Neoplastic change in DLE. Squamous cell and, less commonly, basal cell carcinomas occasionally occur in the scars of DLE, particularly on the scalp, ears, lips and nose. An incidence of 3.3% has been noted in a series of 120 white patients with DLE [1]. They are said to be more common in middle-aged males [2], but in either sex occur only in cases of 20 years' duration or more. Black people with DLE may also develop carcinoma [3,4], especially of the lip. Death may occur from multiple metastases [1,5]. Keratoacanthoma [6], malignant fibrous histiocytoma [7] and atypical fibroxanthoma [8] in lesions have been reported.

Although carcinoma has been considered more common in patients who have had radiotherapy for DLE, 65 out of 100 cases had not had such treatment [9].

Treatment. It is important to carry out a complete medical survey of the patient at the first attendance. Such a survey establishes a baseline by which later progress may be judged. General measures play a large part in successful management. Overwork, mental stress and fatigue are often factors in deteriorating disease, and patients with facial scarring often suffer severe psychological upset and depression [1]. Effective forms of camouflage by covering creams are available and help morale. Patients should be warned against excessive exposure to sunlight, especially those who have noticed exacerbation of lesions by UV light. They should be advised to wear a broad-brimmed hat, and avoid short-sleeved shirts and shorts. A sunscreen cream or lotion should be prescribed. These vary in their degree of protection [2]. A preparation with a UVB protection factor of at least 15 is required, but UVA protection is at least as important. Application should be frequent—probably every 2–3 h in bright sunlight. There are many suitable preparations, and patient acceptability is an important element in the choice of agent. It is important that patients understand the preventative action of these preparations.

Topical therapy can frequently control and sometimes clear lesions without systemic treatment. In one series [3], 43 out of 59 patients could be controlled by applications of 0.025% fluocinolone cream. In another, 0.1% betamethasone 17-valerate cream alone was effective in 68 out of 78 patients, and in a 5-year trial steroid-induced atrophy of the epidermis was not observed [4]. Applications are usually required twice a day. Similar results are given by 0.1% triamcinolone acetonide cream. Unfortunately, the effect is usually only suppressive. The efficacy in resistant cases may be enhanced by applications of the above steroid creams under plastic occlusion, using a self-adherent plastic dressing (e.g. Tegaderm [5]), or by 0.2% fluocinolone or 0.05% clobetasol propionate cream without occlusion.

Topical fludroxycortide (flurandrenolone) cream under a moulded plastic prosthesis has helped persistent painful lesions on the ears [6]. Flurandrenolone (Haelan) tape, in which the topical steroid is on the tacky side of polythene tape, can be cut to size and stuck on individual lesions. Satisfactory results have been obtained by changing the tape weekly. The tape is best for localized lesions on non-hairy and moisture-free areas not subject to excessive movement.

Intralesional corticosteroid injections are helpful in resistant cases [7–9], even on lips, mouth and ears. Triamcinolone acetonide 5–10 mg/mL is injected as superficially as possible into each lesion. Large lesions may require injections at several sites. Injections are usually given at 6-weekly intervals, and from one to 10 may be required. Reversible, and occasionally irreversible, atrophy may result. Intralesional therapy is sometimes surprisingly effective in lesions on the nose and ears and it may also help resistant lesions on the palms and soles [10]. The scalp is usually unresponsive. The Dermojet can be used to deliver intralesional steroid. Intralesional injections of antimalarials, including chloroquine [11], have been tried, but the results were not as good as with corticosteroids and there can be considerable local pain and inflammation. Interferon-α (IFN-α) has also been used intralesionally with success [12]. Among other local measures, cryotherapy, surgical excision [13], painting small lesions with trichloracetic acid and local laser therapy may be helpful. The carbon dioxide laser, and both the pulsed-dye and argon lasers may be valuable for telangiectatic LE [14].

Oral therapy. Most patients referred to hospital will need oral therapy. However, it is always important to reiterate the general measures described above. In addition, vasodilator drugs, particularly calcium-channel blockers such as nifedipine are helpful in those with Raynaud's phenomenon and chilblain lesions, and intravenous prostacyclin may be very helpful in winter, and used before intensive oral therapy in these patients.

For patients with severe, extensive or scarring disease, particularly affecting the scalp, oral prednisolone is often the most helpful initial treatment. A dosage of 0.5 mg/kg, rapidly tapered over 6 weeks is quickly effective, minimizes scarring, and allows the slower acting agents such as antimalarials to work. Long-term therapy with oral steroids is best avoided because of side effects, and there is little doubt that in most cases first-line oral treatment should be with one of the antimalarials (see Chapter 72). Most would start therapy with hydroxychloroquine, initially at 200 mg twice daily, reducing to 200 mg/day once a response is achieved. Chloroquine sulphate is equally effective, usually at a dosage of 200 mg twice daily, but hydroxychloroquine is used first by most prescribers because side effects, particularly eye toxicity, are less likely provided that the dosage limitations of 6.5 mg/kg lean body weight are adhered to [15]. The comparable safe daily dosage for chloroquine is unclear, but is probably around 2.5 mg/kg/day of chloroquine base [15]. Cumulative toxicity is rarely a problem with hydroxychloroquine, although it can occur with chloroquine [16]. For this reason, courses of treatment lasting approximately 6 months are preferred, but this may not be possible in the most severely affected patients who will require on-going therapy. Mepacrine is also useful, and is safe from an ophthalmological point of view [15], but it is often reserved for later use (because of skin pigmentation). It may be used alone, or as part of a combination of antimalarials, which may be more effective than the equivalent amount of each drug given individually [17].

The response to therapy varies: usually, the more tumid lesions with slight scaling respond more rapidly than chronic, atrophic and scarring lesions. Most patients who are going to respond to antimalarials usually do so within 6 weeks. There are few data indicating superiority of one agent over another, but some authors find chloroquine more effective. The milder side effects consist of nausea and vomiting, and patients with such symptoms should be given an alternative antimalarial because some patients can tolerate hydroxychloroquine better than chloroquine, and vice versa. The most serious side effects of antimalarials [18] include corneal deposits, retinopathy, pigmentation of the palate, nails and legs, bleaching of the hair and moustache, exfoliative dermatitis, lichenoid rashes, myasthenia, myopathy, extrapyramidal involuntary movements, neuropathy and mental disturbances, but these are uncommon. Taking an ophthalmological history and arranging for an examination by an optician before treatment in any patient with symptoms not corrected by spectacles may help in avoidance of the ocular manifestations. Monitoring during therapy should include taking an ophthalmic history, and testing reading ability with appropriate charts [15]. More elaborate tests, such as the electro-oculogram and electroretinogram, are no longer believed to be helpful [15].

Approximately 60–75% of all patients are helped by antimalarials. Cigarette smoking reduces the efficacy of treatment with antimalarials, probably by modifying metabolism [19]. Of those who respond, approximately 50% relapse within 6 months, and repeated courses of therapy are usually required. Some patients keep their lesions under control by taking an antimalarial for only a few days at a time. Nevertheless, over the course of several years, most cases treated with intermittent oral antimalarials and topical corticosteroids tend to improve, and some clear completely. Subsequent relapses are often, but not always, less severe than the original lesions. There is no evidence that the continuation of antimalarials after clearance prevents relapses. Hydroxychloroquine appears to be safe in pregnancy [20].

Oral auranofin has helped 50% of patients with long-

standing lesions, particularly on the face and trunk [21]. Some patients may clear completely. A daily dose of 6–9 mg may be needed for up to 1 year. Mild diarrhoea not requiring discontinuation of treatment is the most common side effect, but pruritus, transitory rashes and stomatitis also occur. Liver and renal function must be monitored regularly during treatment. Acitretin [22,23] also appears to be as effective as hydroxychloroquine if given as first-line oral therapy, but tends to be slower in onset and associated with more side effects. Consequently, it is used later, in patients who are unable to tolerate antimalarials or in whom they are ineffective. Unfortunately, when used in these circumstances, neither agent produces response rates much higher than 20% [24]. The same appears to be true of the majority of other agents described as useful in DLE. Etretinate [25] (1 mg/kg/day), preferably combined with chloroquine, has helped patients with chronic hyperkeratotic lesions [26]. Isotretinoin 20–80 mg/day [27] has helped resistant cases, particularly in those with hypertrophic lesions [28]. Dapsone 100 mg/day may help some patients [29,30]. In our experience, ciclosporin is usually unsuccessful in DLE, and others have confirmed this [31,32], possibly because of the resistance to ciclosporin of some circulating suppressor T cells [33]. Oral methotrexate may be useful in patients unresponsive to antimalarials [34].

For cases not responding to topical steroids, antimalarials and sunscreens, oral thalidomide has proved remarkably effective in suppressing lesions [35,36], and also in the treatment of chilblain LE. With an initial dosage of 400 mg/day and a maintenance dosage of 50–100 mg/day, 90% of patients had complete or marked regression of the disease [37]. More recently, lower dosage (100 mg/day) has also been shown to be successful. If used as initial therapy, response rates of 80–90% may be achieved, but when used as second-line treatment the response rate is nearer 50% [24,38]. When treatment was stopped, 71% relapsed, but further courses were effective. Mild side effects were common and 25% had slight to moderate polyneuritic symptoms, which in some patients were persistent. Polyneuropathy was not noticed in a series treated with lower doses [39], although the therapeutic results were not quite as good, and neuropathy can occur with a total dose as low as 3 g [39]. It would seem that 100–200 mg/day, initially for 4–6 weeks, followed by a lower maintenance dosage, should be recommended, with gradual reduction until discontinued. Fertile women should start therapy immediately after menstruation, and must use very strict contraceptive measures because of the teratogenicity of the drug. Patients should be advised not to drive and to avoid alcohol, and the drug must be stopped immediately if polyneuropathy is suspected. Mild side effects of sleepiness, dizziness, constipation, amenorrhoea, dry mouth and dry scaly skin remit on stopping therapy. Impotence may occur.

A number of agents have been reported to help individual cases. Clofazimine (Lamprene) possesses antimalarial activity and suppresses the lesions of DLE in two-thirds of patients. The optimum daily dose is 100 mg. Pink discoloration of the skin is a side effect that is not too disturbing to patients [40]. Danazol may be useful in the treatment of premenstrual exacerbation of DLE [41]. Sulfasalazine (0.5 g three times daily) has been reported to help [42], and phenytoin (100 mg sodium diphenylhydantoin three times daily) may be useful, but 8% have side effects requiring discontinuation of therapy [43]. Beta-carotene is also reported to help some cases [44].

When all of the above have failed in patients with severe and persistent disease, other forms of systemic treatment may be used. Pulsed methylprednisolone 500–1000 mg/day for 2 or 3 days may help resistant lesions, particularly of the scalp. Cyclophosphamide 50–200 mg/day has helped patients with DLE not responding to oral antimalarials or to oral or topical corticosteroids [45]. Intravenous pulses of this drug are also used, usually at a dosage of 10 mg/kg, at 3–4 weekly intervals. It is usually given in combination with intravenous methylprednislone. Azathioprine has helped discoid lesions, even those occurring on hands and feet [46,47]. Undoubtedly, gold by intramuscular injection can be useful [48], but is often very toxic.

IFN-α2a is reported as producing transient improvement [49], and excision of oral lesions also may be practicable [50]. The carbon dioxide (CO_2) [51] and argon lasers [52] may produce improvement of disfiguring LE, although the latter may precipitate DLE [53]. Dermabrasion may help cribriform scarring of the face [54], as may CO_2 laserbrasion. Excision without grafting was successful in a case of verrucous LE following a burn [55].

