnic differences in incidence, often attributed to lifestyle habits.

In the developed world OSCC is uncommon. The incidence varies between countries and between different regions of the same country. For example, parts of France and Newfoundland have the highest incidence in the West, with about 10 times the incidence of oral carcinoma in the UK. Oral cancer is more than twice as common in Scotland than in England and Wales and, for example, even within Scotland there are regional differences.

Potentially malignant states. Some potentially malignant (precancerous) lesions that can progress to OSCC include especially [9] *erythroplasia* (erythroplakia), the most likely lesion to progress to severe dysplasia or carcinoma (see p. 66.96); and *leukoplakia* (see p. 66.85), particularly proliferative verrucous leukoplakia, sublingual leukoplakia, candidal leukoplakia and syphilitic leukoplakia.

Some other potentially malignant (precancerous) conditions include:

- lichen planus—there are also cases of dysplasia with a lichenoid appearance (lichenoid dysplasia);
- discoid lupus erythematosus;
- submucous fibrosis;
- atypia in immunocompromised patients;
- dyskeratosis congenita;
- Paterson–Kelly syndrome (sideropenic dysphagia, Plummer–Vinson syndrome).

One of the main features that appears to precede the onset of malignancy is epithelial dysplasia, although dysplasia can also be seen in regenerating tissue and some non-precancerous lesions such as ulcers, viral infections, candidal infections and granular cell tumours.

Dysplasia varies in severity, and it is the more severe grades that are associated with higher malignant potential.

Predisposing factors (risk factors) [1–3,10–13]. In the developed world, OSCC is seen especially in tobacco users, alcohol users, lower socio-economic groups and ethnic minority groups.

In the developing world, OSCC is seen especially in tobacco users, alcohol users, 'betel quid' users (some 20% of the world's population use betel) and lower socio-economic groups. In peoples from parts of Asia, tobacco-chewing, along with a variety of ingredients in 'betel quid' (betel vine leaf, betel [areca] nut, catechu, slaked lime, together with tobacco), appears to predispose to OSCC, particularly when it is started early in life and is used frequently and for prolonged periods. Various other risky chewing habits, usually containing tobacco, are used in different cultures (e.g. khat, shammah, toombak).

Microorganisms such as *Candida* and human papillomavirus (HPV) have been detected in some potentially malignant lesions and some OSCC, where they may play a role. HPV is especially implicated in tonsillar carcinoma; HPV-16 is particularly implicated.

In contrast, diets rich in fresh fruits and vegetables and vitamin A may have a protective effect.

Clinical features. OSCC may present as the following [1–3] (Fig. 66.28).

Fig. 66.28 Oral squamous cell carcinoma.

Table 66.18 TNM classification of malignant neoplasms.*

Primary tumour size (T)	
Tx	No available information
T_0	No evidence of primary tumour
T_{is}	Only carcinoma *in situ*
T_1, T_2, T_3, T_4	Increasing size of tumour†
Regional lymph node involvement (N)	
Nx	Nodes could not or were not assessed
N_0	No clinically positive nodes
N_1	Single clinically positive homolateral node less than 3 cm in diameter
N_2	Single clinically positive homolateral node 3–6 cm in diameter, or multiple clinically positive homolateral nodes, none more than 6 cm in diameter
N_{2a}	Single clinically positive homolateral node 3–6 cm in diameter
N_{2b}	Multiple clinically positive homolateral nodes, none more than 6 cm in diameter
N_3	Massive homolateral node(s), bilateral nodes, or contralateral node(s)
N_{3a}	Clinically positive homolateral node(s), one more than 6 cm in diameter
N_{3b}	Bilateral clinically positive nodes
N_{3c}	Contralateral clinically positive node(s)
Involvement by distant metastases (M)	
Mx	Distant metastasis was not assessed
M_0	No evidence of distant metastasis
M_1, M_2, M_3	Distant metastasis is present. Increasing degrees of metastatic involvement, including distant nodes

* Several other classifications are available, e.g. STNM (S, site).
† T_1, maximum diameter 2 cm; T_2, maximum diameter 4 cm; T_3, maximum diameter > 4 cm; T_4, massive tumour > 4 cm diameter, with involvement of antrum, pterygoid muscles, base of tongue or skin.

- A red lesion (erythroplasia).
- A granular ulcer with fissuring or raised exophytic margins.
- A white or mixed white and red lesion.
- A lump sometimes with abnormal supplying blood vessels.
- An indurated lump/ulcer, i.e. a firm infiltration beneath the mucosa.
- A non-healing extraction socket.
- A lesion fixed to deeper tissues or to overlying skin or mucosa.
- Cervical lymph node enlargement, especially if there is hardness in a lymph node or fixation.

Enlarged nodes in a patient with oral carcinoma may be caused by infection, reactive hyperplasia secondary to the tumour, or metastatic disease. Occasionally, a swollen lymph node is detected in the absence of any obvious primary tumour.

In patients with OSCC for over 3 years, second primary neoplasms in the aerodigestive tract may be seen in up to 25% and in up to 40% of those who continue to smoke.

Diagnosis. Early diagnosis is important since it improves prognosis and minimizes the extent of interventions [14–16]. There should be a high index of suspicion, especially of a solitary lesion present for over 3 weeks: biopsy is invariably indicated. Clinicians should be aware that single ulcers, lumps, red patches or white patches, particularly if any of these persist for more than 3 weeks, may be manifestations of frank malignancy. Scalpel biopsy is required and toluidine blue staining may help highlight the most appropriate area for biopsy [17–19].

The whole oral mucosa should be examined as there may be widespread dysplastic mucosa ('field change') or even a second neoplasm and the cervical lymph nodes must be examined. Frank tumours should be inspected and palpated to determine extent of spread; for tumours in the posterior tongue, examination under general anaesthesia may facilitate this.

OSCC should be staged according to the TNM classification of the International Union against Cancer, where T represents tumour size, N nodal metastases and M distant metastases (Table 66.18), since this classification relates well to overall survival rate, i.e. the earlier the tumour, the better the prognosis and the less complicated the treatment.

Investigations. The principles include the following.

1 Confirm the diagnosis histopathologically and determine the presence of malignant disease elsewhere.

(a) Are bone, muscles or cervical lymph nodes involved?

(b) Are there other primary tumours (typically in the upper aerodigestive tract—mouth, nares, pharynx, larynx, oesophagus)? There is controversy as to the need for endoscopy in all cases to detect such tumours.

(c) Are there metastases, initially to regional lymph nodes and later to liver, bone and brain? Imaging may detect abnormalities that escape clinical examination.

2 Ensure that the patient is as prepared as possible for the major surgery required, particularly in terms of general anaesthesia, potential blood loss and ability to metabolize drugs.
3 Address any potential dental or oral problems preoperatively, to avoid later complications such as osteoradionecrosis.

The following investigations are therefore almost invariably indicated.

- Lesional biopsy. Incisional biopsy, which is invariably required, should be sufficiently large to include enough suspect and apparently normal tissue. Red, rather than white, areas are most likely to show dysplasia, and hence should be biopsied. Attempts to highlight probable dysplastic areas before biopsy, for example by using toluidine blue dye, are unfortunately not reliable, but may be of some help in deciding which area is best to biopsy where there is widespread 'field change'. An excisional biopsy should be avoided unless the lesion is extremely small, since this is unlikely to have excised an adequately wide margin of tissue if the lesion is malignant, but will have destroyed for the surgeon or radiotherapist clinical evidence of the site and character of the lesion.
- Biopsy of equivocal neck lymph nodes.
- Jaw radiography (often rotating pantomography), although this is inadequate to exclude bone invasion.
- Chest radiography: important as a pre-anaesthetic check, especially in patients with known pulmonary or airways disease, and to demonstrate metastasis to lungs or hilar lymph nodes, ribs or vertebrae.
- MRI or computed tomography (CT) of the primary site, head and neck, and suspected sites of distant metastases, and MRI of the neck to delineate the extent of cervical node metastases. Some units routinely examine chest and abdomen. MRI is particularly useful for determining tumour spread, bone involvement and nodal metastases.
- Electrocardiography.
- Blood tests.
- Full blood picture and haemoglobin.
- Blood for grouping and cross-matching.
- Urea and electrolytes.
- Liver function tests.

In selected cases, the following may also be useful.

- Bronchoscopy: if chest radiography reveals any lesions.
- Endoscopy of the upper aerodigestive tract: especially if there is a history of tobacco use.
- Gastroscopy: if a per-endoscopic gastrostomy is to be used for feeding.
- Liver ultrasound: if there is hepatomegaly or abnormal liver function.
- Doppler duplex flow studies: in planning radial free forearm flaps.
- Angiography: in planning lower limb free flaps.

Treatment. The prognosis of OSCC is around 30% survival at 5 years [20]. The major impact that treatment has had on the prognosis of oral cancer has been in relation to improved anaesthetic and medical care. Surgical reconstruction has also been markedly improved [21] and there are fewer side effects from modern radiotherapy.

The treatment of oral cancer involves one or a combination of radiotherapy, surgery and, very occasionally, chemotherapy. Serious consideration must be given to the complications of the various modalities [22,23] and the quality of life achieved [24,25].

There is now evidence that vitamin A derivatives may be of benefit in patients with premalignant lesions, and in preventing second primary neoplasms [26–27].

Verrucous carcinoma

Verrucous carcinoma is an uncommon, warty, white neoplasm that is rarely ulcerated [1–4]. It may develop from proliferative verrucous leukoplakia (see p. 66.86). Risk factors include a possible association with HPV and some verrucous carcinoma develops as a result of the local use of snuff or tobacco. Confirmation of diagnosis by biopsy is particularly important because verrucous carcinoma responds well to excision but, if irradiated, may undergo anaplastic change, with subsequent acceleration of growth and invasiveness [5]. Methisoprinol may be of value [6].

Florid oral papillomatosis

Florid oral papillomatosis is a rare but well-defined clinical entity of unknown pathogenesis. Risk factors include possible association with HPV, tobacco, and chronic inflammation or irritation.

Florid oral papillomatosis is essentially a verrucous carcinoma, a clinicopathological variant of squamous cell carcinoma also known by a confusing array of names such as Ackerman's tumour, Buschke–Loewenstein tumour, epithelioma cuniculatum, carcinoma cuniculatum and cutis papillomatosis carcinoides of Gottron.

Clinical features. The lesions are exuberant, warty or verrucous, and characterized by their benign appearance on histology, although this is usually associated with a marked capacity for recurrence and and a tendency for carcinomatous change. Its apparent clinical benignity may lead to lengthy periods of misdiagnosis, during which it slowly but relentlessly destroys and extends into underlying tissue but rarely metastasizes to lymph nodes [1–3].

Diagnosis. Biopsy is required, although to those unfamiliar with the diagnosis the relatively bland histological features are often more suggestive of verruca vulgaris or pseudoepitheliomatous hyperplasia than of squamous cell carcinoma. Alternatively, when it extends into underlying tissues, it may be mistaken for a benign adnexal tumour or even a cyst.

Management. Treatment in the early stage of the disease is usually successful. Etretinate therapy (200 mg/day) or chemotherapy with bleomycin may reduce the lesion bulk [4–6]. Surgical or laser excision is favoured. The use of radiotherapy is controversial since in numerous reported cases this has produced an anaplastic squamous cell carcinoma.

Basal cell carcinoma

Actinic radiation is a major aetiological factor in the development of basal cell carcinoma (BCC), greater than 85% occurring on the sun-exposed areas of the head and neck [1]. Fair-skinned individuals who burn and those whose occupations require excessive exposure to sunshine are at greatest risk; the tumour is rare in dark-skinned persons, and 95% occur after the age of 40 years [2].

Other significant risk factors for the development of BCC include prior burns, vaccinations, irradiation, exposure to inorganic arsenic, genetic syndromes (e.g. xeroderma pigmentosum, naevoid BCC syndrome, albinism and Bazex's syndrome) and immunosuppression [3–8].

Clinical features. On the lip these manifest as a pearly, sometimes ulcerated, nodule or papule. Unlike squamous cell carcinomas, BCCs only rarely originate on the vermilion but commonly occur periorally [9–11]. In contrast to squamous cell carcinomas, BCCs more commonly arise on

the upper than the lower lip. The lesions can also arise *de novo* on the vermilion [12] or occasionally the mucosa of the lip, although spread of a tumour from an adjacent site may rarely occur.

BCC has multiple forms that can be simplistically divided as follows.