Subacute cutaneous lupus erythematosus

Definition. Subacute cutaneous lupus erythematosus (SCLE) is a specific 'subset' of lupus first described by Sontheimer *et al*. in 1979 [1]. Patients exhibit mainly cutaneous disease and usually have a good prognosis. Antibodies to the Ro/SS-A antigen are closely associated with this subgroup.

Aetiology. Antibodies to the Ro/SS-A antigen are an almost universal finding in this subset of lupus. That these antibodies may be pathogenic was first suggested by LeFeber *et al*. [2], who demonstrated that sublethal doses of ultraviolet light (UVL) induced the synthesis of Ro/SS-A antigen by cultured human keratinocytes. In addition, they also showed that UVL promoted the expression of Ro/SS-A antigens on the surface of cultured human keratinocytes where they might bind antibodies. In 1988, Ro/SS-A antigen was identified in both adult and neonatal epidermis *in vivo* [3], and subsequent studies have confirmed that UVL increases Ro/SS-A antigen expression on the surface of keratinocytes [2,4,5] and that this is increased by oestrogen [6–8]. Thus, it has been postulated that in photosensitive lupus, UVL exposure leads to increased synthesis and subsequent expression of Ro/SS-A antigen on the surface of keratinocytes where it binds antibody and initiates disease [9]. Further support for this

hypothesis comes from a recent study, which showed that photosensitivity and the titre of Ro/SS-A antibodies correlated with the expression of Ro/SS-A in skin specimens of patients with LE [10].

Although attractive, this hypothesis does not explain why other patients with Ro/SS-A antibodies (e.g. patients with Sjögren's syndrome) do not exhibit photosensitivity and why in the clinical setting Ro/SS-A titres rarely reflect disease activity [11].

HLA antigen status may have a role in disease susceptibility. The most common haplotype in SCLE is HLA-DR3 with HLA-B8, -DR3 being most commonly associated with the annular phenotype and the expression of Ro/SS-A antibodies [12]. HLA-DR2 has been associated with an older age of disease onset and papulosquamous lesions [13]. Recently, two studies [14,15] have reported an association of SCLE with the tumour necrosis factor-α (TNF-α) 308A polymorphism, which may be pathogenic or act as a marker for the HLA A*01, B*08, DRB1*0301 haplotype associated with other autoimmune conditions. Studies of Ro60 exons to see whether sequence alterations might be associated with SCLE have not shown differences between patients with SCLE, DLE or controls [16].

Autoantibody status. SCLE was originally labelled ANA-negative lupus, as these patients often exhibited negative autoantibody screens. This was probably because of the use of test substrates that did not contain suitable antigens for the antibodies found in this group of patients. Using human cell lines as substrates, homogeneous antinuclear antibodies are found in approximately 60% and anti-Ro/SS-A antibodies in approximately 80% of patients [1], rising to higher levels in females [17]. Anticardiolipin antibodies occur in 16% [18].

Histopathology. Histopathologically, SCLE can be differentiated from DLE by the presence of more epidermal atrophy and less hyperkeratosis, basement-membrane thickening, follicular plugging and inflammatory infiltration [19,20]. Colloid bodies and epidermal necrosis are present in more than 50%, especially in those with Ro/SS-A antibodies [21]. Dust-like particles of inter- and intracellular IgG in the basement layers of the epidermis may be a specific feature [22]. It has been suggested that pilosebaceous atrophy is the only significant predictor of DLE versus SCLE [21,23]. Lesional subepidermal immunoglobulin is found in approximately 60%, and is more frequent in papulosquamous (88%) than annular lesions (29%) [1].

Clinical features. This subset [1,24,25], which comprises approximately 10% of patients with LE, have either non-scarring papulosquamous (two-thirds) (Fig. 56.23) or annular polycyclic (one-third) lesions. The disease predominantly affects adults, although SCLE has been reported in a child [26]. Lesions usually occur above the

Fig. 56.23 Subacute cutaneous lupus erythematosus.

Fig. 56.24 Subacute cutaneous lupus erythematosus showing annular polycyclic lesions.

waist and particularly around the neck, on the trunk and on the outer aspects of the arms (Fig. 56.24). The borders may show vesiculation and crusting. Follicular plugging and hyperkeratosis are not prominent, and the lesions resolve leaving grey-white hypopigmentation and telangiectases. The pigmentary changes usually resolve completely. Diffuse non-scarring alopecia and photosensitivity occur in approximately half of patients, and other features include mouth ulceration (especially of the palate), reticular livedo, periungual telangiectasia and Raynaud's phenomenon. Presentation with pityriasiform lesions [2], erythroderma [27] and generalized poikiloderma [28] has

been described. Morphoea [29] and dystrophic calcinosis cutis [30] have followed SCLE.

Approximately half of patients fulfil the criteria for SLE of the American Rheumatism Association (ARA) [31], with arthritis the most frequent feature. Fever, malaise and central nervous system involvement occur, but renal disease is mild and infrequent, although a recent study suggested that the latter may occur in up to 16% of patients [32]. Chronic interstitial pneumonitis has been reported [33] as has hypokalaemic tetraparesis [34]. Occasionally, the annular lesions may resemble the lesions of Rowell's syndrome or the gyrate erythema secondary to occult malignancy [35]. Some patients also have Sjögren's syndrome [36], rheumatoid arthritis, deficiency of the second [37], third [38] and fourth [39] components of complement, Sweet's syndrome [40], Crohn's disease [41], lichen planus [42], hereditary angio-oedema [43,44], porphyria cutanea tarda [45], gluten-sensitive enteropathy [46], toxic epidermal necrolysis [47], inclusion body myositis [48] or calcifying lupus panniculitis [49]. A number of drugs have been reported to precipitate or exacerbate SCLE, including thiazide diuretics [2], griseofulvin [50], terbinafine [51,52], cinnarizine [53], calcium-channel blockers [54] and etanercept [55]. SCLE may occur in the course of PUVA treatment of psoriasis [56], radiation therapy [57] and IFN-β1a therapy [58]. There have been occasional reports of associations with cancer, namely breast carcinoma [59], meningioma [60], hepatocellular carcinoma [61], Hodgkin's disease [62] and lung cancer [63]. Occasional patients develop overt SLE with severe visceral disease [64].

Treatment. The condition in most patients is controlled by sunscreens [65] and topical or intralesional corticosteroids [66]. In those not responding to these agents, antimalarial drugs are often helpful. These can be used as either hydroxychloroquine or chloroquine base, although the former is safer from the ophthalmological point of view and requires less ophthalmological monitoring [67]. The antimalarial mepacrine (quinacrine) does not have ocular side effects but does induce yellow discoloration of the skin. There is evidence that a combination of antimalarials may be more effective than either alone [68] and that they are less effective in smokers [69]. Patients not responding to antimalarials may respond to oral corticosteroids or methylprednisolone [70], etretinate [71], acitretin [72], isotretinoin [73,74], dapsone [75], methotrexate [76,77], thalidomide [78–80], UVA [81], IFN-α [82], long-term cefuroxime axetil [83] or mycophenolate mofetil [84].

Systemic lupus erythematosus [1,2]

Definition. A systemic disease characterized by multisystem organ inflammation, most commonly the skin, joints and vasculature, and associated immunological abnormalities. The main clinical features include fever, rashes and arthritis, but renal, pulmonary, cardiac and neurological involvement may occur, with increased mortality. For any individual patient, the ARA criteria may be used as an aid to diagnosis (Table 56.3).

Incidence. SLE is an uncommon disease [3–9], with incidence estimated at 1–12.5 in 100 000 per year at Leeds General Infirmary; for every case of SLE there are six cases of pernicious anaemia and 10 of leukaemia. The condition is universal, but is three times more common in black people than in white people [3]. Younger black American females are particularly predisposed to the disease [4], although it is rare in native Africans. It is also common in the Chinese and in New Zealand Polynesians [5]. The pattern of disease appears to be different in such ethnic subgroups, with black Americans and Hispanics having the highest rate of internal organ damage [6]. A study in Hawaii gave similar racial variation, with the prevalence in those of Chinese origin being 24.1 in 100 000, whereas that in whites was 5.8 in 100 000 [7]. The incidence of newly diagnosed cases in New York is 10–14 per million population [8]. The prevalence varies from less than 1 in 1000 for black females in New York [9] to approximately 1 in 2000 white females in San Francisco, and recent figures for England and Wales suggest a prevalence of 12.5 in 100 000 women, although this is an underestimate [10]. The observed annual incidence increased from 25 per million in 1955 to 50 per million in 1959 [11]. In Hong Kong, in 1987, the incidence was 2.4 in 100 000 [11], and in Baltimore, in 1985, it was 4.6 in 100 000, a twofold increase over the preceding 15 years. Self-reported physician-diagnosed SLE occurred in 124 in 100 000 in the USA [12]. This suggests that the disorder may be more common than it used to be, but it may also represent better awareness and earlier diagnosis. An epidemiological survey in New York showed that morbidity and mortality rates were highest among black people, followed in descending order by Puerto Ricans and then other white people. Racial differences were independent of housing, overcrowding and migration, but were associated with racial variation in normal gammaglobulin levels, which were higher in black people [6]. A more recent study from England confirms the increased risk of SLE in Afro-Caribbeans and Asians, irrespective of their place of birth [13]. Familial cases occur in approximately 10% [14,15]; relatives of patients with SLE also have an increased incidence of SLE and DLE, rheumatoid arthritis, rheumatic fever, polyarteritis nodosa, dermatomyositis and poikiloderma atrophicans vasculare [16].

The condition tends to occur in early adult life, and the peak age of onset of the first symptom or sign in females is approximately 38 years (35.5 in black women, and 40.7 in white women); it is 44.2 in men [17]. The incidence of the disease is the same in all age ranges, although serositis and Sjögren's syndrome are more common disease manifestations in the elderly [18]. Most authors agree that females outnumber males by a ratio of approximately 8 : 1, but the features in males are the same as in females [19].

Table 56.3 American Rheumatism Association criteria for diagnosis of systemic lupus erythematosus.

1	Malar rash
2	Discoid rash
3	Photosensitivity
4	Oral ulcers
5	Non-erosive arthritis
6	Serositis—pleurisy or pericarditis
7	Renal disorder—persistent proteinuria (> 0.5 g/day) or cellular casts
8	Neurological disorder—seizures or psychosis
9	Haematological disorder—haemolytic anaemia or leukopenia (< 4000/mm) or lymphopenia (< 1500/mm) or thrombocytopenia (< 100 000/mm)
10	Immunological disorder—LE cells or anti-DNA antibody or anti-Sm antibody or false-positive serology for syphilis (longer than 6 months)
11	Antinuclear antibodies

LE, lupus erythematosus.

Aetiology. The aetiology of SLE remains unknown. Aetiological theories must account for the known variations in the incidence of the disease, the marked immune dysfunction, known precipitating factors and the clear familial predisposition.

Genetic factors. There is considerable evidence to suggest that genetic factors play a part in the pathogenesis [1]. The condition has been reported in identical twins [2,3], with a concordance rate of 65% [2]. Of all cases, 4% are familial [4], with marked concordance of disease expression between parents and offspring. The onset of SLE in identical twins occurred within 2 years, compared with an interval of 9 years between siblings and 20 years between parents and offspring [5]. However, the onset of disease in siblings is temporally rather than age-related, indicating a possible environmental factor [6]. Occasionally, identical twins may be discordant for SLE. In this case, the non-affected twin does not have abnormalities of helper and suppressor T-cell numbers and activity, and has different cellular immune responses [7,8]. The incidence of SLE is probably higher in XXY males with Klinefelter's syndrome [9]. Relatives of patients with SLE have a higher incidence of connective tissue disease, hyperglobulinaemia and antinuclear factor than the relatives of matched controls [10,11]. They may also show increased incidence of anti-RNA and lymphocytotoxic antibodies, specific anti-DNA antibody idiotypes [12], anticardiolipin antibodies [13] and impaired suppressor T-lymphocyte function [14], although these are not related to disease expression [15].

Studies of histocompatibility antigens further support a genetic predisposition. White people with SLE have increased frequencies of HLA-B8 [16], -DR3, -A1 and -DR2 [17]. Similar associations have been confirmed in black people [18,19], as has an association with immunoglobulin allotypes Gm 1 and 17 [20]. HLA-DQ antigens may be even more closely related to the risk of developing the disease, and different alleles may be implicated in the risk of developing the disease from those that influence its expression [21]. There is evidence of linkage disequilibrium between B8-DR3 and alleles at the DQ locus, which is prevalent in patients who express anti-Ro antibodies [22].

Eighty per cent of patients (compared with 40% of controls) have null complement alleles [23], mainly at the C4A or B locus [24]. HLA-DR2 and the C4A null allele are independent and additive risk factors in SLE [25]. Deficiency of complement factors C5–9 is relatively common in familial cases of SLE. Genetic factors other than HLA and complement component deficiencies may also be involved [26]. The results of genome scanning of family pedigrees multiplex for SLE, including over 400 sib pairs and 175 affected relatives, suggest an epistatic interaction between chromosome 14p16-15.2 and chromosome 5p15 in European American families [27].

Autoantibodies [1,2]. Non-organ-specific humoral autoantibodies are the hallmark of SLE. A range of autoantibodies may be present in the disease, although some are more disease-specific (anti-double-stranded DNA and anti-Sm antibodies), and some are much more commonly found (antinuclear anti-Ro antibodies). The disease could be produced by the development of such antibodies against tissue antigens to which tolerance has been lost by failure of homeostatic immunological mechanisms. This could occur either because of polyclonal B-cell activation or specific antigenic drive. There is evidence for both mechanisms of production of autoantibodies [3]. There is also considerable evidence that such non-organ-specific autoantibodies are not the primary pathogens: they are not specific to any disease, they are not present in all cases, their titres are independent of the activity of the disease, they are transmitted across the placenta without apparently harming the fetus [4] and they can be transfused into human volunteers without causing any apparent disease. In animal models, however, antinuclear antibodies can intensify experimental inflammatory lesions [5]; there is also evidence for involvement of immune complexes containing antinuclear antibody (either deposited or formed *in situ*) in the renal lesion of SLE as well as in tissue damage in other sites [6]. Recent evidence suggests that these antibodies may be formed against DNA-containing debris which is packaged into a vesicle after cells have undergone apoptosis, so-called 'apoptotic bodies' [7,8]. Anti-DNA antibodies bind the DNA receptor on white blood cells and block the binding and sequestration of free DNA by mononuclear cells [9]. These antibodies also produce the release of IFN-γ from mononuclear cells, enhancing immunological and inflammatory reactions [10]. Anti-Ro or closely related antibodies are implicated in the development of the rash and heart block found in neonatal LE (see p. 56.54), and possibly in other childhood SLE. The antiphospholipid antibodies, including the so-called lupus anticoagulant, are linked to thrombosis and abortion in patients with SLE (see p. 56.69). Conversely, neurofilament autoantibodies occur in 21% of patients with SLE, but do not correlate with neurological involvement [11]. Antiribosomal P proteins are highly specific for lupus psychosis [12]. Recent evidence suggests that there is switching of antibody types between the active and quiescent stages of the disease, with low-affinity IgM antibodies present when the disease is controlled, and high-affinity IgG, often directed against endothelial cells, being present when the disease is active [13]. Antiendothelial cell antibodies are associated with renal and vascular complications [14].

Idiotypes and anti-idiotypes [15]. Idiotypes are the antigenic determinants of immunoglobulin molecules and are found in the variable region of these molecules and the T-cell receptor. Antibodies to these antigens develop (anti-idiotype antibodies), and are themselves capable of stimulating anti-anti-idiotype antibodies. Thus, complicated networks of antibodies develop, which are involved in the mechanisms of autoimmunity and self-recognition. Anti-idiotype antibodies may have some of the capabilities of the original antigen, and may also cross-react with other self-antigens, interfering with the development of tolerance produced by the removal of self-reactive T cells. This interference would allow the development of the 'forbidden clones' originally predicted by Burch and Rowell [16]. Cross-reaction between self-antigens and those derived from extraneous sources such as infection or other environmental agents may provide the original source of anti-idiotype antibodies [17].

Other immune factors. Impaired cell-mediated immunity in SLE has been demonstrated by a variety of techniques. Decreased leukocyte migration inhibition [1], lymphocyte transformation responses to common antigens [2] and decreased skin-test responses to purified protein derivative, candidin and streptokinase-dornase [3] are related to disease activity [4]. T-cell counts are diminished [5] and null cells are increased [6] in active disease. It would appear that there is an imbalance between T and B lymphocytes in the disease, with depressed cellular immunity and an overactive humoral antibody response, possibly related to a relative lack of suppressor and/or inducer T cells [7], although all T-cell types are reduced, and their function is impaired [8]. IL-2 production by peripheral blood leukocytes is impaired, reducing the inhibitory effects of T cells on activated B cells [9].

There is a reduction in activated B cells, but hyperactive B cells are increased in SLE [10], and their differentiation abnormally stimulated by monocytes [11]. Autologous serum has been found to modify leukocyte migration inhibition to liver antigens in SLE [12] and this blocking of cell-mediated immunity, if active *in vivo*, might be a factor in the waxing and waning of clinical activity. There is some evidence that in remission there is a return of immunological suppressor function despite a persisting impairment of T-lymphocyte reactivity [13]. Antibody-dependent cellular cytotoxicity may be another pathogenic factor, and antibodies directed against lymphocyte membranes are found in SLE. Serum-induced cytotoxicity occurs to both T cells [14] and human target cells [15], and immune complexes may be implicated [16]. Circulating immune complexes occur in approximately half of patients, especially those with active and extensive disease [17]. Lymphocytotoxins can be demonstrated in approximately one-third of cases [18]. Killer cell activity is increased [19]. Complement activation occurs, and the anaphylatoxins C3a and C5a are increased during disease exacerbations, possibly contributing to the pathogenesis of the vascular lesions [20].

UV radiation. This may precipitate the onset or exacerbate the course of SLE in up to 60% of patients [1,2]. Phototesting to UVB [3] and UVA [4] shows reduced minimal erythema doses and the development of skin lesions in patients with LE. The mechanism of action of UV radiation in SLE remains unknown, although antibodies to UV radiation-denatured DNA can be demonstrated. There is no defect of DNA repair in SLE [5], and the antibodies to denatured DNA have no clinical or immunological correlations [6]. The expression of Ro antibody can be induced on cultured keratinocytes by UV radiation [7], and this antibody is commonly found in photosensitive patients. However, there is no relationship between absolute levels of Ro and disease activity [8]. Fibroblasts and lymphocytes

from patients with SLE are abnormally sensitive to UVA and UVB exposure [9].

Environmental factors. Lupus-like disorders have been reported in association with a variety of environmental factors [1]. Although early reports suggested that silicone breast implants are more frequently associated with connective tissue diseases including lupus-like syndromes, scleroderma, fibrositis, inflammatory myopathy and autoimmune thyroid disease [2], recent studies show that the incidence is no higher than in control populations [3]. Haemolytic anaemia with high titres of antinuclear and anti-dsDNA antibodies has followed the ingestion of sprouts, seeds and dietary supplements of alfalfa, which contains the amino acid L-canavanine [4]. Heavy metals including cadmium, mercury and gold have also been associated with autoimmunity [5]. Other industrial factors include silica [6,7] and trichlorethylene [8].

Infections, stress, hormonal factors. Other factors may precipitate the onset of SLE, and these include bacterial infection and mental or physical stress. A role for antigens derived from infecting organisms in the generation of anti-idiotype antigens [1] has been suggested, and microbial superantigens may stimulate abnormal T- and B-cell interactions, resulting in the state of autoimmunity found in SLE [2]. Infection is more common in SLE than in those not affected, and depressed generation of serum chemotactic factors may contribute to this increase [3]. Initial phagocytosis by polymorphonuclear neutrophils and macrophages is reduced [4].

As markedly more females than males are affected in early adult life, it has been suggested that endocrine factors may be involved [5]. In addition, 20% of female patients have premenstrual flares of skin disease, and a small number present after initiation of oestrogen-containing contraceptive therapy [6]. Levels of circulating androgens are reduced in women with SLE compared with normal controls [7], and men with SLE have reduced testosterone levels [8], indeed hypogonadism from whatever cause may be an aetiological factor in SLE [9]. Prolactin is an immunoregulator, and is secreted by immunologically active cells, suggesting an autocrine effect [10]. Normal humoral and cellular immune responses are greater in females than in males, but this may be a result of the influence of oestrogen on gene expression, rather than on immune responses [11]. A late menarche is associated with an increased risk of SLE in Japanese patients [12]. There is some evidence that neuroendocrine factors play a part in immunity, which could to some extent explain the influence of stress factors in the disease [13].

Viruses. An infective cause for SLE has long been postulated. Myxovirus-like tubular structures have been found in the endothelium of arterioles, venules and capillaries of the subpapillary plexus and in the cells of the dermal infiltrate in both involved and uninvolved skin [1], as well as in the endothelial cells of glomeruli in patients with renal involvement resulting from SLE. They are also present in approximately one-quarter of patients with various types of renal disease, but not in normal subjects [2]. They have not been confirmed as viruses [3], and indeed can be induced by the action of IFN [4], suggesting an immunological rather than viral origin. Equally, they could represent cellular material phagocytosed by endothelial cells. If they are genuine virus particles, they could act as a precipitating factor in predisposed subjects. The high incidence of antibodies to reovirus double-stranded RNA (70%) [5] and raised titres of antibody to measles and rubella antigens [6], suggest potential viral involvement, but this may be only an expression of T-cell suppression in this disease. There is no evidence of retrovirus infection in SLE [7], but endogenous retroviral DNA sequences are found [8]. Recently, a number of cases of SLE have been reported following acute parvovirus infection [9]. Warts are more frequent than expected, especially in elderly patients, although the incidence of wart virus antibodies is decreased [10], implying a defective immune mechanism. There is an inverse relationship between the occurrence of warts and rheumatoid factor.

Drugs. The precipitation of SLE by drugs [1–3], especially the antihypertensive hydralazine, is well known. However, there are features to suggest that drug-induced SLE differs from the spontaneous disease: it is uncommon in black people, it occurs in an older age group, renal and central nervous system involvement are infrequent, antihistone antibodies are frequent, anti-DNA antibodies are absent and serum complement is normal. Hydralazine is known to inhibit binding of complement component C4, and this action, with subsequent lack of control of complement activity, may explain the development of lupus-like syndromes.