- Nodular: the most frequent type around the lips presents as a waxy translucent nodule with fine telangiectasias, often ulcerated.
- Morphoeic: an atrophic plaque resembling a scar, with an aggressive infiltrative growth pattern and high rate of recurrence after excision.
- Superficial: appears as an erythematous plaque with elevated borders and central atrophy or ulceration. It is rare around the lips.

Although the tumour rarely metastasizes, it is responsible for considerable functional and cosmetic morbidity.

Multiple lesions are commonly encountered and the various forms have overlapping clinical features. BCC can be frequently pigmented, resembling melanomas and other melanocytic lesions. BCC may of course be a feature of naevoid BCC syndrome (Gorlin–Goltz syndrome, see p. 66.39). Furthermore, in addition to having a significantly increased risk for new skin cancers, patients with BCC have been shown to have an increased risk of developing non-cutaneous cancers, including respiratory cancers, testicular cancer, breast cancer and non-Hodgkin's lymphoma [13,14].

Diagnosis. BCC of the lips must be differentiated from other nodules, including squamous cell carcinoma, keratoacanthoma, trichoepithelioma and sebaceous adenoma. Since lesions that arise periorally are often aggressive, and early detection and confirmation by biopsy will prevent infiltration and destruction of the underlying structures.

Management. Various treatment modalities for BCC include scalpel, electrosurgery, cryosurgery and laser surgery, radiation, curettage and intralesional chemotherapy. Selection of the treatment modality depends on size, site and histological pattern of the tumour as well as the age of the patient. Since lip lesions are often of the nodular or morphoeic types, Mohs' micrographic surgery, utilizing microscopically controlled excision, potentially offers the highest cure rate with the greatest preservation of tissue. The cure rate for BCC is over 90% [15].

Keratoacanthoma

Keratoacanthoma is a benign, often rapidly growing lesion that probably arises from the supraseboglandular part of a sebaceous gland. Keratoacanthomas are common, self-limiting, proliferative tumours that arise most frequently in men after the sixth decade of life [1,2].

The lesions mimic squamous cell carcinoma both clinically and microscopically. Although some believe keratoacanthomas represent well-differentiated squamous cell carcinomas, significant differences between the two entities have been demonstrated [3]. A number of well-documented variants, many with generally distributed eruptive keratoacanthomas, have been described. One variant, Ferguson–Smith syndrome, is a familial trait.

Aetiology. The role of actinic damage is strongly supported by the fact that the majority of lesions occur on sun-exposed skin (90%), with up to 10% occurring periorally or on the vermilion border of the lips. HPV has also been suggested as an aetiological agent [4], and increased numbers of keratoacanthomas have been reported in immunocompromised patients.

Clinical features. Keratoacanthomas often manifest at the vermilion border, as indurated dome-shaped nodules displaying a characteristic central, keratin-filled, crusted and frequently darkened crater. Cutaneous lesions are asymptomatic but oral and lip lesions are frequently painful [5–7]. Intraoral keratoacanthomas are rare [8,9]. They usually appear as an ulcer with a rolled margin, clinically indistinguishable from squamous cell carcinoma, usually on the anterior or maxillary gingiva. It is unclear whether intraoral keratoacanthomas regress

spontaneously, as all have been excised for diagnosis. Keratoacanthomas grow rapidly, attaining a size typically greater than 1 cm, may be locally invasive and result in significant tissue damage but, if left untreated, many undergo spontaneous involution after 1–2 months.

Diagnosis. Keratoacanthomas require differentiation from squamous cell carcinoma. When lesions develop intraorally or on the lips, they should immediately be subjected to biopsy for confirmation, since squamous cell carcinomas at these sites frequently metastasize.

Management. Management is often by surgical excision. Intralesional therapy with methotrexate or 5-fluorouracil can also be employed with excellent results. Other suggested medical therapies include intralesional interferon alpha-2a and systemic isotretinoin [10–12].

Other oral malignant primary neoplasms

The following comprise up to 10% of all oral malignant tumours.

1 Salivary gland tumours.
2 Malignant melanoma.
3 Lymphomas: non-Hodgkin's lymphomas are increasingly seen in the fauces in HIV disease and immunocompromised persons.
4 Sarcomas.
5 Kaposi's sarcoma: oral Kaposi's sarcoma is typically seen in HIV disease or other immunocompromised persons and especially in the posterior palate as a brown or purple macule that becomes nodular and ulcerates.
6 Some odontogenic tumours.
7 Maxillary antral carcinoma (or other neoplasms).
8 Langerhans' cell histiocytosis.
9 Neoplasms of bone and connective tissue.
10 Other neoplasms.

Abrikossoff's tumour

Abrikossoff's tumour is a disease that develops between the second and sixth decades of life, more frequently among women and blacks. The head and neck area is affected in 45–65% of cases and, of these, 70% are located intraorally (tongue, oral mucosa, hard palate) [1].

The benign form shows polygonal cells with granular eosinophilic cytoplasm and small nuclei. The malignant form, however, is associated with a high mitotic index and pleomorphic cellular tissue.

The clinical feature of either is a swelling covered by mucosa of normal clinical appearance. Histological examination is required. The treatment is surgery.

REFERENCE

1 Becelli R, Perugini M, Gasparini G, Cassoni A, Fabiani F. Abrikossoff's tumor. *J Craniofac Surg* 2001; **12**: 78–81.

Metastatic oral neoplasms

Metastases to the oral tissues are rare, accounting for only 1% of all oral tumours and most appear in bone, especially the mandibular premolar or molar area or condyle. Most oral metastases originate from carcinomas of breast, lung, kidney, thyroid, stomach, liver, colon or prostate [1–10].

Metastases may present with pain, paraesthesia, sensory loss, loosening of teeth, delayed healing of an extraction wound or pathological fracture. Metastases may occasionally appear as an alveolar or gingival swelling or ulcer.

Tumour deposits arise from lymphatic or haematogenous spread.

Clinical features. Metastases usually present as a lesion arising in the jaw, sometimes only revealed coincidentally by imaging, at other times causing symptoms. In up to one-third of patients the jaw lesions are the first manifestation of the tumour. Non-Hodgkin's lymphomas are frequently gingival or faucial in location.

Many metastases are asymptomatic but others manifest with:

- pain;
- paraesthesia or hypoaesthesia;
- swelling;

- tooth mobility;
- non-healing extraction sockets;
- pathological fracture;
- radiolucency or radio-opacity.

Diagnosis. Diagnosis is from history and clinical features supplemented by radiography and histopathology.

Treatment. Radiotherapy, surgery or chemotherapy.

Ulcers in association with systemic disease

Aphthae (see p. 66.43) are occasionally associated with systemic disease. However, a wide range of systemic diseases, especially haematological, gastrointestinal and dermatological disorders, may cause other oral lesions which, because of the moisture, trauma and infection in the mouth, tend to break down to leave ulcers or erosions. Oral ulceration is also frequently caused by infections and can be caused by iatrogenic problems such as drugs or irradiation (see Table 66.13).

Haematological diseases

Deficiency states

Low iron, folate or vitamin B_{12} levels may predispose to aphthae. A few of these patients also have anaemia, sometimes with other oral features such as glossitis or angular stomatitis, but many have a deficiency state with no established anaemia [1,2]. Occasionally, patients with deficiency of B vitamins may develop other types of oral ulcer, and sometimes epithelial dysplasia [3].

Leukopenias and agranulocytosis

White cell dyscrasias and HIV infection are also often complicated by oral ulceration (Fig. 66.29). Oral ulceration may be a major symptom in patients with leukopenias, and may be the first manifestation of drug-induced agranulocytosis. Painful, deep, irregular ulcers, often with only a minimal inflammatory halo, involve the mouth and/or pharynx and tend to extend and penetrate slowly. In cyclic neutropenia, ulcers appear episodically at 21-day intervals in association with the neutropenic episodes. Severe periodontitis is often also a feature of leukocyte and other immune defects and the patients may suffer from recurrent infections elsewhere [1–3]. Methotrexate can cause oral ulceration in the absence of leukopenia.

Fig. 66.29 Aphthous-like ulceration in HIV disease.

Fig. 66.30 Herpes simplex lingual recurrence, and candidiasis in leukaemia: similar lesions may be seen in HIV infection.

Leukaemias

Oral ulceration may be a prominent feature, especially in the acute leukaemias. Other oral manifestations of leukaemia include mucosal pallor, gingival haemorrhage, gingival swelling, petechiae and ecchymoses [1–4]. Oral infections with *Candida albicans* and Gram-negative bacteria including *Pseudomonas* species, *Escherichia coli*, *Proteus*, *Klebsiella* and *Serratia* species are common, especially in acute leukaemias, and may act as a portal for septicaemia [5]. Herpes simplex or zoster–varicella virus ulcers are also common (Fig. 66.30). Chemotherapy complicates the situation because it too can produce oral ulceration [1,6].

Other findings include paraesthesia (particularly of the lower lip), extrusion of teeth or bone, painful swellings over the mandible and parotid swelling (Mikulicz's syndrome) [7].

Granulocytic sarcoma

SYN. CHLOROMA

Granulocytic sarcomas are rare in the oral cavity. Most present with swelling or symptoms related to skeletal involvement [1–3]. The maxilla is particularly involved [1,4].

Lymphomas

Some 2–10% of lymphomas present first in the oral cavity. Of these oral lymphomas, 80% are composed of follicular centre cells or post-follicular cells [1–5]. Lymphomas usually occur on the pharynx or palate, but occasionally on the tongue, gingivae or lips; they may appear as oral swellings, which sometimes ulcerate and may cause pain or sensory disturbance. Oral herpes zoster and herpes simplex infections are common in patients with lymphomas.

There is an increased incidence of oral lymphomas in HIV disease [6] including oral plasmablastic lymphomas [7,8].

Lethal midline granuloma. Lethal midline granuloma is the term sometimes used to include a spectrum of conditions including Wegener's granulomatosis, polymorphic reticulosis (lymphomatoid granulomatosis) and idiopathic midline destructive disease.

Wegener's granulomatosis. Although not a lymphoma, Wegener's granulomatosis is discussed here. Oral manifestations are common and may be the first sign of Wegener's granulomatosis [9–20]. A painless progressive

swelling of the gingiva in a previously healthy mouth, particularly associated with swollen inflamed papillae, should arouse suspicion of Wegener's granulomatosis. The gingival enlargement may have a fairly characteristic 'strawberry-like' appearance. Wegener's granulomatosis may also present with oral ulceration, failure of an extraction socket to heal or occasionally swelling of the lip or salivary gland.

Polymorphic reticulosis (syn. lymphomatoid granulomatosis). The most common oral presentation of polymorphic reticulosis is palatal ulceration but ulceration may occur elsewhere [17].

Idiopathic midline destructive disease [21–23]. Downward spread from nasal disease can lead to palatal necrosis and ulceration in idiopathic midline destructive disease. Occasionally the disease presents with delayed healing of an extraction socket.

Pseudolymphoma

Rare tumour-like lymphoproliferative infiltrates that lack the malignant potential of lymphomas may be seen intraorally, notably in the palate [1].

REFERENCE

1 Wright JM, Dunsworth AR. Follicular lymphoid hyperplasia of the hard palate: a benign lymphoproliferative process. *Oral Surg* 1983; **55**: 162–8.

Histiocytoses

The histiocytoses typically produce lytic bone lesions but gingival swelling, periodontal destruction with loosening of teeth, non-healing extraction sockets and mouth ulceration may be seen. ^{111}In-pentetreotide imaging may be useful in diagnosis of Langerhans' cell histiocytosis [1–7].

Multicentric reticulohistiocytosis

Oral lesions are seen in up to 50% of patients with multicentric reticulohistiocytosis [1]. Lesions are collections of histiocytes that form nodular or granular lesions, particularly in the labial or buccal mucosa. The temporomandibular joint may also be involved as part of the polyarthropathy.

REFERENCE

1 Katz RW, Anderson KF. Multicentric reticulohistiocytosis. *Oral Surg* 1988; **65**: 721–5.

Hypereosinophilic syndrome

Oral erosions affecting buccal, gingival or labial mucosae may be a feature of the hypereosinophilic syndrome [1–4] and may herald cardiac involvement [2]. Etoposide therapy may be effective [4].

Hypoplasminogenaemia

Gingival swelling and ulceration are features of hypoplasminogenaemia [1].

REFERENCE

1 Scully C, Gokbuget AY, Allen C *et al*. Oral lesions indicative of plasminogen deficiency (hypoplasminogenemia). *Oral Surg Oral Med Oral Pathol Oral Radiol Endod* 2001; **91**: 334–7.

Gastrointestinal diseases

Aphthae in gastrointestinal diseases are discussed on p. 66.45. Other types of mouth ulcer are also sometimes found in ulcerative colitis and Crohn's disease.

Pyostomatitis vegetans

The oral lesions termed pyostomatitis vegetans are deep fissures, pustules and papillary projections. Less than 50 cases have been recorded and most patients have had inflammatory bowel disease, i.e. ulcerative colitis or Crohn's disease [1–12]. The course of these lesions tends to follow that of the associated bowel disease [1–5].

Although the oral lesions may respond at least partially to topical therapy (e.g. corticosteroids), systemic treatment is often needed [1–5,12].

Orofacial granulomatosis (OFG)

Aetiology. Crohn's disease can affect the mouth but some patients appear to develop similar oral lesions because

of an adverse reaction to various food additives, such as cinnamaldehyde or benzoates, butylated hydroxyanisole or dodecyl gallate (in margarine), or to menthol (in peppermint oil) or cobalt, although these reactions are by no means always relevant [1–15]. For example, the lesions in only one of nine patients in one study had any relationship to food intake [15]. The genetic background [16], any role of allergy [17] and diverse possible other aetiological factors such as *Mycobacterium paratuberculosis* [18] is unclear.

The term 'orofacial granulomatosis' is preferred in some centres since it is unclear where in the spectrum of Crohn's disease/sarcoidosis/allergy/infection these lesions (and related conditions such as Melkersson–Rosenthal syndrome and granulomatous cheilitis) lie [8,19–21].

Pathology. Non-caseating granulomas and lymphoedema may be seen but the granulomas tend to be sparse and deep, close to the muscle.

Clinical features. Ulcers classically involve the buccal sulcus where they appear as linear ulcers, often with granulomatous masses flanking them.

Mucosal lesions also include thickening and folding of the mucosa to produce a 'cobblestone' type of appearance and mucosal tags. Purple granulomatous enlargements may appear on the gingiva. The lips or face may swell and there may be splitting of the lips and angular stomatitis [22,23].

Diagnosis. The oral history is not specific, and investigation of the gastrointestinal tract is mandatory. Investigations such as chest radiography, serum angiotensin-converting enzyme and a gallium scan may be required to exclude sarcoidosis. Patch tests may be indicated to exclude reactions to various foodstuffs or additives.

Treatment. Elimination diets may be warranted in patients with OFG if allergy is suspected [11]. Topical or intralesional corticosteroids may effectively control the oral lesions [6]. Intralesional corticosteroid injections may also reduce the swelling. The injection of up to 10 mL triamcinolone (10 mg/L) into the lips after local analgesia may be effective [15,24–26]. The injections may have to be repeated every 4–6 months once a response plateau has been reached. Systemic corticosteroids are rarely indicated and in any event not all patients respond [26]. Metronidazole may be of value in some cases [3].

Clofazimine in a dose of 100 mg twice daily for 10 days, then twice weekly for 4 months appears to help the majority of patients [27,28]. Clofazimine appears to be most effective during the early stages and works by clearing granulomas.

Crohn's disease

Crohn's disease lesions are indistinguishable from OFG.

Dermatological diseases

Several dermatoses can be associated with oral ulcers or erosions; lichen planus (LP) is the most common, pemphigus the most serious and pemphgoid is intermediate.

Lichen planus (see Chapter 42)

Oral LP may affect up to 1–2% of the population and is probably about eight times more common than cutaneous LP. The oral mucosa may be involved alone or in association with lesions on skin or other mucosa, and oral lesions may precede, accompany or follow lesions elsewhere [1–4]. The association of oral LP with gingival involvement, together with vulvovaginal lesions, has been termed the *vulvovaginal–gingival syndrome*.

Aetiology. Most oral LP is idiopathic but significantly greater anxiety and depression are observed among patients with oral LP compared with controls [5].

Some lichenoid lesions may be related to dental materials: the prevalence of positive reactions to potential allergens in the North American Contact Dermatitis Group (NACDG) is higher in oral LP for chromate, gold and thimerosal [6]. Other lichenoid reactions may be caused by GVHD, drug use (e.g. non-steroidal anti-inflammatory agents), diabetes [7] or liver disease. Chronic liver disease, especially chronic active hepatitis and hepatitis C virus (HCV) infection, may be associated with erosive LP in persons of southern European, Japanese or some other extractions [8] and there may be anticardiolipin antibodies [9]. In persons of northern European extraction, oral LP is only rarely associated with liver disease or with hepatitis C, hepatitis G or transfusion-transmitted virus [10–12].

Pathology. The pathology is similar to that of cutaneous LP, although sawtooth rete ridges are rarely seen in oral biopsies, and other epithelial changes may be less distinct.

Clinical features. The common oral lesions of LP are bilateral white lesions in the buccal and/or lingual mucosa. They may be reticular, papular or plaque-like (Figs 66.31–66.35). They are often symptomless but may cause soreness [1–4].

Erosive LP, which frequently affects the dorsum and lateral borders of the tongue or the buccal mucosae on both sides, is uncommon. The erosions are often large, slightly depressed or raised with a yellow slough, and have an irregular outline (Fig. 66.34), but they are not always as painful as might be imagined. The surrounding mucosa is often erythematous and glazed in appearance, with loss of filiform papillae of the tongue, and there are often pathognomonic whitish striae. LP may also produce

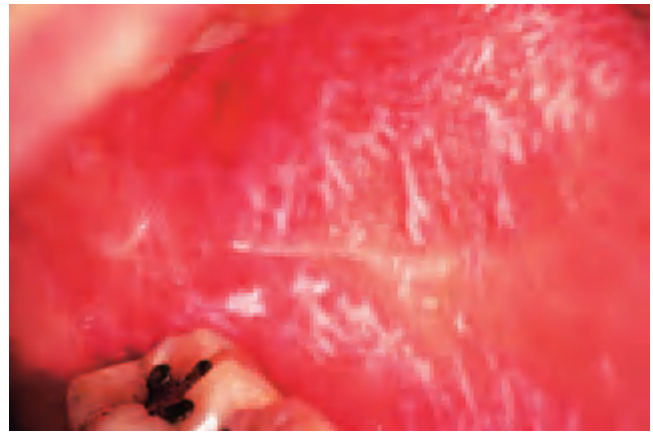

Fig. 66.31 Lichen planus: reticulopapular lesions in the common oral site, the buccal mucosa.

Fig. 66.32 Lichen planus: plaque-like lesions resemble leukoplakia.

Fig. 66.33 Lichen planus on the tongue.

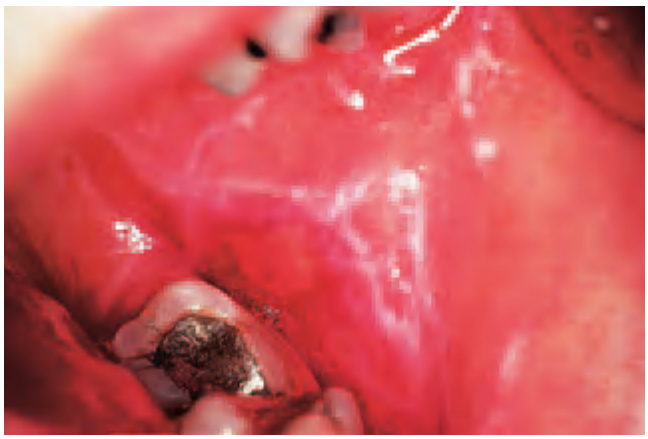

Fig. 66.34 Erosive lichen planus.

Fig. 66.35 Lichen planus on the gingivae: white and desquamative lesions.

a desquamative gingivitis (see p. 66.100). Candidiasis may complicate oral LP.

Reticular LP is the most frequent clinical presentation in both HCV-positive and HCV-negative patients. HCV-positive patients particularly have lip, tongue and gingival lesions [13].

Prognosis. There appears to be a predisposition for some oral LP, particularly the non-reticular forms, to develop carcinoma—possibly a risk of up to 5% over 10 years [1–4].

Diagnosis. Biopsy with immunofluorescence is often indicated to exclude keratosis, chronic ulcerative stomatitis with stratified epithelium-specific antinuclear antibodies, lichen sclerosus, lupus erythematosus, malignancy and other disorders.

Management. Treatment is not always necessary, unless there are symptoms. Unfortunately, although the natural history of cutaneous LP is one of remission in most cases, in few patients with oral LP does the disorder remit, and thus treatment is indicated for symptomatic oral LP [1–4,14].

- Predisposing factors should be corrected. It may be wise to consider removal of dental amalgams if the lesions are closely related to these, or are unilateral, but there are no tests (e.g. patch tests) that will reliably indicate which patients will benefit from this.

If drugs are implicated, the physician should be consulted as to possible changes in therapy. If there is diabetes or HCV infection, this should be treated by a physician.

- Improvement in oral hygiene may result in some subjective benefit. Thus good oral hygiene should be maintained. Chlorhexidine or triclosan mouthwashes may help.
- Symptoms can often be controlled with topical medication: topical corticosteroids, such as betamethasone valerate aerosol or pastes containing fluocinonide, fluocinolone, triamcinolone, betamethasone valerate or clobetasol [15,16]; or topical tacrolimus [17,18]. Antifungals may help, especially where there is candidal superinfection.

1 *Mild LP*. Topical corticosteroids are the mainstay of therapy (e.g. triamcinolone acetate, betamethasone or fluocinolone). Erosive and gingival lesions are often recalcitrant. Next, high-potency corticosteroids such as clobetasol, fluocinonide or fluticasone may be employed initially and then changed to a lower potency drug.

2 *Moderate LP*. If there is severe or extensive oral involvement, topical ciclosporin or tacrolimus may be of significant benefit, often being used with a high-potency or super-potent topical steroid such as clobetasol, fluticasone or mometasone. Topical creams or pastes can be applied in a suitable customized tray or veneer to be worn at night. This regimen is useful in the management of LP-related desquamative gingivitis recalcitrant to other therapies.

3 *Severe LP*. In severe LP in multiple sites, patients may require systemic corticosteroids, azathioprine, cyclophosphamide, hydroxychloroquine, acitretin, thalidomide or ciclosporin. Dapsone is occasionally effective.

- Other therapies for LP include retinoids, dapsone, low-molecular-weight heparin [19] and many others, but either their efficacy has not been well proven or they have unacceptable adverse effects.
- Patients with non-reticular LP should be monitored to exclude development of carcinoma. Tobacco and alcohol use should be minimized.

Fig. 66.36 Pemphigus vulgaris: irregular persistent oral erosions.

Pemphigus (see Chapter 41)

Oral lesions are the rule in pemphigus vulgaris (PV), but rare in the superficial forms of pemphigus [1].

Pemphigus vulgaris. The main antigen in PV is desmoglein (Dsg) 3. However, 50% of patients with PV also have autoantibodies to Dsg1 (the main antigen in pemphigus foliaceus) and the proportion of Dsg1 and Dsg3 antibodies appears to be related to clinical severity. Those cases of PV which are predominantly oral have only Dsg3 antibodies. Dsg1 autoantibodies are found in over 50% of cases of PV, and the frequency may differ with race since they are found in a significantly greater proportion of patients of Indian origin than white northern Europeans [1–4]; such variations may be HLA-related [5].

Typically, an individual patient develops a single variant of pemphigus, although cases have been described of transition to another variant, presumably through epitope spread, and the clinical manifestations of a single variant can change over time, possibly related to changes in the proportions of Dsg1 and Dsg3 autoantibodies.

The oral mucosa is almost invariably involved in PV and oral lesions are commonly the presenting feature (Fig. 66.36). Bullae appear on any part of the oral mucosa including the palate, but break so rapidly that they are rarely seen [1,6–12]. Usually, the patient presents with large, painful, irregular and persistent red lesions which, by the time they become secondarily infected, can be difficult to differentiate clinically from those of other erosive conditions, such as pemphigoid and other immune blistering disorders, although intact bullae are more commonly seen in these, whereas the Nikolsky sign is more often positive in pemphigus. Oral lesions of PV are typically seen in adults, rarely in childhood.

The prevalence of oral involvement varies: one multicentre study involving patients from several countries showed that Bulgarian patients with PV had oral mucous

Table 66.19 Immunostaining in oral mucosal vesiculobullous disorders.

† Non-specific deposits.

membrane lesions less frequently (66%) than Italian (83%) or Israeli (92%) patients [8]. Rarely in PV there can be an acquired macroglossia [11] or desquamative gingivitis [12].