Cutaneous involvement in drug-induced SLE may be vasculitic [4], bullous [5], erythema multiforme-like [6] or resemble pyoderma gangrenosum [7]. Cases have been reported of hydralazine-induced lupus with Sweet's syndrome [8]. It was thought that the clinical manifestations of drug-induced lupus resolved when the drug was withdrawn, but this is not necessarily so, and patients with hydralazine-induced syndromes may have hyperglobulinaemia and other abnormalities before the administration of hydralazine [4,9]. Patients who develop antinuclear antibodies during treatment with hydralazine need not have the drug stopped unless they have features of the lupus syndrome [10], which occurs in 6.7% of patients after 3 years' treatment with hydralazine [11]. It is dose-dependent, occurring in 5.4% on 100 mg/day and 10.4% on 200 mg/day, but not at all on 50 mg/day. The incidence is much higher in women (11.6%) than in men (2.8%). Some authors suggest that hydralazine can be safely used in SLE in conjunction with immunosuppression [12]. Twenty-four cases of lupus induced by minocycline [13] have been reported. It usually occurs after 2 years of therapy. Patients who require more than 1 year's therapy should have ANA and liver function tests monitored. Other drugs, particularly certain anticonvulsants and procainamide, are known to precipitate SLE-like syndromes (Table 56.4). Drugs recently associated with lupus syndromes have been reviewed [1].

Drugs have been implicated in precipitating or activating SLE in 3–12% of cases [14]. There is an increased incidence of HLA-DR4 in drug-induced SLE [15] and the ratio of females to males is 4 : 1, indicating a possible genetic predisposition. It appears that individuals who are slow acetylators are more likely to develop drug-induced LE or LE-like syndromes [16]. The determination of acetylator type and DR typing may enable susceptible patients to be identified. In spontaneous SLE, however, there appears to be a preponderance of slow acetylators [17], although this

Table 56.4 Drugs inducing systemic lupus erythematosus-like syndromes.

Acebutolol	Oral contraceptives, including:
Allopurinol	Chlormadinone
Aminoglutethimide	Ethinylestradiol
p-Aminosalicylic acid	Etynodiol diacetate
Atenolol	Medroxyprogesterone
Captopril	Mestranol
Carbamazepine	Norethindrone
Chlorpromazine	Norethisterone
Clobazam	Norethynodrel
Clofibrate	Oxprenolol
Co-trimoxazole	Oxyphenisatin
Diphenylhydantoin	Penicillamine
Ethosuximide	Penicillin
Gold salts	Phenylbutazone
Griseofulvin	Phenothiazine
Guanoxan	Phenytoin
Hydralazine	Pindolol
Hydrochlorothiazide	Piroxicam
Hydroxyurea (hydroxycarbamide)	Practolol
Ibuprofen	Primidone
Interferon	Procainamide
Isonicotinic acid hydrazide	Propranolol
Isoquinazepon	Propylthiouracil
Labetalol	Quinine
Leuprolide acetate	Recombinant interferon
Lithium carbonate	Streptomycin
Methyldopa	Sulfasalazine
Methylphenylethylhydantoin	Sulphonamides
Methylthiouracil	Tertalol
Methysergide	Tetracycline
Minocycline	Timolol eye drops
Minoxidil	Trimethadione
Nitrofurantoin	Valproate
	Venocuran
	Vostatin/simvastatin

is disputed [18]. There does not appear to be a correlation between acetylator phenotype and clinical manifestations, antinuclear factor or activity of the disease [19].

Antihistone antibodies are not drug-specific, although different drugs do induce antibodies to different histone epitopes, and the antibodies are often present well before clinical manifestations occur [20]. Indeed, 50% of procainamide-treated patients develop immunological abnormalities, whereas only 20% develop clinical disease [21]. Of patients with drug-induced lupus syndromes, 82% have antihistone antibodies, compared with 32% of those with serological changes only [20].

Relationship of genetic and environmental factors and autoimmunity. The relationship of genetic factors, possible virus infection and depression of cell-mediated immunity has led to the suggestion that genetic factors might allow virus replication in the thymus and in T cells, inducing damage to these cells and hence defective cellular immunity. The age pattern of the disease and its female predominance suggest that these abnormalities appear to affect only a specific susceptible genotype, involving three dominant X-linked alleles. Phenotypic expression then depends on accumulated randomly occurring changes in lymphoid stem cells, with three 'forbidden' clones of lymphocytes developing [1–4], and with hyperglobulinaemia and autoantibody formation from hyperactive B cells and the lack of T-cell suppression following. Normal defence mechanisms, which are more effective in females, prevent these changes persisting, but may be impaired by infections, drugs, UV radiation and stress, thus precipitating the disease. Organ involvement is determined by genetically controlled antigenic expression in target tissues. Such a concept would explain the sex differences, the occurrence

of clinical and subclinical autoimmune disease and antibodies in the relatives of patients, the apparent spontaneous onset in many cases, and the precipitation and exacerbation of clinical manifestations by factors impairing the defence mechanisms.

Pathology (Table 56.5). The pathological changes of SLE have been well described. The primary lesions of SLE are fibrinoid necrosis, collagen sclerosis, necrosis and basophilic body formation, and vascular endothelial thickening. The basophilic (haematoxylin) bodies are aggregates of homogeneous material staining blue with haematoxylin and staining positively for DNA by the Feulgen technique. This material is similar to that of the homogeneous nuclear material of the LE cell.

Macroscopic appearances. Despite the widespread clinical manifestations and fatal outcome, it is often disappointing to find no macroscopic changes at autopsy. Sometimes, terminal changes and infection obscure the picture. Frequent macroscopic findings include pleurisy with adhesions and effusion, and pericarditis, especially if the patient has died with uraemia. The verrucose vegetations of Libman–Sacks endocarditis are diagnostic (Fig. 56.25) [1]. These are small firm warty deposits, up to 0.5 cm in diameter, adherent to the valves of both sides of the heart and adjacent endocardium of the ventricles, chordae tendinae and on the papillary muscles. Sometimes, lesions of subacute bacterial endocarditis may be superimposed on the warty lesions.

Microscopic appearances. Usually, pathological diagnosis requires histology, but in some cases histological changes can be demonstrated only by immunohistological techniques (Fig. 56.26) [2]. Immunohistology is also useful in diagnosing SLE in patients with a rash.

Skin. There is no single diagnostic pathological feature in the skin, but a combination of features aids diagnosis [3]. Some changes, such as hyperkeratosis without parakeratosis, and keratotic plugging of the hair follicles and glandular orifices, are similar to those found in chronic DLE. There may also be some atrophy or acanthosis of the prickle cell layer. Liquefaction degeneration of the basal cell layer is common. Epidermal necrolysis has been

reported [4]. The dermal tissues may be oedematous, and sometimes vesicle formation occurs at the dermal–epidermal junction, with dilatation of the superficial vessels and perivascular lymphocytic infiltration. Occasionally, dermal mucinosis occurs, especially in papular lesions [5] and in areas of alopecia [6]. Pigment-containing chromatophores may occur in the infiltrate. Sometimes, the infiltrate is widely distributed in the upper portion of the dermis, being most pronounced in the more chronic type of lesions. Using monoclonal antibodies, the infiltrate is shown to consist of abundant T cells and Ia-positive cells, with rather fewer B cells and macrophages. Helper or inducer T cells and suppressor or cytotoxic T cells occur in equal numbers [7]. Fragmentation, splintering and oedema of the elastic tissue occur. Changes in the walls of blood vessels are relatively infrequent, but hyaline changes and fibrinoid degeneration occur.

Immunohistology [8,9]. Immunoglobulins, predominantly IgG, but less frequently IgM and IgA, together with complement (C1, C3) can be demonstrated at the dermal–epidermal junction by immunofluorescence techniques [10,11]. They occur in more than 80% of skin lesions of DLE and SLE, and may be preceded by basement-membrane abnormalities in erythematous and purpuric lesions [12]. Deposits occur more frequently in light-exposed areas and are invariably present in acute lesions, although in early and late stages the test may be negative. If IgG, IgM and IgA are all present, the diagnosis of SLE is likely, and the more common combination of IgG and IgM is also suggestive. Single immunoglobulins favour another diagnosis (see DLE). The basement-membrane phenomenon can also be demonstrated in the uninvolved skin in three-quarters of active cases of SLE if the biopsy specimens are taken from the exposed skin, preferably from the dorsum of the wrist or forearm. Biopsy specimens from the unexposed skin are positive in only approximately 50% of cases, which may or may not have more severe renal disease and decreased long-term survival [13,14]. Variability in the presence of immunoglobulins and complement in adjacent sites of both light-exposed and light-protected areas probably accounts for differences between series. Biopsy specimens taken from oedematous areas may be negative. The presence of IgG in unexposed normal skin rarely occurs without SLE, and indicates a poorer prognosis than the presence of IgM or the absence of deposits. An IgM band may be found in other diseases, and without other evidence is not sufficient to make a diagnosis of LE [15]. IgM can be found in 80% of lesion-free sun-exposed skin in patients with actinic keratoses [16]. Deposits also occur in patients without rashes or may be present before other features of LE develop. Positive tests may come and go depending on activity, and decrease after treatment or in remission. Deposits in uninvolved skin may occasionally occur in systemic sclerosis, mixed connective tissue disease, dermatomyositis, anaphylactoid purpura, hypocomplementaemic vasculitis, rheumatoid arthritis, pemphigoid and dermatitis herpetiformis. This basement-membrane phenomenon can also be demonstrated in the uninvolved skin in patients with the so-called transitory type of DLE [17]. This is a subgroup of DLE, described by Baart de la Faille-Kuyper [18], with cutaneous lesions of DLE and immunoglobulins at the dermal–epidermal junction in uninvolved skin, as in SLE, but no definite clinical or serological evidence of the latter. The basement-membrane phenomenon is negative in uninvolved skin in other cases of DLE. The staining may be homogeneous or granular, or there may be larger aggregates under the dermal–epidermal zone [19]. Burnham and Fine describe homogeneous, thready and stippled patterns [20], which are different from the 'tubular' band of bullous pemphigoid [21]. The stippled band occurs in uninvolved skin, thready bands in new lesions and homogeneous bands in older chronic lesions. The band type depends on the type of skin lesion and does not distinguish between DLE and SLE. The presence of complement at the dermal–epidermal junction in patients with widespread SLE without renal disease may be associated with a lowering of the serum complement [22]. Both fibrin and properdin have been demonstrated in the lesions of SLE [23]. Properdin deposition in normal skin appears to correlate with disease activity [24]. The presence of properdin suggests that the alternative pathway of complement activation is involved, but nevertheless the classical pathway is the primary complement pathway involved in SLE. In drug-induced SLE, deposits of IgG, IgM and C3 at the dermal–epidermal junction may disappear when clinical symptoms regress [25].

Epidermal nuclear deposits, usually giving a speckled IgG pattern, occur in the basal epidermal nuclei and cells of the lower epidermis in nearly one-third of patients [26]. Immunoglobulin (IgG, IgA and IgM), with or without complement, can be found in the walls of blood vessels in skin lesions and uninvolved skin. There may be homogeneous fluorescence of the subendothelial part of the vessel wall, or intramural or perivascular granular fluorescence, and these changes are present in discoid, transitory and systemic LE. Homogeneous staining occurs in the uninvolved skin of 20% of patients with DLE and over 80% of patients with transitory or systemic LE. Electron microscopy of involved and uninvolved skin has shown deposits of proteins on the dermal side of the dermal–epidermal junction and in small blood vessels, resembling morphologically those present in 'wire-loop' lesions in the kidney [27].