Diagnosis should be confirmed by biopsy and immune studies. A biopsy of perilesional mucosa should be taken for H+E sections and immunostaining (Table 66.19) and serum collected for autoantibody titres, which can help diagnosis and monitoring of disease activity. Differential binding of anti-Dsg antibodies suggests that both human skin and monkey oesophagus should be used in the diagnosis of PV, since patients with predominantly oral disease may only have Dsg3 antibodies, which are not always detectable using human skin [13]. Oral smears for cytology are of little practical value.

Treatment is largely based on systemic immunosuppression using corticosteroids, with azathioprine, dapsone, methotrexate, cyclophosphamide, gold or ciclosporin as adjuvants or alternatives; this has significantly reduced the mortality [1,14]. Adverse effects of these drugs are common, though deflazacort may have slightly fewer effects [15]. Mycophenolate mofetil offers the hope of relatively safer immunosuppression with no nephrotoxicity or hepatotoxicity [16,17].

Mucosal lesions are recalcitrant, often only healing after skin lesions have resolved when immunosuppressive therapy is given, and they may persist even though skin lesions are controlled. Topical corticosteroids may then help, or possibly prostaglandin E_2 [18]. Tacrolimus may well prove to have a place in the control of oral lesions [19].

Paraneoplastic pemphigus. Apart from PV, the other important pemphigus variant affecting the mouth is paraneoplastic pemphigus, usually associated with lymphoproliferative disease or thymoma [1], although one case associated with OSCC has been reported [2]. Oral lesions may be the sole manifestation [3] and have also been seen in all reported cases of paraneoplastic pemphigus [4–8]. Oral lesions may be seen in isolation [1].

Painful extensive stomatitis, painful paronychia and lichenoid papules may be seen, and histology may show lichenoid changes, acantholytic blister formation and apoptotic keratinocytes. Direct immunofluorescence is positive for IgG both in the epidermal intercellular spaces and along the basement membrane zone. Indirect immunofluorescence is similarly positive in a PV pattern.

There is often only a partial response to intravenous corticosteroids. Recent therapeutic advances include the use of anti-CD20 monoclonal antibody (rituximab) [9] and mycophenolate [10].

Subepithelial immune bullous diseases

A spectrum of immune-mediated subepithelial bullous diseases can present with oral blisters and/or erosions, and with immune deposits at the epithelial basement membrane zone. Several distinct groups, and probably several overlap syndromes, are now recognized to exist.

Mucous membrane pemphigoid (see Chapter 41). Mucous membrane pemphigoid is a mucocutaneous, immune-mediated,

Fig. 66.37 Pemphigoid: vesicles and desquamative gingivitis.

subepithelial blistering disease characterized by autoantibodies to different molecules in the basement membrane zone [1,2]. The mouth may be involved as part of a wider disease, though in many patients only oral lesions are seen. Sera of oral pemphigoid patients selectively and specifically bind to human α6 integrin, a 120-kDa protein that appears to be a target antigen in this particular variant [3].

Mucous membrane pemphigoid involves the oral mucosa in more than one-third of cases, commonly causing gingival lesions [1,2,4,5]. The usual lesion, desquamative gingivitis, is characterized by erythematous, glazed, sore gingivae (Fig. 66.37). Bullae are less common, and are seen particularly on the soft palate. They rupture to form erosions [1–5].

The bullae in mucous membrane pemphigoid are subepithelial and tend to persist for longer than those of pemphigus. Oral lesions may scar but this is uncommon. The bullae are typically filled with serous fluid and should be distinguished from superficial mucoceles (see p. 66.81), epidermolysis bullosa acquisita, dermatitis herpetiformis and linear IgA disease. Occasionally blisters are blood-filled, and then must be differentiated from angina bullosa haemorrhagica (see p. 66.80).

A biopsy is required for diagnosis [5]. Serum autoantibodies to epithelial basement membrane may be detected in a few patients (see Table 66.19) but many have immune deposits at the epithelial and mucous gland basement membrane zone. A very small minority of patients have an associated internal malignancy which should be excluded.

Topical corticosteroids usually help if the lesions are restricted to the oral mucosa; azathioprine may be an alternative [6]. Systemic corticosteroids may occasionally be required but tetracyclines with or without nicotinamide may help [7,8]. Dapsone may be useful, especially in the treatment of desquamative gingivitis [9,10]. The evidence for efficacy of tacrolimus or mycophenolate mofetil is weak [11,12].

Vegetating cicatricial pemphigoid (syn. pemphigoid vegetans). A subset of bullous pemphigoid, although clinically indistinguishable from pemphigus vegetans and sometimes producing oral blisters and erosions, vegetating cicatricial pemphigoid shows linear deposits of IgG and C3 at the epithelial basement membrane zone on oral biopsy but no circulating basement membrane antibodies [1].

Palate and gingiva have been especially involved in the rare cases described [2,3].

Dermatitis herpetiformis and adult linear IgA disease. Oral lesions may occur in dermatitis herpetiformis and in most patients with linear IgA disease. Macules, papules, petechiae, vesicles, bullae and erosions are the usual manifestations [1–10]. These disorders must be differentiated, especially from pemphigoid, angina bullosa haemorrhagica, superficial mucoceles and LP.

Salivary IgA antigliadin antibodies may be found but this is not useful diagnostically. Dapsone and sulfapyridine are the most effective therapeutic agents along with a gluten-free diet in dermatitis herpetiformis.

Erythema multiforme (see Chapter 74). The aetiology of erythema multiforme (EM) is unclear in most patients, but appears to be an immunological hypersensitivity reaction with the appearance of cytotoxic effector cells ($CD8^+$ T lymphocytes) in the epithelium, inducing apoptosis of scattered keratinocytes and leading to satellite cell necrosis.

Predisposing factors. There may be a genetic predisposition, with associations of recurrent EM with HLA-B15(B62), HLA-B35, HLA-A33, HLA-DR53 and HLA-DQB1*0301. HLA-DQ3 has been proven to be especially related to recurrent EM and may be a helpful marker for distinguishing this herpes-associated EM from other diseases with EM-like lesions. Patients with extensive mucosal involvement may have the rare HLA allele DQB1*0402 [1].

The reaction is triggered by the following.

- *Infective agents*, particularly herpes simplex virus (herpes-associated EM), which is implicated in 70% of recurrent EM. Bacteria (*Mycoplasma pneumoniae*, and many others), other viruses, fungi or parasites are less commonly implicated [2,3].
- *Drugs* such as sulphonamides (e.g. co-trimoxazole), cephalosporins, aminopenicillins, quinolones, barbiturates, oxicam non-steroidal anti-inflammatory drugs, anticonvulsants, protease inhibitors, allopurinol and many others may trigger severe EM or toxic epidermal necrolysis in particular [4,5].
- *Food additives or chemicals* such as benzoates, nitrobenzene, perfumes, terpenes.
- *Immune conditions* such as BCG or hepatitis B immunization, sarcoidosis, GVHD, inflammatory bowel disease, polyarteritis nodosa or systemic lupus erythematosus (SLE).

Clinical features. Most patients with EM (70%), of either minor or major forms, have oral lesions. The oral mucosa may be involved alone or in association with skin lesions. Mucosal lesions begin as erythematous areas that blister and break down to irregular, extensive, painful erosions with extensive surrounding erythema. The labial mucosa is often involved, and a serosanguinous exudate leads to crusting of the swollen lips [6–11].

Mucosal erosions plus typical or raised atypical targets and epidermal detachment involving less than 10% of the body surface and usually located on the extremities and/or the face characterize herpes simplex-induced EM major.

Mucosal erosions plus widespread distribution of flat atypical targets or purpuric macules and epithelial detachment involving less than 10% of body surface on the trunk, face and extremities are characteristic of drug-induced Stevens–Johnson syndrome [12].

Diagnosis. A diagnosis of EM can be difficult to readily establish, and there may be a need to differentiate from

viral stomatitides, pemphigus, toxic epidermal necrolysis and the subepithelial immune blistering disorders (pemphigoid and others). There are no specific diagnostic tests.

The diagnosis is mainly clinical; the Nikolsky sign is negative. It may be helpful to undertake serology for *Mycoplasma pneumoniae* or herpes simplex virus, or other microorganisms. Biopsy of perilesional tissue with immunostaining and histological examination may help, although pathology can be variable and immunostaining is not specific.

Management. Spontaneous healing can be slow, up to 2–3 weeks in EM minor and up to 6 weeks in EM major. Treatment is thus indicated but controversial. No specific treatment is available but supportive care is important; a liquid diet and intravenous fluid therapy may be necessary. Electrolytes and nutritional support should be started as soon as possible. Oral hygiene should be improved with 0.2% aqueous chlorhexidine mouthbaths.

The use of corticosteroids is controversial [13–14].

- EM minor may respond to topical corticosteroids, although systemic corticosteroids may still be required.
- EM major should be treated with systemic corticosteroids (prednisolone 0.5–1 mg/kg/day tapered over 7–10 days) and/or azathioprine or other immunomodulatory drugs. Levamisole [15] and thalidomide have occasionally been used to some effect. Plasmapheresis possibly has a place in the management of severe disease.

Antimicrobials may be indicated [16,17].

- Aciclovir in EM related to herpes simplex virus (HSV). Give a 5-day course at the first sign of lesions, or give 400 mg four times daily for 6 months for prophylaxis in EM related to HSV. Continuous therapy with valaciclovir 500 mg twice a day has also been reported to be effective [17].
- Tetracycline is indicated in EM related to *Mycoplasma pneumoniae*.

Toxic epidermal necrolysis

SYN. LYELL'S DISEASE

Toxic epidermal necrolysis is a rare clinicopathological entity, with a high mortality, characterized by extensive detachment of full-thickness epithelium. Toxic epidermal necrolysis and Stevens–Johnson syndrome appear to be severity variants of the same disease, which differs from EM. The distinction from EM is unclear, however, but most cases of toxic epidermal necrolysis are drug-induced and the lesions are extremely widespread [1,2].

Recently, an increased number of cases in patients with HIV/acquired immune deficiency syndrome (AIDS) has been recorded [3].

Clinical features. Toxic epidermal necrolysis presents with cough, sore throat, burning eyes, malaise and low fever, followed after about 1–2 days by skin and mucous membrane lesions. Oral lesions can be seen in over 95% of patients with toxic epidermal necrolysis. The entire skin surface and oral mucosa may be involved, with up to 100% sloughing off. Gingival lesions are common and clinically are inflamed, with blister formation leading to painful widespread erosions. The blisters and erosions may precede the skin lesions by a day or so and may persist [3–6].

Diagnosis. Sheet-like loss of the epithelium and a positive Nikolsky sign are characteristic. Biopsy of perilesional tissue with immunostaining and histological examination are essential to the diagnosis. Histopathological examination is characteristic, showing necrosis of the whole epithelium detached from the lamina propria.

Management. Patients must be admitted to an intensive care unit as soon as possible for management [7]. There is no specific therapy for oral lesions but 2% lidocaine (lignocaine) and 0.2% aqueous chlorhexidine mouthbaths may provide symptomatic relief.

Lichen sclerosus (see Chapter 56). Oral lichen sclerosus et atrophicus is uncommon but since it presents with whitish plaques, papules or a reticular pattern, or erosions, all features of LP [1–8], it may be underdiagnosed. Histologically, however, lichen sclerosus has epithelial atrophy with hyperkeratosis, oedema in the papillary corium and the lymphocytic infiltrate is less close to the epithelium than in LP. It has been suggested that mucosal lichen sclerosus is more common than formerly thought and may even cause dysplasia [5].

Chronic ulcerative stomatitis with epithelial antinuclear antibodies. Chronic erosive or ulcerative stomatitis often presents as desquamative gingivitis with or without lesions on buccal or lingual mucosa and sometimes resembles LP, and may be associated with lichenoid histology, but is associated with antinuclear antibodies directed against stratified squamous epithelia [1–3]. These autoantibodies are directed against a 70-kDa epithelial nuclear protein homologous to the p53 tumour suppressor and the p73 putative tumour suppressor, and shown to be a splicing variant of the *KET* gene [4,5].

The lesions may respond to hydroxychloroquine [1–3].

Lupus erythematosus (see Chapter 56)

Almost half of the patients with SLE suffer from oral lesions, which begin as red patches that break down to irregular slit-like ulcers which often heal with scarring [1]. Lesions particularly affect the palate. Sjögren's syndrome may occur in SLE. Oral petechiae and herpetic infections are also common. Rarely, dental surgery has been followed by facial swelling [2].

Similar erosions, with a white border, occur in discoid lupus erythematosus (Fig. 66.38). Discoid lupus erythematosus may predispose to oral carcinoma [3]. Oral ulceration has also been described in drug-induced lupus.