Internal organs. The characteristic microscopic features in the internal organs include haematoxylin bodies in the heart valves and elsewhere, periarterial fibrosis of the spleen, and the so-called 'wire-loop' lesions in the kidneys.

In the heart, microscopic changes, including fibrinoid necrosis, may occur in normal-looking valves. The vegetations of Libman–Sacks endocarditis [1] occur in 50% of cases coming to autopsy [28], and arise from proliferation of ground substance and connective tissue cells [29], which raise the endothelium. Focal necrosis occurs in these areas, and basophilic bodies are frequently seen. Later, infiltration with inflammatory cells occurs, together with fibrosis. Focal atrophy and fibrosis occur in the myocardium, but myocarditis is unusual.

The lungs frequently show pulmonary oedema and infective changes, but specific abnormalities are uncommon. Pulmonary parenchymal lesions or pleuritis occurred in 18% of one series [30], and other findings included interstitial fibrosis, pulmonary vasculitis, haematoxylin bodies and pneumonitis. A mucinous basophilic oedema of the alveolar walls occurs, with a hyaline alveolar lining membrane similar to hyaline membrane disease of the newborn. Alveolar wall thickening and vascular changes similar to those of Hamman–Rich syndrome may be found.

The liver may show infiltration of the portal tracts with lymphocytes, histiocytes and plasma cells. The so-called 'onion skin' appearance in the spleen is caused by concentric periarterial fibrosis around central and penicilliary arteries.

The lymph-node enlargement is usually associated with retention of normal architecture, but sometimes necrosis and haematoxylin bodies may be found.

The so-called 'wire-loop' appearance in the kidneys is caused by thickening and hyalinization of the capillary basement membrane of the glomerular tufts. Although this change may be seen in other diseases such as systemic sclerosis, chronic glomerulonephritis and malignant nephrosclerosis, the changes in SLE are more likely to be localized to one part of the glomerulus. Thickening of the glomerular capillary basement membrane and alterations in reticular tissue in the media of arterioles are associated with deposits of IgG and C3 [31]. Lupus nephritis has been divided into three types [32]: focal proliferative (lupus glomerulitis) and membranous, which are relatively benign, and diffuse proliferative (lupus) glomerulonephritis, which has a poor prognosis. In focal proliferative nephritis, a mild proliferation is confined to parts of some of the glomeruli and electron microscopy shows no electron-dense material. In membranous lupus nephropathy, there is irregular thickening of the glomerular basement membrane with epimembranous deposition of electron-dense material. The most common renal disorder is diffuse proliferative nephritis, in which there is irregular endothelial cell proliferation, fibrinoid necrosis, hyaline thrombi and interstitial inflammatory changes. Electron-dense deposits are seen on electron microscopy in subendothelial, subepithelial and mesangial areas. Heavy proteinuria with large numbers of red and white cells and casts in the urine suggests glomerulonephritis [33]. Although most cases of the nephrotic syndrome and renal vein thrombosis show membranous glomerulonephritis, focal proliferative glomerulonephritis has also been reported [34].

Germinal centres in the thymus are frequently increased [35]. Abnormal epithelial hyperplasia in the thymus is said to occur in all cases of SLE, but the change is not specific [36].

There may be evidence of widespread vasculitis in other organs and in the central nervous system. Although the vasculitis in the nervous system is usually mild, it can be florid [37]. Gammaglobulin deposits and complement have been found in the choroid plexus when immunohistology of the cerebrum, cerebellum and brainstem has shown no abnormality [38]. This, together with the finding of low cerebrospinal fluid complement levels [39], suggests an immune-complex pathogenesis for the involvement of the central nervous system.

Clinical features. See Table 56.6 for an analysis of the clinical features of several series.

Table 56.6 Clinical features of systemic lupus erythematosus.

Clinical feature	Percentage
Fever	90
Arthritis and arthralgia	90
Skin lesions	80
Renal involvement	67
Lymphadenopathy	50
Pleurisy	40
Raynaud's phenomenon	35
Pericarditis	25
Hepatomegaly	25
Central nervous system involvement	25
Abdominal symptoms	20
Splenomegaly	15

Presenting symptoms. The disease may affect many systems of the body, and the presentation and course are by no means uniform. Large series of cases have been reported [1–8] including one from the Far East [9]. The subject has been reviewed [8,10]. Despite the female sex predominance, clinical gender differences are not found, although men may be more liable to fits and renal failure [11].

The initial manifestations vary. In one series of 200 cases, the first changes were articular in 58% and cutaneous in 13.5% [12]. Presentation with renal abnormalities, psychiatric disturbances, pericarditis, pleurisy, abdominal pain and pyrexia of uncertain origin are less common.

In fulminating cases, there is usually marked constitutional disturbance, with fever, loss of weight, anorexia, malaise and joint pains; the skin may be involved later, if at all. On the other hand, the evolution can be gradual, starting with localized skin lesions and systemic involvement developing later. Fatigue is a prominent symptom, both at presentation and subsequently [13]. The diagnosis in many cases is made only by considering the condition in a patient with an obscure illness. As most cases are females, sex is an important diagnostic point. Although weight loss is a feature in nearly 50% of the cases, some patients may gain weight, and 18% actually did so in the Leeds series, which included several patients with long histories. Menstruation is irregular in 18% and absent in 75%. The onset in 15% of females is after the menopause. Sometimes, there is a previous history of sensitivity to drugs such as penicillin, gold or sulphonamides. Raynaud's phenomenon occurs in the course of the illness in approximately 35% of patients, and others frequently have chilblains and a poor peripheral circulation. Approximately 2% of patients with Raynaud's phenomenon eventually develop SLE. Sometimes, there may be other apparent precipitating factors, such as exposure to the sun, stress, trauma and infection. Rarely, hypothermia may occur, often precipitated by therapy [14].

Skin. Approximately 80% of cases have a rash at some stage, and in up to 25% it is the presenting sign [1]. The prevalence varies between series. Findings from a typical UK population are shown in Table 56.7 [2].

The cutaneous changes may be broadly divided between: (i) those specific for LE, and showing the characteristic histopathological appearances of LE; and (ii) those that are less specific in their origin and not showing LE histological changes. Many of these are also seen in the other connective tissue diseases.

Specific changes. Cutaneous erythema is the most common feature, particularly on light-exposed areas (Fig. 56.27). A butterfly blush or discrete maculopapular eruption with fine scaling on the butterfly area of the cheeks or elsewhere is also frequently found (Fig. 56.28). Photoaggravation brought about by increased sensitivity to sunlight occurs in approximately 33% of patients at Leeds, but up to 73% has been reported from America [3]. This may relate to the amount of sunlight. UV radiation such as that found in discos [4], fluorescent lighting [5] and UVA from photocopiers [6] may also cause exacerbations. Oedema, especially of the face, may resemble contact dermatitis, seborrhoeic eczema, dermatomyositis or erysipelas, and

Table 56.7 Cutaneous features of systemic lupus erythematosus in 73 patients. (From Yell *et al*. [2].)

Cutaneous feature	Percentage
Butterfly rash	51
Facial oedema	4

Scarring DLE alopecia	14
Non-scarring alopecia	40
Chilblain lupus	20
Mouth ulceration	31
Bullous eruptions	8
Photosensitivity	63
Raynaud's phenomenon	60
Chronic urticaria (> 36 h)	44
Cutaneous vasculitis	11
Livedo reticularis	4
Episcleritis	4
Cheilitis	4

DLE, discoid lupus erythematosus; LE, lupus erythematosus.

Fig. 56.27 Systemic lupus erythematosus: typical symmetrical slightly scaling erythema of the face and neck.

Fig. 56.28 Systemic lupus erythematosus of the dorsa of hands and forearms. Identical changes may occur in discoid lupus erythematosus. Note the chloroquine pigmentation of the distal part of the nails.

Fig. 56.29 Systemic lupus erythematosus: gross involvement of the back.

can follow tooth extraction [7]. Occasionally, more acute lesions with bullae may follow exposure to the sun (Fig. 56.29), and bullae may be haemorrhagic [8,9].

Epidermal necrosis may give an appearance resembling toxic epidermal necrolysis [10]. In other cases, lesions are like those of erythema multiforme (Rowell's syndrome; see p. 56.14). Very rarely, the skin may show centrifugal annular erythema like that of SCLE. Lesions resembling chronic discoid lesions are initial manifestations in approximately 10% of patients and occur in the course of the disease in approximately 33%. Discoid lesions may be more common in men [11]. Discoid lesions may also be found as the acute phase of SLE settles [12].

Non-specific changes. Sometimes, lesions may be minimal. This is particularly so in the case of the reticulate telangiectatic erythema seen on the thenar and hypothenar eminences of the palms, on the pulps and dorsum of the fingers and, to a lesser extent, on the toes and over the lateral borders of the feet and heels. The lesions on the palms may be confused with the palmar erythema of liver disease. They are bluish red and may show small whitish areas of scarring. The changes occur particularly on the dorsa of the distal phalanges and between the joints, but sometimes there may be small vascular necroses on the tips of the fingers and alongside the nails (Fig. 56.30). The nail folds may show hyperkeratotic and ragged cuticles (Fig. 56.31). Splinter haemorrhages may sometimes be seen in the nails [1], and other changes include pitting, ridging, onycholysis, striate leukonychia [2] and red lunulae [3]. Nail changes occur in approximately 25% of patients [4]. Recurrent Osler's nodes may occur in the absence of infective endocarditis [5]. Clubbing has been reported [6]. Dilatation of the nail fold capillaries also occurs, but this is seen in other conditions. Biopsies from the nails and from areas of palmar erythema show marked dilatation of superficial capillaries [7].

Hair changes. Alopecia occurs in over 50% of patients, especially in the active phase of the disease. This takes the form of diffuse loss of hair with a reddish scalp or, less frequently, permanent scarring alopecia, similar to that found in DLE. The hair is usually coarse, dry and fragile, especially on the frontal margin. This leads to an unruly appearance with short, broken-off hair, the so-called 'lupus hair' (Fig. 56.32) [1]. This occurs in 30% of patients, predominantly females [2]. The hair recovers as the disease becomes inactive, but 'lupus hair' usually persists longer than alopecia. The shortened hairs are unbroken and are probably brought about by slowed anagen growth.

Urticarial lesions and vasculitis. Persistent non-itching urticaria-like weals are common, and may respond to dapsone if associated with C1q deficiency. Urticarial lesions occurred in 7% of one series, but in 20% of patients at Leeds, and were considered to be brought about by immune-complex deposition [1]. SLE may present as hypocomplementaemic urticarial vasculitis [2]. Widespread

Fig. 56.32 Unruly 'lupus hair' with diffuse alopecia.

purpura, resulting from thrombocytopenia or cutaneous vasculitis, is a common finding. Leukocytoclastic vasculitis may lead to purpuric macules, up to 1 cm in diameter, and in certain cases purpuric urticarial lesions may be found. Purpura can also be a result of corticosteroid therapy. Livedo reticularis, a mottled or bluish red discoloration, which blanches on pressure and is not affected by temperature changes, may develop, especially on the outer aspects of the arms. It occurs most frequently in patients who later develop central nervous system lupus [3]. The appearance of livedo reticularis in association with flares of cerebral vasculitis has been noted [4]. Superficial ulceration can occur in areas of livedo. Atrophie blanche [5] and lesions similar to those of malignant atrophic papulosis (Degos' disease) [6] are other features of vasculitis. Patients with the perniotic lesions of 'chilblain lupus' (see p. 56.13) may go on to develop SLE. These lesions may ulcerate, as may the hyperkeratotic keratodermatous skin sometimes found. A subset has been described in which perniotic lesions on the dorsum of the knuckles and toes, fingers and the pulps and palmar and plantar surfaces is associated with anti-Ro antibody [7]. Chronic pyoderma gangrenosum occurs, and has been the presenting feature of hydralazine-induced SLE [8]. Follicular pyoderma resulting from infection has also been described [9]. Large areas of acute gangrene (e.g. of the buttocks) may separate during systemic corticosteroid therapy, and require grafting.

Large vessel disease. Gangrene of the tips of the fingers and toes [1] may develop insidiously. At first the digits become blue and cold and may be painful. Radiography of the fingers in cases with peripheral ischaemia shows absorption of the distal part of the terminal phalanges, as in systemic sclerosis. Later, the phalanges may become exposed, and spontaneous separation of the tips of the fingers may occur. Amputation of digits may be required. Occlusion of large- and medium-sized arteries can occur suddenly and result in gangrene requiring amputation of a limb [2,3]. This may be the result of vasculitis or thrombosis. Patients with thrombosis frequently have antiphospholipid antibodies [3]. Major vessel occlusion can occur in childhood [4]. Leg ulcers (Fig. 56.33) occur in approximately 10% of patients, usually near the malleoli but sometimes on the feet and elsewhere, from breakdown in reticular livedo and in areas of cutaneous vasculitis. Erythromelalgia (pain in the feet aggravated by heat and dependence and relieved by cooling and elevation) may be a presenting feature [5].

Mucinosis. Although mucin deposition is a common and often prominent histological feature of cutaneous lupus, specific clinical patterns of mucinosis also occur. Papular or nodular lesions resulting from mucinous deposits in the dermis without microscopic features of LE have been reported [1], and form a distinct entity which may be the presenting feature of LE [2]. Multiple firm non-tender dermal papules and nodules, between 5 and 15 mm in diameter, occur on the upper part of the body and extremities [3–6]. The overlying epidermis appeared normal. Hyperpigmented acral papular mucinosis has also occurred in one patient with total alopecia [6].

Connective tissue changes. Hardening, binding-down and pigmentation of the skin of the face and limbs may resemble systemic sclerosis, although the typical mat-like telangiectases of the latter are usually absent. Calcinosis is rare [1], but occasionally widespread and large palpable deposits may develop [2] or be found radiologically [3]. Subcuta-

neous nodules occur in approximately 5% of patients [4]. They resemble rheumatoid nodules, although there may be no evidence of arthritis. They occur mainly over the backs of the proximal phalangeal joints and wrists, but are also found on the elbows, knees, occiput and the flexor aspects of the fingers. They may respond to hydroxychloroquine [5]. Some are histologically identical with classic rheumatoid nodules [6], others are probably caused by vasculitis and thrombosis [7]. Panniculitis, similar to LE profundus, can occur in the course of the disease or can be the presenting sign [8–10]. Lesions may break down, resolve with oral corticosteroids or require surgery and grafting. Relapsing nasal and auricular chondritis have been described [11]. The nose and ears are tender, warm, swollen and red, but cartilage collapse does not occur as in polychondritis. Treatment with corticosteroids is effective.

Pigmentary changes. Pigmentary disturbances are not uncommon. Whole areas can show hypopigmentation. A bluish black pigmentation of the skin results from antimalarial therapy [1].

Other cutaneous changes. In the Chinese, hyperkeratotic follicular erythematous papules, sometimes becoming pigmented or confluent, occur on the trunk and limbs. Psoriasiform lesions and hyperkeratosis of the palms and soles are found [2,3]. Widespread ichthyosis and warty excrescences on knees and elbows may occur [4]. Eruptive dermatofibromas have been reported [5]. Acanthosis nigricans has been reported in lupoid hepatitis [6]. Herpes zoster is more frequent than expected in SLE [7], and scabies is more severe and may be of the crusted type [8].

Bullous SLE (Fig. 56.34) [1]. Blistering is uncommon in SLE. In the classic disease, separation of the epidermis and dermis occurs as a result of severe liquefaction degeneration of the basal layer and dermal oedema. A separate subset called bullous SLE has been defined, with distinct clinical and histopathological features, the latter resembling dermatitis herpetiformis [2]. Subepidermal vesicles contain neutrophils with microabscesses, and nuclear 'dust' and fibrin at the tips of dermal papillae. Immunohistology, however, shows linear deposition of IgA, IgG and IgM and, to a lesser extent, C3 at the basement membrane, resembling bullous pemphigoid and unlike the IgA seen in the dermal papillae in dermatitis herpetiformis.

Electron microscopy shows the immunoreactants to be in the sublamina densa [3] and not in the lamina lucida as in pemphigoid, although the immunopathological changes are variable and may indicate that a number of basement-membrane antigens can act as targets [4]. This has subsequently been confirmed [5]. In particular, a form resembling epidermolysis bullosa acquisita (EBA) has been described [6]. The target antigen in some patients is type VII collagen, but other antigens may be involved in bulla formation [7].

Clinically, the bullous lesions are predominantly on the face, neck and upper trunk, but may be more widespread, and may heal with milia formation. One-third have mouth lesions. Photosensitivity may occur. The patient may initially present with lesions resembling erythema multiforme [8]. Glomerulonephritis is common, and associated with hypocomplementaemia and anti-DNA antibodies. Circulating antibasement-zone antibodies have many features of EBA antibodies. The demonstration of such antibodies may precede the development of SLE by many years [9]. It is not yet established whether patients with EBA antibodies are a unique subset of bullous LE or whether they represent the coexistence of two separate diseases, although it has been suggested that the spectrum of bullous LE should include all cases of bullous disease occurring in patients with SLE [1]. Rarely, drugs, including hydralazine [10] and IFN-α [11], may precipitate bullous SLE. Dapsone alone or in combination with prednisone is the treatment of choice. It is not always successful and may even exacerbate the disease [7]. The authors have used thalidomide successfully in these resistant cases.

Pemphigus erythematosus [1]. Erythematous, scaly, hyperkeratotic or crusted lesions, sometimes adversely affected by the sun, occur in a butterfly distribution on the cheeks and in a seborrhoeic distribution on the trunk of patients with Senear–Usher syndrome (see Chapter 41). This combines the immunological features of pemphigus and LE. Direct immunofluorescence shows immunoglobulin and complement in the intercellular substance and at the dermal–epidermal junction of perilesional and, to a lesser extent, of light-exposed and non-exposed skin. Circulating pemphigus-like antibodies and antinuclear factor occur in 80–100%, but anti-DNA and ENA antibodies are not found. Recently, antidesmoglein antibodies have been demonstrated [2]. The condition occurs spontaneously, but has been induced by penicillamine, propranolol, captopril, pyritinolol and thiopronine. Topical steroids alone may control the condition, but systemic steroids, immunosuppressives or dapsone may be required.

Mucous membrane lesions [1–3]. Mucous membrane lesions occur in 26% of cases, usually on the palate (82%) (Fig. 56.35), buccal mucosa or gums, in active phases of the disease [3]. Lesions start as small erythematous or purpuric areas, which break down to form shallow and sometimes painful ulcers, with a dirty yellow base and surrounding reddish halo. There may be difficulty in swallowing. Histology and immunohistology show changes similar to

Fig. 56.35 Systemic lupus erythematosus involving the palate.

those in the skin. Light microscopy can usually distinguish between LE and lichen planus [4]. Immunofluorescence is usually positive [5]. Repeated sore throats and oral ulceration may be presenting features [6]. The appearances can resemble a *Candida* infection, and sometimes *Candida* is present as a secondary infection. The lips may become cracked, oedematous and crusted in acute cases. Infarction of the tongue, with anticardiolipin antibodies, was the presenting feature in one case [7]. Cheilitis occurs in approximately 6%, the lips having a silvery appearance, with erythema, scaling and blurring of the vermilion border [1]. The larynx is occasionally involved. Ulceration of the mucosa of the nasal septum occurs in approximately 5%. Perforation of the nasal septum is a complication of exacerbations and presents with epistaxis [8]. Erythema of the vulva and perianal area occurs and vulval ulceration may develop, but is less common than oral ulcers. Patients may present with vulval and vaginal ulceration. Orogenital ulceration has been reported with hydralazine-induced lupus [9].

Arthritis [1]. Involvement of the joints occurs at some time in approximately 90% of patients, arthralgia being more common than arthritis. A rheumatoid-like deformity is present in approximately 25% of cases, with marked soft-tissue swelling, especially of the dorsa of the fingers, hands and wrists, although joint erosions on X-ray are not a feature. The deformity is usually less, but the soft-tissue swelling is more marked than in rheumatoid arthritis [2]. Jaccoud's syndrome, severe deformity of the hands with ulnar deviation and swan-neck configuration, often with little pain and good function, occurred in 13% and fixed flexion contractures of the elbows in 11% in one series [3]. Arthritis mutilans of the distal interphalangeal joints of the hands can occur [4]. The elbows, shoulders, knees and feet may also be involved and soft-tissue nodules may occur, usually indicating calcinosis. Temporomandibular joint involvement may be indicated by locking or dislocation, tenderness and pain on mastication [5]. Features distinguishing SLE from rheumatoid arthritis are shown in Table 56.8. Migratory polyarthritis with inflammation, effusion and erythema occur less frequently. Sacroiliitis occurs in male patients [6]. SLE may rarely present with polymyalgia rheumatica [7]. *Salmonella* infections occur in patients with SLE, and may be associated with septic arthritis [8,9].

Table 56.8 Features distinguishing systemic lupus erythematosus (SLE) from rheumatoid arthritis (RA).

Distinguishing feature	SLE (%)	RA (%)
Deforming arthritis	25	Common
Subcutaneous nodules	5	25
Radiological erosions	Rare	Common
Involvement of kidneys	Common	Rare
Positive LE cell test	80	15
Positive ANA test	90	20
Rheumatoid factor present	40	80

ANA, antinuclear antibody; LE, lupus erythematosus.

Heart. Cardiac involvement in SLE is common, and increases with the duration of the disease [1]. Pericarditis is the most frequent cardiac manifestation, but the incidence of 87% in one review [2] must have been the result of selection. Fibrinous pericarditis is frequently found, but sometimes a large effusion may occur and reabsorb on adequate corticosteroid therapy. Rarely, a large effusion can develop within hours, giving rise to cardiac tamponade [3] and requiring aspiration. The incidence of classic endocardial lesions (Libman–Sacks endocarditis) is difficult to estimate, but the diagnosis is rarely made clinically. Lesions were found at autopsy in only four out of 30 patients in one series [4] and in 50% of patients in another [5]. The valves on the left side of the heart are commonly

involved. Both systolic and diastolic murmurs may be found depending upon the site of the lesion, and bacterial endocarditis can occur on the damaged heart valves. Aortic incompetence may occur without involvement of the mitral valve [6] at an early stage of the disease before steroids are used, or when the condition is well controlled. Tricuspid regurgitation has been reported [7]. Echocardiography is helpful in diagnosis [8], and valve replacement has been successful [9].

Coronary arteritis results in myocardial infarction [10]. Infarction may also result from atherosclerosis in young patients [11]. Antiphospholipid antibodies may be demonstrated in such patients [12]. The myocardium may also be affected and results in cardiac failure [13]. The diagnosis can be confirmed by endomyocardial biopsy [14]. Alterations in rhythm include atrial fibrillation and heart block of all types. This may be associated with both Ro and U_1-RNP antibodies [15].