Systemic corticosteroids, often with an immunosuppressant, may be required in severe cases.

Fig. 66.38 Chronic oral lesions in discoid lupus erythematosus.

Other collagen–vascular diseases

Dermatomyositis and mixed connective tissue disease may be associated with non-specific mucosal erosions [4].

Oral involvement in Reiter's syndrome may include red patches or superficial painless mucosal erosions which may resemble erythema migrans (geographical tongue) both clinically and histologically.

Infective diseases

Oral ulceration is common worldwide in some viral infections, typically in the herpesvirus or enterovirus infections seen in childhood. It can also be seen in several bacterial diseases, notably acute necrotizing gingivitis (but also in tuberculosis and syphilis), but is rare in fungal infections in the developed world, although the deep mycoses may be responsible for infection in the developing world, in travellers or in the immunocompromised.

Herpesviruses

Oral infection is common with the herpesviruses, which thereafter remain latent, are often excreted in saliva (especially in immunocompromised persons), and are sometimes implicated in clinical recurrences and malignant complications.

Herpes simplex stomatitis

Aetiology. HSV infection is a very common oral infection. In general, HSV-1 causes primary herpetic stomatitis (and the secondary infection of recurrent herpes labialis). There are no precise distinctions nowadays, presumably with more frequent orogenital and oroanal sexual practices, and oral infection with HSV-2 is also frequently seen [1,2].

With improving socio-economic circumstances and standards of hygiene, a larger number of children are not exposed to HSV and enter adult life without immunity. Cases of primary herpetic stomatitis are therefore now seen occasionally in adults, and the manifestations can be severe. HSV is usually transmitted in saliva and can be shed in asymptomatic individuals [3,4].

Clinical features. The incubation period is 3–7 days. Many infections with HSV occur in childhood and are subclinical and, where there is disease, it varies greatly in severity. In many it is trivial and misdiagnosed or passed off as 'teething' [5,6].

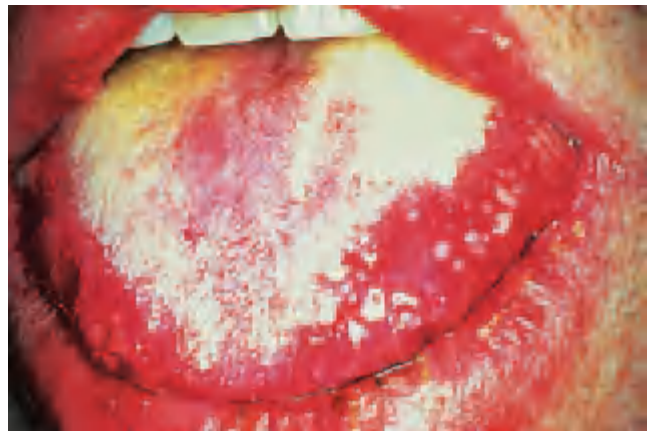

Fig. 66.39 Scattered ulcers and a furred tongue in primary herpetic stomatitis.

Primary herpetic stomatitis typically presents with malaise, anorexia, irritability, fever, enlarged and tender anterior cervical lymph nodes, and a diffuse, purple, boggy gingivitis (hence the alternative term *herpetic gingivostomatitis*), especially anteriorly, with multiple vesicles followed by round or ovoid ulcers 1–3 mm in diameter scattered across the oral mucosa and gingiva (Fig. 66.39) in an acute illness lasting only up to about 14 days [1,2]. In immunocompromised persons, diagnosis can be difficult since herpes may manifest with chronic ulcers [7–11].

Prognosis. Herpetic stomatitis resolves spontaneously in 7–14 days but HSV remains latent in the trigeminal ganglion. The most obvious sequel is that about one-third of patients are thereafter predisposed to recurrences. HSV is shed intermittently into the saliva [3,4]. HSV is implicated in many instances of EM (see p. 66.67) and may cause chronic ulcers in the immunocompromised (see below).

Diagnosis. The main differential diagnoses of herpetic stomatitis in otherwise healthy persons are chickenpox and other viral causes of mouth ulcers, and acute leukaemia. In immunocopromised persons, the differential is wider. A full blood picture, white-cell count and differential, and viral studies may therefore be required [1,2,12,13]. The latter include the following:

- Culture: this takes days to give a result.
- Electron microscopy: this is not always available.
- Polymerase chain reaction (PCR) detection of HSV DNA: this is sensitive but expensive.
- Immunodetection: detection of HSV antigens is of some value. Conventional enzyme-linked immunosorbent assays (ELISA) for serum antibodies have poor sensitivity and specificity; newer assays based on HSV glycoproteins

Fig. 66.40 Primary herpetic stomatitis with extraoral lesions.

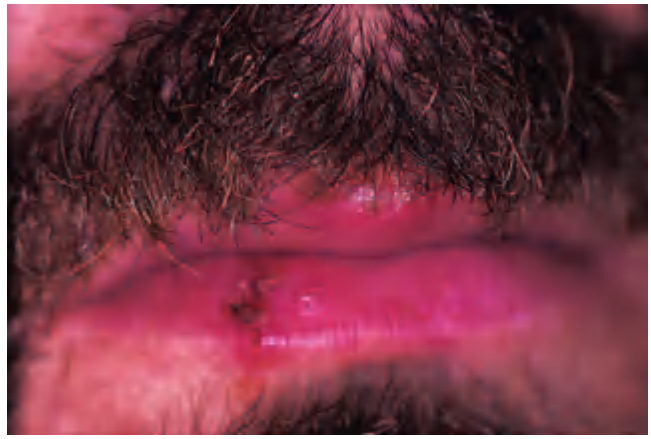

Fig. 66.41 Herpes labialis.

are comparable with Western blot assays. A rising titre of serum antibodies is confirmatory but only gives the diagnosis retrospectively.

- Smears for viral-damaged cells: now rarely used.

Treatment. Specific antiviral agents are most useful in the very early stages of disease (though most patients present later) and for immunocompromised patients who may otherwise suffer severe infection. Both oral and intravenous aciclovir appear to be effective, as are the newer antivirals [14,15].

For most, however, management is supportive with antipyretic analgesics (e.g. acetaminophen/paracetamol), sponging with tepid water and a high fluid intake. Analgesics (as elixirs or syrups for children) and, in adults, lidocaine mouthbaths help ease discomfort and 0.2% aqueous chlorhexidine mouthbaths aid resolution.

An antihistamine such as promethazine may help sedate an irritable child.

Recurrent labial HSV infection. Primary oral infection by HSV may produce perioral lesions (Fig. 66.40). However, recurrent herpes labialis involving the lip is the more common cause of blisters at the mucocutaneous junction (Fig. 66.41) [1,2]. The lesions arise at the mucocutaneous junction as itching papules which progress to vesicles, pustules and then scab. They are unsightly and occasionally become infected with *Staphylococcus* or *Streptococcus*, resulting in impetigo (Fig. 66.42). In immunocompromised persons, extensive and persistent lesions may result. In atopic persons, the lesions may spread to produce eczema herpeticum (Fig. 66.43). Aciclovir has been the standard treatment used as a 5% cream, although penciclovir 1% is more effective [16].

Recurrent intraoral HSV infection. Chronic oral herpetic ulcers, often with a raised white border and sometimes with a dendritic appearance, may occasionally affect

Fig. 66.42 Impetigo.

apparently healthy individuals, especially at sites of trauma, for example following palatal infiltration of a local anaesthetic. Chronic indolent lesions, usually ulcerative or nodular, may be seen in patients with neutropenia or chronic leukaemia; in patients with more severe immunosuppression, such as acute leukaemia or HIV infection, more aggressive chronic ulcers may be seen [7–11]. Aciclovir may be indicated systemically [8].

Chickenpox

SYN. VARICELLA (see Chapter 25)

Chickenpox affects children predominantly and may present with mouth ulcers that resemble those of herpetic stomatitis, but there is no gingivitis [1]. There may be a contact history. Many primary infections with varicella-zoster virus are subclinical or produce so few lesions as to pass almost unnoticed. Varicella-zoster virus remains latent in sensory ganglia and may be reactivated to produce shingles.

Herpes zoster

SYN. SHINGLES

If shingles affects the maxillary or mandibular divisions of the trigeminal nerve, mouth ulcers are usually seen [2,3].

Clinical features. The pain of trigeminal zoster may simulate toothache. Severe pain often precedes, accompanies and follows the rash, and post-herpetic neuralgia may persist for months or years.

The rash is restricted to a dermatome and is unilateral, but sometimes a few chickenpox-type lesions can be found elsewhere. Oral ulcers appear in the distribution of the involved nerve division [3]. There is ulceration of one side of the tongue, floor of mouth and lower labial and buccal mucosa if the mandibular division of the trigeminal nerve is involved. One side of the palate, the upper gingiva and buccal sulcus are involved in maxillary zoster. Rarely, mandibular or maxillary zoster may disturb the formation of developing teeth [4] or cause jaw necrosis [5].

If the geniculate ganglion of the facial nerve is affected, there may be unilateral facial palsy, with vesicles in the ipsilateral ear and ulcers in the soft palate ipsilaterally (Ramsay–Hunt syndrome) [6].

Occasionally there is misdiagnosis of toothache, leading to extraction, the true diagnosis becoming apparent only when the rash appears. Zoster resolves spontaneously but post-herpetic neuralgia can be distressing.

Management. An underlying immune defect, such as AIDS or malignancy, should be excluded in patients with zoster, although most zoster is related simply to lesser problems in advanced age.

Treatment is mainly supportive but antivirals such as aciclovir can be useful. Analgesics are indicated in zoster, although the pain may prove refractory to even potent analgesics [7], when antidepressants such as amitriptyline and fluphenazine may have a place [8].

Epstein–Barr virus infections (see Chapter 25)

Epstein–Barr virus (EBV) is responsible for infectious mononucleosis and is found in pharyngeal epithelium and appears in the saliva of patients and for several months after clinical recovery. Infection appears to be spread by close oral contact, especially kissing. It is typically a disease of the student population.

Infection is often subclinical. Infectious mononucleosis is also protean in its clinical manifestations, which include particularly lymphadenopathy, sore throat, fever, malaise and rashes. In the anginose type (sore-throat type), the throat is sore with soft-palate petechiae and a whitish exudate on oedematous tonsils. There may be non-specific oral ulceration or pericoronitis [1]. The glandular type of infectious mononucleosis is characterized by generalized lymph node enlargement and splenomegaly; the febrile type is characterized by fever.

Similar syndromes may be caused by cytomegalovirus (CMV), human herpesvirus (HHV)-6, toxoplasmosis and HIV. Characteristic of infectious mononucleosis are large numbers of atypical mononuclear cells in the blood and a wide variety of serological changes, particularly heterophil antibodies, which are detectable by the Paul–Bunnell or Monospot tests, usually during the first or second week of illness. Several other antibodies against EBV appear during the course of infectious mononucleosis, but the most frequent is the antibody to viral capsid antigen, the titre of which reaches a peak at about 4 weeks.

No specific treatment is available for infectious mononucleosis, but supportive care is important, not only because of the potential for airways obstruction but also because of the associated lassitude. Systemic corticosteroids are required if there is pharyngeal oedema severe enough to hazard the airway.

EBV is also commonly found in the mouths of immunocompromised patients [2–5], and is implicated in oral hairy leukoplakia (see p. 66.89), oral ulceration [6] and some oral lymphomas, although any relationship with other malignancies such as OSCC is controversial [7,8].

Cytomegalovirus infection

CMV may cause a glandular fever type of syndrome, and rarely causes oral ulceration. Indolent CMV-induced oral ulcers may be seen in immunosuppressed patients and in AIDS [1–4].

Herpesviruses 6, 7 and 8

Oral lesions have yet to be demonstrated in infections with HHV-6 or HHV-7. However, HHV-8 is implicated in oral Kaposi's sarcoma [1–4]. Treatment with highly active antiretroviral therapy (HAART) may reduce HHV-8 infection [5].

Enteroviruses

Herpangina

Aetiology. Herpangina is caused by Coxsackieviruses mainly. The incubation period is 3–7 days and young children are predominantly affected.

Clinical features. Many infections are subclinical but features of the clinical syndrome include malaise, anorexia, irritability, low fever, slightly enlarged and tender anterior cervical lymph nodes and mouth ulcers, predominantly on the soft palate [1].

Diagnosis. There may be a contact history. It is possible to culture Coxsackieviruses in suckling mice if absolutely necessary.

The main differential diagnosis is primary herpetic stomatitis, but in herpangina there is less fever, no acute gingivitis and ulceration is mainly restricted to the soft palate.