Hypertension occurs in approximately 35% of patients. Alterations in the electrocardiogram (ECG) in the course of the illness may be helpful in diagnosing or in confirming the presence of cardiac involvement. There is some evidence that treatment with corticosteroids increases the incidence and degree of hypertension, coronary atherosclerosis and heart failure [5]. Reduced exercise tolerance occurs and may be caused by abnormal myocardial dynamics on exercise [16].

Fig. 56.36 Pulmonary infiltration in systemic lupus erythematosus. This cleared in approximately 2 years on treatment with corticosteroids.

Lungs [1]. The incidence of involvement of the pulmonary system varies between series, and the radiological changes [2,3] depend on the stage of the disease. Transient pleurisy is the most common feature, and in approximately two-thirds of these cases some fluid develops, occasionally haemorrhagic. Pleural effusions can be massive and used to be treated by pleural powder poudrage [4] or pleurectomy [5], but this is now uncommon. Pleural thickening can be shown radiographically. Involvement of the lungs is less frequent, and is shown mainly as transient infiltration, sometimes with mottling and reticulation (Fig. 56.36) [6]. Acute pneumonitis with severe dyspnoea and fever may be a presenting manifestation of SLE [7], and cases have been reported with disseminated intravascular coagulation [8]. There is a high incidence of anti-Ro antibodies in pneumonitis [9]. Diffuse fibrosis, like that occurring in systemic sclerosis, is not found [10]. Shrinking lung syndrome is probably caused by diaphragmatic fibrosis [11]. Pulmonary hypertension occurs [12], and pulmonary haemorrhage can be dangerous [13]. When dyspnoea, pleuritic pain and fever occur with linear shadows on radiography, recurrent pulmonary infarction may be simulated. Fibrosing alveolitis has been reported, as well as haemopneumothorax [14]. Hilar lymphadenopathy may cause confusion with other diseases [15]. Unlike those of systemic sclerosis, the pulmonary changes may resolve with steroid therapy. Pulmonary function tests may be abnormal, even in those showing no radiological abnormality. Impairment of pulmonary diffusion (trans-

fer factor) occurred in 42–80% [16,17], and is more common than reduction in lung volumes [18]. Such reduction in pulmonary function persists but is rarely progressive [19]. Function of the diaphragm may also be deficient [17], and bilateral elevation of the diaphragm with linear shadows over the lower zones is characteristic of SLE. Death may occur from overwhelming pneumococcal infection [20]. *Pneumocystis carinii* infections should be considered in all steroid-treated patients who present with respiratory distress and pulmonary infiltration [21]. The diagnosis is confirmed by biopsy. Nocardial infection with lung abscesses [22,23] and Legionnaires' disease [24] have been reported. Tuberculosis occurred in 5% in one series, and may be missed [25]. Laryngeal involvement is rare and indicated by stridor and hoarseness, and may be life-threatening. It can occur in inactive disease [23], and may be complicated by nocardiosis [26].

Renal changes. The renal changes [1] in SLE are very important in assessing the prognosis (see p. 56.64). Most patients will have renal involvement, as histological evidence of nephritis may occur without proteinuria or microscopic urinary abnormality [2] and with normal renal function [3]. Sometimes, proteinuria and casts may occur transiently with febrile exacerbations. Renal disease in lupus accounts for 3% of end-stage renal failure, and is an important cause of mortality in SLE [4]. The need for regular screening by urinalysis, blood pressure monitoring, assessment of renal function and early renal biopsy is critical [5]. Impaired renal tubular potassium secretion can lead to persistent hyperkalaemia [6]. Usually, renal exacerbations are associated with high titres of antinuclear factor, elevated DNA binding and low serum complement, but occasionally these features may revert to normal in severe relapse [7].

The course is variable, and albuminuria and casts may persist for years without marked deterioration in renal function. Kidney damage, if this is going to develop, usually appears early (within the first 3 years) [5] and is more frequent and severe in younger patients [8]. However, renal involvement may appear as long as 34 years after diagnosis of SLE [9]. A relatively benign course is associated with membranous lupus nephropathy [10]. This occurs in approximately 8% of patients with SLE. Clinically, proteinuria and microscopic haematuria occur some years after other evidence of the disease. Prednisone treatment does not seem to influence proteinuria or renal function in this type.

Some cases develop typical signs of the nephrotic syndrome, and renal vein thrombosis has been reported [11,12]. The development of pleuritic pain in a patient with SLE and the nephrotic syndrome should alert the clinician to the possibility of renal vein thrombosis and pulmonary emboli [13]. Massive ascites as the major manifestation of SLE has been reported [14]. The mean survival time of these patients is 8 months [8], although those with normal serum cholesterol levels have a better prognosis. A normochromic normocytic anaemia, unresponsive to iron, is common. Although the serum gammaglobulin is frequently raised, it can be normal or low in association with severe renal involvement. Some patients, after minimal signs of renal involvement for years, die with symptoms of malignant hypertension.

Cystitis with reduction of bladder capacity and thickening of the bladder wall may be a primary manifestation of SLE [15]. Pulmonary haemorrhage may occur more frequently in these patients [16]. A strong correlation between lupus cystitis and gastrointestinal involvement has been noted [17].

Gastrointestinal tract [1]. Anorexia, nausea and vomiting sometimes occur, and impairment of oesophageal motility has been reported [2], especially in patients with Raynaud's phenomenon. Motility studies show absent or impaired contractions in one-third of patients [3]. Abnormalities may occur in any part of the oesophagus but particularly in the upper third, and such dysfunction is not related to activity of the disease. Fewer patients complain of dysphagia or show radiological abnormalities. Pain, vomiting, diarrhoea, malabsorption [4,5], gluten-sensitive enteropathy [6] and protein-losing enteropathy [7], or evidence of obstruction or bleeding, result from intestinal involvement. Pneumatosis cystoides intestinalis and spontaneous pneumoperitoneum are rare [8], but have been reported in a patient with antinuclear-negative SLE [9]. Patients with arteritis may present as an acute surgical emergency, and this complication may be fatal [10]. Small intestinal ulceration occurs in patients with antiphospholipid antibodies [11]. Mesenteric arteriography may be helpful in showing irregularities of the small intestinal arteries [12]. Pancreatitis [13,14] occurs in both children and adults and is often fatal. It can be associated with subcutaneous fat necrosis and calcinosis cutis [15]. Ulcerative colitis [16] and colonic perforation [17] also occur. Mesenteric lymphadenopathy may be associated with hilar lymphadenopathy [18].

Lymphangiographical changes can resemble those seen in early malignant lymphoma [19]. Painless ascites, in the absence of the nephrotic syndrome, congestive heart failure or hepatic cirrhosis, may be the presenting feature [20,21]. It is presumably a result of peritoneal serositis. Infarction of the tongue can be another presentation [22].

Hepatic lesions [1]. These may be more common than previously recognized [2]. Liver disease is present in approximately one-third of patients, but it is usually mild and often asymptomatic. Histology usually shows steatosis or mild hepatitis. Lesions include granulomatous hepatitis, chronic active hepatitis, cirrhosis, death from liver failure and hepatic infarction. Nodular regenerative hyperplasia occurs [3], and hepatic veno-occlusive disease has been reported [4]. Subclinical liver disease indicated by mild transaminase elevation occurs in approximately 8% [5]. LE cells are sometimes found in hepatitis. The condition, inappropriately named 'lupoid hepatitis', involves mainly young females who have a benign cirrhosis and evidence of adrenal overactivity such as acne, hirsutism, pigmentation, amenorrhoea and abdominal striae. Other features include febrile upsets, polyarthritis, hyperglobulinaemia and other protein abnormalities. Smooth muscle and mitochondrial antibodies may be demonstrated. Patients with chronic active hepatitis may show extensive purplish telangiectasia [6].

Thyroid disease. Both hyperthyroidism and hypothyroidism occur in SLE [7–9], and there is a high frequency of abnormal thyroid function tests and thyroid autoantibodies in patients without diagnosed thyroid disease [10,11].

Nervous system [12–15]. Approximately 50% develop neuropsychiatric features from the disease itself [16]. There is no direct correlation between neurological and psychiatric disease and clinical or laboratory indices of disease activity [14]. Livedoid vasculitis of the skin may be an important prodromal sign of central nervous system (CNS) lupus [17]. Anticardiolipin antibodies may or may not be present. Migraine can be a feature [18,19]. Epilepsy, resulting from small thromboses in cerebral vessels affected by vasculitis, can be the presenting manifestation of SLE, particularly in patients with high titres of anticardiolipin antibodies. The incidence of epilepsy is difficult to evaluate, owing to selection of cases in series from special clinics. Peripheral sensorimotor [20] and autonomic neuropathy occurs [21,22], brought about by vasculitis in the vasa nervorum. It is important to distinguish this from the neuropathy induced by chloroquine [23]. Trigeminal neuropathy, with numbness and pain in the face [24], deafness [25], transverse myelitis [26,27], which may occur in pregnancy [28], optic neuritis [29], aseptic meningitis [30], Guillain–Barré syndrome, and a case presenting as disseminated encephalomyelitis, have been reported [31]. Patients may present with clinical features of multiple sclerosis, and in this variant there is a high incidence of chronic biological false-positive Wassermann reactions and mitochondrial antibodies [32]. Occasionally, a single cranial nerve may be involved. Sometimes, signs simulate an intracranial mass [33], and pseudotumour cerebri because of raised intracranial pressure occurs [34]. Subarachnoid haemorrhage [35] and massive spontaneous subdural haematoma have been reported [36]. Parkinsonism is rare [37]. The association of chorea with SLE has been reviewed [38]: two cases of chorea were reported in a series of 175 patients with SLE [39], and the authors have seen this association in two girls aged 3 and 16 years. Chorea gravidarum also occurs [40]. SLE may also cause psychiatric symptoms, including anxiety, hypomania, emotional lability, memory defects and depression. Psychiatric symptoms [41,42] are found in approximately 20–30%. Patients may respond to the disease with hypochondriasis, depression and hysteria [43]. Pseudocyesis has been reported [44].

Dislike of a patient by the physician may be a clue to serious psychiatric impairment resulting from SLE in that patient [45]. The electroencephalogram (EEG) [46], conventional brain scanning [47] and oxygen-15 brain scanning [48] may be helpful in the diagnosis of cerebral LE, and abnormalities are related to clinical progress [47]. Cranial computed tomography (CT) may show focal areas of infarction and cerebral atrophy [49]. The latter may be caused by steroid therapy rather than the disease [50]. Calcification occurs in cerebral LE. Magnetic resonance imaging (MRI) may be helpful [51] and show abnormalities not found on CT, but its use is limited [52]. Autoantibodies to neuronal antigens can be demonstrated in approximately 20% of patients with SLE [53], especially in those with neuropsychiatric features [54]. Antiribosomal P protein antibodies seem to be associated with psychosis [55]. Patients with multiple strokes followed by dementia are likely to have antiphospholipid antibodies [56]. Depressed levels of C4 in the cerebrospinal fluid (CSF) are found in patients with CNS involvement, but not in patients with active SLE without CNS manifestations [57].

Toxoplasmosis of the brain may occur as an opportunistic infection in patients with SLE and the manifestations resemble cerebral lupus [58].