Treatment. The condition is self-limiting and treatment is supportive only.

REFERENCE

1 Bell EJ, Williams GR, Grist NR *et al*. Enterovirus infections. *Update* 1983; **26**: 967–78.

Hand, foot and mouth disease (see Chapter 25)

Aetiology. Hand, foot and mouth disease is caused particularly by Coxsackie A viruses but sometimes by Coxsackie B viruses or enteroviruses.

Clinical features. The incubation period is 3–10 days and, although young children are predominantly infected, there are occasional outbreaks in adults. Many infections are subclinical but features of the clinical syndrome include the following.

- General features: malaise, anorexia, irritability and fever may be present but usually only in severe cases.
- Anterior cervical lymph nodes may occasionally be slightly enlarged and tender.
- Mouth ulcers are round or ovoid, usually sparse and may affect any site [1–3].
- Rash: painful, sometimes deep-seated vesicles may appear, usually on the hand and/or feet, particularly on digits or at the base of the phalanges.

Hand, foot and mouth disease is self-limiting and only rarely complicated by systemic illness such as encephalitis. The condition tends to be more severe when it occurs in adults.

Diagnosis and management are as for herpangina.

Fig. 66.44 Acute necrotizing gingivitis showing typical ulceration of interdental gingival papillae. This was in HIV infection.

Bacterial infections

Acute necrotizing (ulcerative) gingivitis and noma

Aetiology. There is no firm evidence of communicability of acute necrotizing gingivitis, although it may occur in epidemic form, especially in institutions or in the military (trench mouth). Viral respiratory infections, overwork and fatigue, smoking or immune defects may precede the onset of disease, suggesting depression of immunity as a predisposing cause. A similar lesion may be a feature of HIV infection and related diseases.

A mixed, mostly anaerobic, flora (the fusospirochaetal complex), consisting mainly of *Fusobacterium nucleatum* (*F. fusiformis* or *Bacillus fusiformis*) and *Borrelia vincentii*, is associated with this infection [1,2].

Clinical features. The mouth ulceration is usually restricted to the gingiva, specifically the interdental papillae, which appear blunted (Figs 66.44 & 66.45). The history is characteristic, with an acute onset of gingival soreness, bleeding and halitosis. Acute necrotizing gingivitis occurs especially in the anterior part of the mouth where the affected gingiva are extremely tender to touch and readily bleed on minimal pressure. Occasionally the ulceration extends elsewhere on the gingiva, or onto the adjacent mucosa. There is often enlargement of the cervical lymph nodes and there may be pyrexia and malaise.

Prognosis. Failure to adequately treat acute necrotizing gingivitis may predispose to recurrence and, in malnour-

Fig. 66.45 Untreated acute necrotizing gingivitis can lead to extensive gingival ulceration and irreparable damage.

ished or immunocompromised individuals, may lead to noma (cancrum oris) [3–7]. Similar lesions of gangrenous stomatitis are increasingly reported in HIV disease.

Diagnosis. Diagnosis is mainly from gingival lesions in primary herpetic stomatitis, leukaemias and HIV disease. A bacteriological smear may be helpful.

Treatment. Gentle cleansing with a hydrogen peroxide mouthwash and a soft toothbrush is remarkably effective. Oral metronidazole 200 mg should be given three times daily for 3–7 days to limit the tissue destruction. Penicillin is equally effective. The patient should also be referred for dental advice [1].

Syphilis

Oral ulcers may be seen at any stage but particularly in secondary syphilis [1–3]. In primary syphilis, a primary chancre (hard or Hunterian chancre) may involve the lips, tongue or palate. A small, firm, pink macule changes to a papule which ulcerates to form a painless round ulcer with a raised margin and indurated base [4]. Chancres heal spontaneously in 3–8 weeks but are highly infectious

Fig. 66.46 Gumma.

Fig. 66.47 Hutchinson's maxillary central incisors.

and are associated with enlarged, painless regional lymph nodes.

Secondary syphilis follows after 6–8 weeks, with oral lesions in about one-third of patients [1,3]. These are highly infectious and are usually fairly painless ulcers (mucous patches and snail-track ulcers).

The most characteristic oral lesion of tertiary syphilis is a localized granuloma (gumma) that varies in size from a pinhead to several centimetres, affecting particularly the palate, or the tongue. Gummas break down to form deep chronic punched-out ulcers that are not infectious (Fig. 66.46). However, the most common oral manifestation of tertiary syphilis is leukoplakia, which particularly affects the dorsum of the tongue and has a high potential for malignant change.

Congenital syphilis may, when the permanent teeth erupt, present with dental anomalies such as Hutchinson's teeth (Fig. 66.47). Oral ulcers are rare.

Exudate from a suspected oral lesion of syphilis should be examined for treponemes by dark-ground microscopy; however, since the diagnosis can be confused by oral commensal treponemes, lesions should first be thoroughly swabbed with a sterile gauze or cotton-wool and then gently scraped with a sterile spatula, the scraping being examined immediately by dark-ground microscopy. Serology is indicated. Biopsy is not usually indicated, but lesions are characterized by a dense plasma cell infiltrate.

Gonorrhoea

Oral mucosal erythema, sometimes with oedema and ulceration, is occasionally seen in oropharyngeal gonorrhoea. Oropharyngeal asymptomatic carriage of gonococci is more common, found in around 4% of those attending clinics for sexually transmitted diseases [1,2].

Tuberculosis

Oral lesions can develop in pulmonary tuberculosis but are not common. A chronic ulcer, usually of the dorsum of the tongue, is the most common oral presentation but jaw lesions or cervical lymph node involvement may be seen [1–4]. Atypical mycobacteria are not uncommonly involved.

Mycobacterial oral ulcers, particularly caused by *Mycobacterium avium–intracellulare*, have been reported as a complication of AIDS and occasionally in apparently healthy individuals [5]. Cervicofacial infection is occasionally caused by *M. chelonei*, usually in the form of lymph node abscesses, or occasionally as intraoral swellings [6–9].

Epithelioid (bacillary) angiomatosis (see Chapter 27)

Oral lesions clinically and, to some extent, histologically reminiscent of Kaposi's sarcoma have been seen in HIV disease [1–3], sometimes as the first manifestation of HIV infection [3].

REFERENCES

Fungal infections

Oral fungal infections, apart from candidiasis, which rarely causes mouth ulcers in Western societies, are usually seen in the West only in immunocompromised or debilitated patients, including those with AIDS. However, they may be seen occasionally in otherwise healthy persons from the tropics (Table 66.20).

Aspergillosis. Rhinocerebral aspergillosis may ulcerate through to the mouth. This is a rare event, except in the severely immunocompromised [1]. Occasionally, solitary aspergillosis arises as a consequence of endodontic treatment where root canal filling material enters the antrum [2] but this does not cause oral ulceration. Surgical débridement is usually indicated.

Table 66.20 Rare orofacial fungal infections.

Infection	Oral manifestations
Aspergillosis	Aspergilloma Rhinocerebral type causes palatal necrosis Disseminated in immunocompromised patients
Blastomycosis	
North American	Oral ulcers or suppurating granulomas
South American (paracoccidioidomycosis)	Oral ulcers and lymphadenopathy
Coccidioidomycosis	Rarely oral ulcers
Cryptococcosis	Oral ulcers
Histoplasmosis	Lumps or ulcers in mouth
Phycomycosis (mucormycosis, zygomycosis)	Antral involvement with palatal ulceration in immunocompromised patients, especially diabetics
Sporotrichosis	Oral lesions rare

Blastomycoses. Blastomycoses may produce oral lesions which are typically mulberry-like, ulcerated swellings especially seen on the gingiva and alveolus [1,2].

REFERENCES

Geotrichosis. Geotrichosis is a rare, livid, sharply defined enanthema of the oral mucosa with ulcerations seen in immunocompromised persons, such as those with leukaemia or HIV infection. *Geotrichum capitatum* is responsible and there may also be pneumonic lung infiltrates [1].

Treatment includes amphotericin, 5-fluorocytosine and itraconazole.

Mucormycosis. Rhinocerebral mucormycosis typically commences in the nasal cavity or paranasal sinuses and invades the palate to produce a black necrotic ulcer, although it might occasionally commence in the palate [1–3]. Most cases are seen in diabetics or in immunocompromised patients such as those with AIDS [4]. Biopsy and radiography are required for diagnosis. Treatment is surgical débridement together with amphotericin intravenously and/or azoles.

Protozoal infestations

Leishmaniasis is rare in northern Europe and the USA; it is not uncommon, however, in hotter climes and may cause ulcers in the mouth or more commonly on the lips [1–4], and is seen increasingly in HIV disease [5–9] or in other immunocompromised persons.

Immune defects

Human immunodeficiency virus infection [1–5]
(see Chapter 26)

Oral ulceration in patients infected with HIV may be due to any of the causes of mouth ulceration (see p. 66.42), and aphthous-like ulcers are also seen. However, it is important to exclude infections, mainly herpesviruses. There are also occasional examples of mouth ulcers due to mycobacteria, *Rochalimaea*, syphilis, *Histoplasma*, *Cryptococcus*, leishmaniasis and others. Malignant disease (mainly Kaposi's sarcoma or non-Hodgkin's lymphoma) may result in lumps that can ulcerate.

Aphthous-like ulcers in HIV may respond to local treatment or, failing that, 100 mg thalidomide at night for 2 weeks and then 100 mg every fifth day may prove effective [5].

Other mouth ulcers should be treated as appropriate.

Vasculitides

Periarteritis nodosa

Transient submucosal oral nodules may occur singly or in crops along the path of vessels and especially in the tongue. Other mucosal lesions include erythema, papules, haemorrhages, ulceration or necrosis [1–4].

Giant cell arteritis
SYN. HORTON'S DISEASE

Patients may suffer ischaemic pain during mastication, intermittent claudication of the tongue [1] or, rarely, facial palsy [2] or lumps [3,4]. Ulceration and necrosis of the tongue [5–11] or occasionally the lip [12] have also been observed [2,3].

Iatrogenic conditions

Mucositis

Mucositis, sometimes called *mucosal barrier injury*, is the term given to the widespread oral erythema, ulceration and soreness that is a common complication of a number of therapeutic procedures involving chemotherapy, radiotherapy or chemoradiotherapy, used largely in the treatment of cancer but also in the conditioning prior to bone marrow transplantation (i.e. haematopoietic stem cell transplantation). Mucositis appears 3–15 days after cancer treatment, earlier after chemotherapy than after radiotherapy.

Mucositis invariably follows external beam radiotherapy involving the orofacial tissues, and is also common in upper mantle head and neck radiation, and particularly in total body irradiation.

Some 40–90% of patients on chemotherapy develop mucositis. Patients on fluorouracil and cisplatin in particular develop mucositis, while etoposide and melphalan cause particularly severe mucositis. Oral mucositis is particularly severe after haemopoietic stem cell transplantation, because of radiation damage and myeloablation, and the course follows the polymorphonuclear leukocyte count.

The impaired mucosal barrier in mucositis predisposes to life-threatening septic complications; the prevalence of an oral focus in febrile neutropenia has been reported in up to 30% of cases [1–4].

Mucositis typically presents with pain (which can be so intense as to interfere with eating and significantly affect the quality of life), erythema, ulceration and sometimes bleeding.

Diagnosis is clinical and it is helpful to score the degree of mucositis in order to monitor progression and therapy.

Management. The basic strategies in management of mucositis aim at pain relief, efforts to hasten healing and prevention of infectious complications. However, prophylaxis is the goal.

Pain relief is usually achieved with opioids given by patient-controlled analgesia and benzydamine can aid relief. Oral cooling with ice chips ameliorates chemotherapy-induced mucositis [5,6].

Other treatments currently used but for which hard data for reliable efficacy are unavailable include the following.

- Medications to reduce salivation and thus exposure of the mucosa to chemotherapeutic drugs that are secreted in saliva.
- Anti-inflammatory medications.
- Cytokines such as interleukin (IL)-1, IL-11, TGF-beta3 and keratinocyte growth factor.
- Granulocyte–macrophage colony-stimulating factor (GM-CSF) and granulocyte colony-stimulating factor (G-CSF).
- Thalidomide: an angiogenesis-inhibiting drug.
- Amifostine: a cytoprotector.
- Melatonin: the pineal hormone.
- Protegrin antimicrobial peptides, which possess activity against Gram-positive and Gram-negative bacteria and yeasts.
- Low-energy lasers.
- Other agents such as sucralfate, tretinoin, glutamine and misoprostol [1–4,6].

Monitoring microbial colonization and the institution of antiviral prophylaxis and antifungal prophylaxis, to avoid colonization and superinfection, is particularly important in patients with low neutrophil counts.

Invasive fungal infections of the oral cavity can be associated with systemic fungal infection and are indications for the use of liposomal amphotericin.

Bone marrow transplantation (haematopoietic stem cell transplantation)

Oral complications are common and can be a major cause of morbidity following bone marrow transplantation. Mucositis, infections, bleeding, xerostomia and loss of taste result from the effects of the underlying disease, chemotherapy or radiotherapy, and GVHD. The ventrum of the tongue, buccal and labial mucosa and gingiva may be affected by ulceration or mucositis [1–6].

Graft-versus-host disease

The oral manifestations of acute GVHD consist of painful mucosal desquamation and ulceration, and/or cheilitis, and the presence of lichenoid plaques or striae. Small white lesions affect the buccal and lingual mucosa early on, but clear by day 14. Erythema and ulceration are most pronounced at 7–11 days, and may be associated with obvious infection. Candidiasis is common, as is herpes simplex stomatitis (occasionally zoster) and there may be oral purpura, especially in adults [1,2].

The oral lesions in chronic GVHD are coincident with skin lesions, and include generalized mucosal erythema, lichenoid lesions, mainly in the buccal mucosa, and xerostomia. There may be depressed salivary IgA levels in minor gland saliva [3]. Xerostomia is most significant in the first 14 days after transplant and is a consequence of drug treatment, irradiation and/or GVHD.

Lip biopsy is useful in the diagnosis of chronic GVHD and should include both mucosa and underlying minor salivary glands [4]. Histology shows changes similar to those seen in Sjögren's syndrome.

Drugs

A wide range of drugs can occasionally induce mouth ulcers, by a variety of effects [1]. Oral use of caustics or agents such as cocaine can cause erosions or ulcers [2]. Oral ulcers are regularly produced by cytotoxic agents [3] (see Mucositis above). Aphthous-like ulcers may follow the use of the potassium channel blocking cardioactive agent nicorandil [4].

Drugs may also cause mucocutaneous lesions. Oral ulcers of a lichenoid type may follow exposure to non-steroidal anti-inflammatory drugs and other agents (see p. 66.61). Erythema multiforme may follow the use of a range of drugs (see p. 66.67). Drug-induced mouth ulcers may also resemble toxic epidermal necrolysis (see p. 66.68) or may have features reminiscent of other dermatological disorders.

The ulcers usually resolve in 10–14 days if the offending drug can be identified and withdrawn.

Acrodynia

SYN. PINK DISEASE

Oral and perioral ulceration, hypersalivation, gingivitis and early tooth loss are features of acrodynia caused by mercury poisoning, now rarely seen [1].

REFERENCE

1 Dinehart SM, Dillard R, Rainer SS *et al*. Cutaneous manifestations of acrodynia (Pink disease). *Arch Dermatol* 1988; **124**: 107–9.

Disorders of uncertain pathogenesis

Angina bullosa haemorrhagica

SYN. LOCALIZED ORAL PURPURA

This is the term given to a benign, fairly common condition of unknown aetiology that usually presents in the elderly with oral blood blisters. These subepithelial blisters are seen mainly in the soft palate and after a few hours rupture to leave ulcers (Fig. 66.48). The patients appear well otherwise, with no detectable immunological or bleeding disorder [1–3]. Occasional cases are related to the use of corticosteroid inhalers. Only symptomatic care is available.

3 Stephenson P, Scully C, Prime SS *et al*. Angina bullosa haemorrhagica: lesional immunostaining and haematological findings. *Br J Oral Surg* 1987; **25**: 488–91.

Monoclonal plasmacytic ulcerative stomatitis

Ulcerative stomatitis may occasionally appear with a lichenoid rash, related to a plasmacytic infiltrate [1,2].

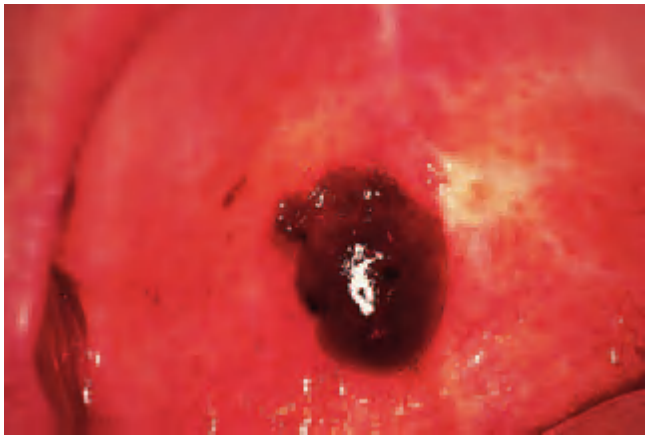

Fig. 66.48 Angina bullosa haemorrhagica: a large blood blister in a typical site on the soft palate. The adjacent whitish lesions are from scarring after a previous biopsy.

Mucocutaneous lymph node syndrome

SYN. KAWASAKI DISEASE (see Chapter 27)

Mucocutaneous lymph node syndrome is a disorder of uncertain, but possibly infectious, aetiology. Male children are predominantly affected.

At least one oral feature should be present for the diagnosis to be made. The oral and pharyngeal mucosa become generally red and sore and the lips dry and fissured. There may be oral ulceration and a 'strawberry tongue' appearance [1,2].

Cervical lymphadenopathy, conjunctivitis and fever also occur, followed later by the characteristic desquamation of the skin of the hands and feet.

Early therapy with immunoglobulin is essential to avoid cardiac complications.

2 Terezhalmy GT. Mucocutaneous lymph node syndrome. *Oral Surg* 1979; **47**: 26–30.

Superficial mucoceles

Superficial extravasation mucoceles of the intraoral minor salivary glands in the palate, buccal mucosa or labial mucosa are not uncommon, especially associated with oral LP in middle-aged or elderly women. This is a benign self-limiting condition that may cause confusion with vesiculobullous disorders [1].

REFERENCE

1 Eveson JW. Superficial mucoceles: pitfall in clinical and microscopic diagnosis. *Oral Surg* 1988; **66**: 318–22.

Necrotizing sialometaplasia

Necrotizing sialometaplasia is an uncommon, benign, self-limiting condition seen predominantly in the posterior hard palate of young adult males, most of whom smoke tobacco [1]. A painless deep ulcer persists for several weeks before spontaneously healing. Biopsy reveals necrosis and pseudoepitheliomatous changes probably resulting from squamous metaplasia following infarction of minor salivary glands. This benign lesion must be differentiated from malignancy.

REFERENCE

1 Kinney RB, Burton CS, Vollmer RT. Necrotizing sialometaplasia: a sheep in wolf's clothing. *Arch Dermatol* 1986; **12**: 208–10.

Mucha–Haberman disease

Erythematous and ulcerative oral lesions have been reported in pityriasis lichenoides et varioliformis acuta (Mucha–Haberman disease) [1,2].

Metabolic disorders

Glucagonoma

Oral ulceration can be a severe manifestation in glucagonoma [1].

REFERENCE

1 Ditty FR, Lang PG. Cutaneous and oral changes as the only manifestations of the glucagonoma syndrome. *South Med J* 1982; **75**: 222–4.

Oral soreness

Most oral pain is of local aetiology, usually resulting from odontogenic infections. Neurological, vascular and referred causes are less common, but must also be excluded. Psychogenic pain is all too frequent and this is discussed below.

Chronic oral soreness may be particularly caused by ulceration, or by mucosal lesions in geographical tongue,

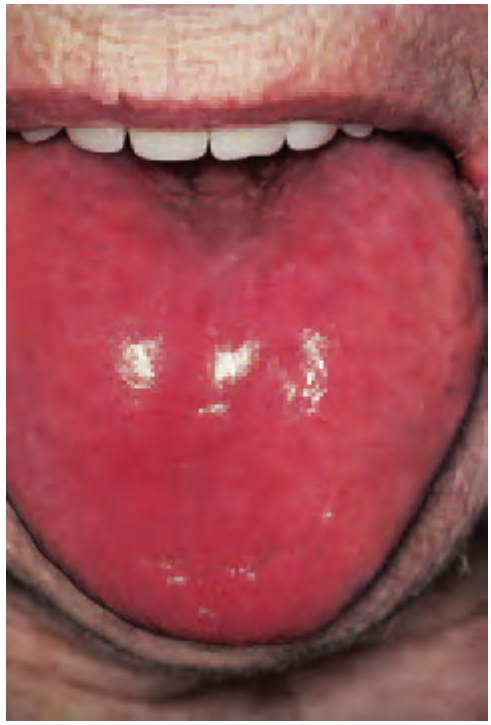

Fig. 66.49 Atrophic glossitis in vitamin B_{12} deficiency.

LP or deficiency states. Geographical tongue and burning mouth syndrome are the common causes of a sore tongue. LP is the most common cause of chronic soreness in the buccal mucosae. Desquamative gingivitis is the common cause of persistently sore gingivae.

Geographical tongue (see p. 66.94)

Lichen planus (see p. 66.61)

Deficiency glossitis

Aetiology. Deficiency glossitis may be related particularly to deficiency of iron, folate or vitamin B_{12}, and may then be associated with angular stomatitis and/or mouth ulcers. Deficiencies of other B-group vitamins occasionally cause glossitis, usually in chronic alcoholics or in those with malabsorption [1–3].

Pathology. Epithelial atrophy, rarely with some dysplasia, is seen.

Clinical features. In anaemic glossitis the tongue is red, sore and smooth (Fig. 66.49). Occasionally pernicious anaemia can also produce red areas or patterns of red lines.

In many other patients the tongue can become sore but appear clinically completely normal and such patients' complaints are liable to be mislabelled as psychogenic.

Diagnosis. A full blood picture and assays of iron, folate and vitamin B_{12} are essential in management, as sore tongue can be the initial symptom of a deficiency and can precede any fall in the haemoglobin level.

Treatment. The cause of the deficiency should be sought before replacement treatment is given.

Burning mouth syndrome

SYN. ORAL DYSAESTHESIA; GLOSSOPYROSIS; GLOSSODYNIA

Burning mouth syndrome (BMS) most frequently affects middle-aged and elderly females [1–4].

Aetiology. Several organic lesions, for example haematinic deficiency states, erythema migrans, ulcers, mucositis, LP and candidiasis, can cause oral soreness or burning sensation.

BMS with a tongue of normal clinical appearance may be seen in deficiency states, and with psychogenic causes, drugs (e.g. angiotensin-converting enzyme inhibitors such as captopril, enalapril, lisinopril; protease inhibitors; cytotoxic agents; clonazepam) and diabetes mellitus. A monosymptomatic hypochondriasis or an underlying anxiety about cancer or venereal disease with perhaps excessive tongue activity appear to be the basis for the complaint of BMS in many patients (Table 66.21) [1–8].

Uncommon causes that may need to be considered include hypothyroidism, lupus erythematosus, hypersensitivity (to sodium metabisulphite, nuts, dental materials and other substances) and galvanic reactions to metals in the mouth [9–12]. However, BMS is often a medically unexplained symptom.

Clinical features. Although the tongue is most frequently involved, the patient may also occasionally complain of burning lips, gums or palate. The burning sensation is usually bilateral and often relieved by eating and drinking [1]. In contrast, oral discomfort associated with inflammatory lesions is typically aggravated by eating.

Diagnosis. Oral examination very occasionally reveals an organic cause. Xerostomia should be excluded as this may predispose to candidiasis. Laboratory screening for anaemia, diabetes, a deficiency state or candidiasis should be undertaken.

Table 66.21 Causes of burning mouth.

Local
Candidiasis
Other infections
Geographical tongue
Lichen planus
Oral submucous fibrosis
Dentures
Systemic
Psychogenic
Cancerophobia
Depression
Anxiety states
Hypochondriasis
Deficiency states
Pernicious anaemia and other vitamin B deficiencies
Folate deficiency
Iron deficiency
Diabetes
Drugs (captopril)

Management. Few patients with BMS have spontaneous remission in the short term, and thus an attempt at treatment is indicated. Reassurance, treatment of any defined underlying organic abnormality and, occasionally, psychological treatment, antidepressants or psychiatric care are indicated, but active dental or oral surgical treatment, or attempts at 'hormone replacement', in the absence of any specific indication, should be avoided. However, treatment is rarely completely successful, although the condition only infrequently becomes severe. Fortunately, about 50% remit spontaneously over 6 or 7 years.

- Patients should avoid anything that aggravates symptoms, such as sparkling wines, citrus drinks and spices.
- Reassurance and attention to any factors such as dentures or haematinic deficiencies may be indicated. There are few treatments of proven benefit [13]. Cognitive–behavioural therapy or a specialist referral may be indicated [14].
- Some patients respond to medication:
  (a) effects of vitamin B are controversial [15,16];
  (b) topical benzydamine 0.01% rinse or spray [17];
  (c) although antidepressants must be given for at least 2–3 weeks to achieve any antidepressive effect, most patients with medically unexplained symptoms show benefit within 1 week [18–20];
  (d) topical capsaicin cream 0.025% (Zacin) or 0.075% (Axsain);
  (e) clonazepam tablet sucked locally;
  (f) α-lipoic acid systemically [21].

White lesions

Acquired white lesions in the mouth are usually innocuous keratoses or caused by cheek biting or chemical burns, but infections, dermatoses (usually LP), neoplastic disorders and other conditions must be excluded (see Table 66.9). Congenital lesions are discussed on p. 66.24.

Cheek biting

SYN. MORSICATIO BUCCARUM

Cheek biting causes a whitish shredded appearance usually of the buccal or lower labial mucosa at the occlusal line (adjacent to where the teeth meet) (Fig. 66.50) [1–3]. The habit is most common in tense or anxious individuals who may also show bruxism, mandibular pain dysfunction or other oral features of psychogenic disorders. The

Fig. 66.50 Frictional keratosis and cheek biting (morsicatio buccarum) at the occlusal line.

lesion is benign but may simulate white-sponge naevus (see p. 66.24).

Burns

Chemical burns (due, for example, to holding mouthwashes in the mouth or drugs against the buccal mucosa) or burns caused by heat, cold or irradiation can cause white sloughing lesions of the mucosa [1–8]. Such lesions typically heal spontaneously within 1–3 weeks.

Lichen planus

See Chapter 42.

Candidiasis

Up to 50% of the healthy population harbour *Candida albicans* as an oral commensal. Carriage is more common in cigarette smokers. *Candida* resides particularly on the posterior dorsum of the tongue [1–5].

Infection is likely to result from xerostomia, local disturbances in salivary flora such as occurs during broad-spectrum antimicrobial treatment, or depressed immune responses [1–4]. Of the several clinical presentations of oral candidiasis, only thrush, candidal leukoplakia and chronic mucocutaneous candidiasis present as white lesions; the other types, acute and chronic atrophic candidiasis, are red (Table 66.22).

Table 66.22 Intraoral candidiasis.

Type of candidiasis	Usual age at onset	Predisposing factors*
Acute pseudomembranous candidiasis (thrush)†	Any	Local: dry mouth, antimicrobials General: corticosteroids, leukaemia, HIV
Acute atrophic candidiasis ('antibiotic mouth'; antibiotic sore mouth)	Any	Broad-spectrum antibiotics or corticosteroids
Erythematous candidiasis	Any	HIV especially
Chronic atrophic candidiasis (denture-induced stomatitis)	Adults	Denture wearing, especially at night
Chronic hyperplastic candidiasis (candidal leukoplakia)†	Usually middle-aged or elderly	Tobacco smoking, denture wearing, immune defect
Median rhomboid glossitis	Third or later decades	Tobacco smoking, denture wearing, HIV
Chronic mucocutaneous candidiasis†	Usually first decade	Often immune defect; rarely endocrinopathy

HIV, human immunodeficiency virus.
* Immune defects can predispose to any form.
† White lesions.

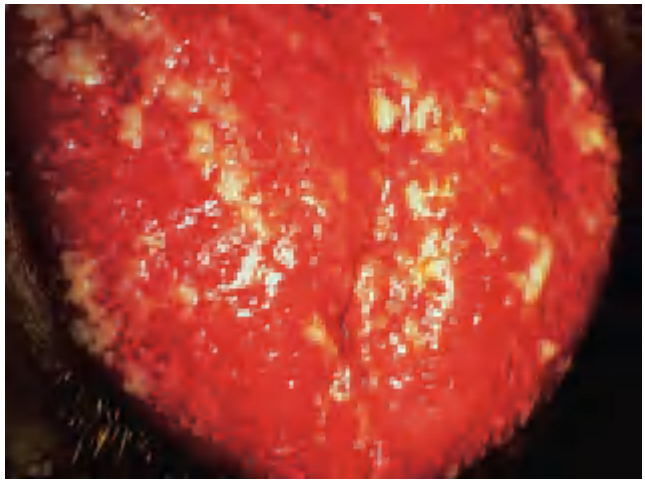

Fig. 66.51 Thrush: scattered white lesions on an erythematous background.

Thrush

SYN. ACUTE PSEUDOMEMBRANOUS CANDIDIASIS

Healthy neonates, who have yet to develop immunity to *Candida* species, may develop thrush. In other patients, predisposing factors include antibiotic or corticosteroid use, xerostomia and severe T-cell immune defects associated with immunosuppression (e.g. given to prevent graft rejection in organ transplantation) or immunodeficiencies such as leukaemia or HIV disease. Oral candidiasis is a common and early feature of HIV infection and may be a portent of developing AIDS [1–4].

The soft creamy patches of thrush, which resemble milk curds, can be wiped off the oral mucosa with gauze, leaving an area of erythema (Fig. 66.51).

Chronic candidiasis

Long-standing oral candidiasis may produce tough, adherent white patches (chronic hyperplastic candidiasis or candidal leukoplakias) which can have a premalignant potential, and may be indistinguishable from other leukoplakias except by biopsy. Candidal leukoplakias may, however, be speckled. In only a few patients with this type of chronic oral candidiasis can either a local cause or underlying immune defect be identified [1–3]. Chronic mucocutaneous candidiasis syndromes are rare (see Chapter 31).

Diagnosis. The diagnosis of oral thrush is usually clinical but it tends to be overdiagnosed by physicians. In contrast, erythematous candidiasis is probably underdiagnosed. In immunosuppressed patients, a Gram-stained smear should be taken to distinguish thrush from the plaques produced by opportunistic bacteria. Hyphae seem to indicate that the *Candida* organisms are acting as pathogens and not simple commensals.

Suspected candidal leukoplakia should be biopsied, both to distinguish it from other non-candidal plaques and also because of possible dysplasia. Although candidal hyphae and a neutrophil infiltrate may be seen on haematoxylin and eosin staining, PAS will demonstrate the purple staining of the hyphae.

Treatment

Acute candidiasis. Except in healthy neonates, possible predisposing causes should be looked for and treated. Topical polyenes such as nystatin or amphotericin, or imidazoles such as miconazole are often indicated but, in HIV infection, fluconazole may be required.

Chronic hyperplastic candidiasis. The oral lesions of chronic hyperplastic candidiasis may respond poorly to the polyenes. These cases, and some cases of chronic mucocutaneous candidiasis, may respond only to flucytosine, ketoconazole, fluconazole or itraconazole [1,6–8].

Leukoplakia

The World Health Organization defines leukoplakia as a white patch or plaque on the mucosa that cannot be rubbed off and that is not recognized as a specific disease entity [1], which implies a diagnosis of exclusion (e.g. of LP, candidiasis). The term is also used irrespective of the presence or absence of epithelial dysplasia, although there is a small premalignant potential to some keratoses [1–3].

Leukoplakia is common in adults: around 1% are affected, although some populations show higher prevalences. Most cases are seen in the 50–70 age group [4–9].

Leukoplakia can be totally benign or sometimes can be precancerous or a marker for cancer elsewhere in the upper aerodigestive tract.

Oral keratoses

Aetiology. The cause of most keratoses is unknown (idiopathic keratoses or leukoplakia) but some are caused by chronic irritation, particular lifestyle habits or infective agents [10–17].

Tobacco-induced keratoses. Consumption of tobacco products has long been causally connected with oral cancer and is a common cause of keratosis. Tobacco use also predisposes to cancers elsewhere in the upper aerodigestive tract, bladder and other sites. Tobacco use should thus be discouraged; the drug amfebutamone (Zyban) may help users break the habit.

Tobacco chewing. Tobacco is chewed in many parts of the world and may induce keratosis. In many communities from the developing world, tobacco is a component of betel quid, along with areca nut and betel leaf, and sometimes slaked lime and spices. Sometimes betel is used without tobacco (pan or paan), though others use paan with tobacco. Oral carcinoma can result.

Reverse smoking (bidi). In some communities, especially in Asia, cigarettes are smoked with the lit end within the mouth. Palatal or other oral carcinoma can result.

Cigarette-induced keratoses. Mild keratosis may be seen especially on the palate, lip (occasionally nicotine-stained) and at the commissures, along with nicotine-stained teeth. Malignant change is uncommon.

Pipe smoking. Diffuse whiteness over the palate is termed 'smoker's keratosis' or 'stomatitis nicotina'. The palatal minor salivary gland orifices appear red against this white background. Malignant change is uncommon.

Cigar smoking. Cigar smokers may develop stomatitis nicotina and nicotine-stained teeth. Malignant change is uncommon.

Snuff dipper's keratosis and other smokeless tobacco lesions. Snuff may produce keratosis—white hyperkeratotic lesions caused by snuff-dipping (holding flavoured tobacco powder in the oral sulcus or vestibule), together with gingival recession at the site of use, often the buccal sulcus. Malignant change is rare.

Other aetiological factors

- Proliferative verrucous leukoplakia is often associated with HPV. Malignant change is uncommon.
- Candidal leukoplakias may be associated with an increased risk of malignant change, although it is uncommon.

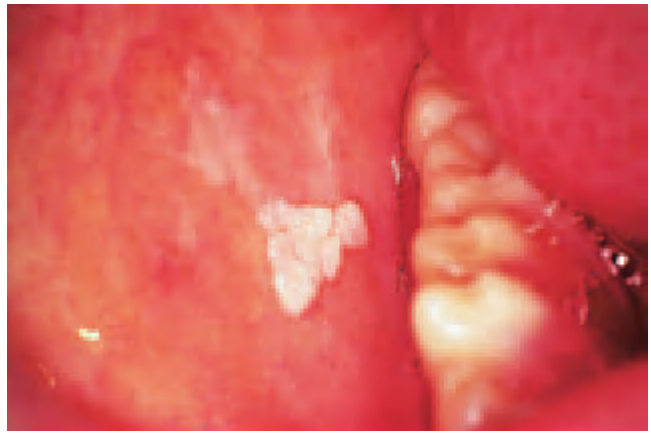

Fig. 66.52 Homogeneous leukoplakia in the buccal mucosa.

- Syphilitic leukoplakia is rarely seen now. Malignant change is uncommon.
- Hairy leukoplakia is caused by EBV and seen especially in HIV disease. Malignant change is not recorded.

Clinical features. Leukoplakias vary in size: some are small and focal, others more widespread, occasionally involving very large areas of the oral mucosa; in other patients several discrete separate areas of leukoplakia can be seen. Leukoplakia has a wide range of clinical presentations, from homogeneous white plaques that can be faintly white or very thick and opaque, to nodular white lesions or lesions admixed with red lesions [1–4]. The malignant potential depends on the following.

Appearance. Homogeneous leukoplakia, the most common, presents with uniformly white plaques, common in the buccal (cheek) mucosa and usually of low premalignant potential (Fig. 66.52).

Non-homogeneous or heterogeneous leukoplakias are nodular, verrucous and speckled leukoplakias that consist of white patches or nodules in a red, often eroded, area of mucosa (Fig. 66.53). They have a high risk of malignant transformation and are therefore far more serious.

Site. High-risk sites for malignant transformation include the soft palate complex and ventrolateral tongue and floor of the mouth (where sublingual keratosis has a particularly high risk of malignant change; Fig. 66.54). Sublingual keratosis is more common in women than men, has a typical 'ebbing-tide' appearance clinically and has a high malignant potential.

Aetiological factors

- Proliferative verrucous leukoplakia is a diffuse white and/or papillary lesion seen in elderly patients, often associated with HPV, and shows an inexorable slow progression over one or two decades to verrucous or squamous cell carcinoma.

Fig. 66.53 Speckled leukoplakia.

Fig. 66.54 Sublingual keratosis.

• Candidal leukoplakias may be associated with an increased risk of malignant change. Chronic candidal infection is common in speckled leukoplakias and *C. albicans* can cause or colonize other keratoses, particularly in smokers, and is especially likely to form speckled leukokplakias at commissures. It may be dysplastic and have higher malignant potential than some other keratoses. Candidal leukoplakias may respond to antifungals and cessation of smoking.
• Syphilitic leukoplakia, especially of the dorsum of tongue, is a feature of tertiary syphilis rarely seen now, although the malignant potential is high.