Involvement of the eyes. The eye changes in SLE have been reviewed [1]. They include lid oedema, conjunctivitis and subconjunctival haemorrhages, lacrimal hyposecretion, episcleritis, scleritis, anterior and posterior uveitis, retinal cytoid bodies, retinal haemorrhages and branch- and main-trunk arterial and venous occlusions. All the changes can occur without hypertension. Optic neuritis is uncommon [2] but may be the presenting feature, causing confusion with multiple sclerosis [2]. The retinal cytoid bodies—oval, whitish areas alongside arteries and veins—are not specific to SLE, and are thought to be brought

about by damage to the endothelium of capillaries, which allows the passage of plasma and red cells into the nerve fibre layer. Depigmentation of the retina may be present. Retinal lesions rarely cause visual impairment, but blindness can occur [3]. Lupus retinopathy was found in approximately 8% in one large series and was associated with active disease and lupus cerebritis, and was a marker for poor prognosis [4]. Retinal changes can be demonstrated in nearly one-third of patients by fluorescein angiography, and are associated with active disease [5]. Visual impairment may be the presenting symptom of SLE [6]. Symptoms of corneal involvement occur in more than half of patients, and 88% have corneal staining with fluorescein [7].

Involvement of the ears. Sudden bilateral loss of hearing, presumably because of vasculitis of the arteries of the cochlea, may be dramatic and permanent. One patient's hearing responded to plasma exchange [1].

Muscle changes. Muscle pain occurs in approximately 50% of patients, and this may be confused with the pain of arthritis. Muscle weakness is a less common feature. Electromyographic abnormalities correlate better with weakness than myalgia. The serum aldolase level is frequently raised but the serum creatine phosphokinase is usually normal [1]. A vacuolar myopathy is considered to be specific [2]. Calcinosis may occasionally occur [3,4]. Very rarely, there may be a myasthenic reaction and SLE can follow, or be associated with myasthenia gravis [5,6]. Lupus with muscle disease may follow thymectomy for myasthenia gravis [5]. A thymoma may sometimes be found [7].

Involvement of tendons [1,2]. Tendon rupture is rare, and involves particularly the weight-bearing tendons such as the patellar, quadriceps and Achilles tendons, but it may also occur in the tendons of the hands [3] or biceps [4]. Tendinous laxity may precede rupture and be partly attributable to hyperparathyroidism secondary to chronic renal failure [5]. It may be bilateral. Usually, the patient has been on corticosteroids for a long time. Surgical suture can be successful. Abnormalities of the feet with clawing of the toes and flexion contractures have been designated 'lupus foot' [6,7].

Calcification. Calcification may occasionally occur. Nine patients in one series of 130 cases had calcification [1]. This is more frequent in the legs, and may be bilateral and diffuse in the skin or deeper soft tissues, or be unilateral and localized. Sometimes, there are large deposits or nodules in the subcutaneous tissues [2]. It can occur without preceding local inflammation or ulceration, and may antedate other manifestations of SLE by as long as 7 years [3]. Periarticular calcification in the hand has been reported [1]. Calcification of the arteries of the legs may occur in early adult life. The myopathy of SLE may result in calcification [4]. A case of SLE with hypercalcaemia has been reported [5]. The serum calcium returned to normal when the patient had responded to treatment with corticosteroids and intravenous pulse cyclophosphamide.

Bone changes. Avascular bone necrosis [1] occurs in 5–7% or more of patients and is considered to be part of the disease, although it may be exacerbated by corticosteroid treatment [2,3], especially in high doses. It may be more frequent in patients with the lupus anticoagulant [4]. It occurs in relatively mild cases of SLE [5]. The risk is increased in patients with Raynaud's phenomenon [6]. The femoral head or condyle is most frequently involved [7], but the condition also may involve the knees, ankles, humerus, metatarsals and the carpal bones causing wrist pain [8]. It is commonly bilateral, with involvement of multiple joints. It is rarely crippling, although it may proceed to destruction of the joint. X-rays may be normal, but the diagnosis is often clear on MRI [9]. Symptomatic improvement may occur from local or systemic corticosteroids [10]. The condition is thought to be associated with increased pressure in the bone marrow because of altered venous drainage, and core decompression may be successful [11] clinically but not radiologically [12]. Total hip replacement may be required if it fails, or in the late stages [3]. There may be patchy sclerosis and cystic changes in the bones of the hands and feet, and metacarpophalangeal and metatarsophalangeal joints may rarely show subcondylar erosions and adjacent sclerosis [13]. Osteonecrosis, possibly resulting from infarction, has been found in as many as 13 joints during corticosteroid treatment [14].

Other manifestations of systemic involvement include lymphadenopathy, which occurs in more than 50% of cases, and splenomegaly. Swelling of the parotid, submaxillary and lacrimal glands sometimes develops. Classic Sjögren's syndrome occurred in 1.4% in one series [10], but some features of Sjögren's syndrome have been found in practically all cases of SLE on detailed investigation [15].

SLE in childhood [1]. The clinical picture, course and treatment are similar to the disorder in adults, but on the whole children have more severe disease [2]. The earliest age of onset reported is 3 months [3]. Bullous SLE may resemble chronic bullous disease of childhood [4]. In one series [5], 30% had CNS involvement and 87% had renal disease (diffuse proliferative lupus nephritis, 34%). Overall survival was 85% at 10 years and 77% at 15 years after onset. Children with CNS lupus did no worse than other patients, and this has been noted by others [6]. The prognosis of patients with renal disease is now better than earlier reports suggested. Enlargement of the liver, spleen and lymph nodes is more common in childhood cases. Pancreatitis associated with cutaneous panniculitis and calcinosis has been reported [7]. Prolonged therapy with high-dose steroids may increase disease-related damage; this may be avoided by judicious use of immunosuppressives [8]. Autologous stem cell transplantation has been used successfully [9].

SLE in the elderly [10]. The onset of disease over 60 years occurs in nearly 20% of patients and is often insidious. There is an increased incidence of lung disease and Sjögren's syndrome, and a lower incidence of renal disease and mesenteric vasculitis [11], and antibodies to Ro and La are frequent. There appears to be an association with HLA-DR3.

SLE in pregnancy [1,2]. Fertility is normal if renal function is good [3]. Worsening of SLE is uncommon in pregnancy [4], especially in those on immunosuppressive therapy [5]. Clinical remission for 6 months before conception should indicate an uncomplicated pregnancy and a live birth [6]. Inactive disease is not associated with disease recurrence [7]. The outcome with renal involvement is comparable with those whose kidneys are not affected [8]. Permanent deterioration in renal function occurs in less than 10% [3]. There is a higher risk of premature delivery, fetal loss and perinatal mortality in all patients. Abortion occurred in 8% and perinatal mortality was 13% in one series [9]. The increased risk of fetal death may be because of immune complex deposition on the trophoblast basement membrane [10], or the transplacental passage of antiphospholipid antibodies. Anticardiolipin antibodies, especially of the IgG isotype [11] or the lupus anticoagulant, are associated with a markedly increased fetal loss in all stages of pregnancy, but the presence of these antibodies without a previous history of fetal loss or thrombosis is not an indication for treatment [1]. With a history of recurrent fetal loss, treatment with prednisone and aspirin may be effective [12]. With good obstetric care, close follow-up, and treatment with low-dose aspirin if antiphospholipid antibody is present, a success rate of 71% has been reported [13]. The authors have seen successful pregnancies following *in vitro* fertilization in patients with SLE and the lupus anticoagulant.

Therapeutic abortion is not indicated and only causes added stress, nor is caesarean section required. It is important to avoid excessive trauma, haemorrhage or shock. The dosage of corticosteroids should be temporarily increased at the time of delivery and postpartum. Corticosteroids do not appear to cause impairment of growth or malformation in the fetus, but high-dose steroids during early pregnancy can cause cleft palate. Babies of mothers with untreated SLE are usually smaller than expected, and corticosteroids may assist growth of the fetus *in utero* [8]. If the patient is on azathioprine, this should be continued [9]. There is no evidence of an increase in the malformation rate [14].

Oestrogen-containing contraceptives, even at low dosage, should be avoided in women with SLE. If mechanical methods of contraception or intrauterine devices are not possible, pure progestogens may be an alternative [15]. Breastfeeding is probably safe if the patient is on aspirin or low-dose steroids, but should probably be avoided if other immunosuppressives are used.

Neonatal lupus erythematosus

Definition. Neonatal lupus erythematosus (NLE) is a disorder thought to be caused by the transplacental passage of maternal antibodies. The most frequent clinical manifestations are cutaneous lesions and congenital heart block (CHB).

Aetiology. Aylward [1] was the first to report CHB in the siblings of a mother with Mikulicz's disease (Sjögren's syndrome) in 1928. McCuiston and Schoch [2], however, were the first to suggest that the association of NLE and maternal systemic lupus may be related to the transplacental transfer of 'a transmittable aetiological agent' (maternal antibodies). This suggestion subsequently gained credence from the fact that the NLE skin lesions resolve as maternal antibodies are cleared from the infant's serum [3].

The first associated antibody described [4] and the serological marker most commonly associated with NLE is the Ro/SS-A antibody. This has been reported to be present in between 82% of infants and 92% of mothers [5] and 100% of NLE patients [6–8]. Two main Ro/SS-A proteins exist (52 and 60 kDa), and studies have suggested that the former is more frequently found in CHB [9,10] while the latter is more frequently associated with cutaneous disease [11], although this is by no means a universal finding. La/SS-B antibodies are less frequently found, one study detecting these in approximately 50% of NLE infants and 60% of mothers (usually in association with Ro/SS-A antibodies) [5]. U_1-RNP antibodies are much less frequently found but have been reported as the only antibody in some patients with cutaneous NLE [12,13]. In this and subsequent reports, U_1-RNP antibodies have not been associated with CHB.

Evidence that these antibodies may be pathogenic comes from the studies of Lee *et al.* [14] who showed that purified Ro antibody bound to human skin grafted onto nude mice, in a pattern similar to that found in typical LE lesions. In addition, Ro/SS-A antigen is present in neonatal skin [15]. These antibodies have also been shown to bind to Ro/SS-A and La/SS-B antigen in human fetal cardiac conducting tissue [16–18] where they can cause conduction abnormalities [19,20].

It is unlikely that these antibodies represent the whole story, however, as they are non-specific for NLE, occurring in Sjögren's syndrome and SCLE. They are also found in approximately 0.5–2% of the normal population when assessed by immunodiffusion and in 5–11% when assessed by enzyme-linked immunoabsorbent assay (ELISA) [5]. Some studies have suggested that disease expression may be related to HLA status, the HLA-DR3 haplotype (especially when associated with DQA1 and DQB1), having been associated with the immune response to Ro/SS-A [21,22]. These, and a previous study [8], suggest that the HLA haplotype is important for antigen production in the mother but not necessarily relevant in the infants. Other workers argue that these antibodies are only indirectly related to disease, the disease process being caused by either: (i) the 52 kDa Ro/SS-A showing homology with the 5-HT_4 serotoninergic receptor, binding to which then mediates cardiac damage [10]; or (ii) the presence of antibodies to a completely separate 57 kDa protein [23].

Clinical features

Cutaneous. Approximately half of NLE infants manifest skin lesions [5], which may be present at birth or occur in the first few weeks of life. The most common finding is an erythematous, slightly scaly eruption on the face and periorbital skin (raccoon sign/owl-eye/eye mask) (Fig. 56.37), with the scalp, trunk, extremities, neck and intertriginous areas involved in decreasing order of frequency [24]. The eruption can be exacerbated by UV exposure and there are reports of the rash being precipitated by phototherapy for neonatal jaundice [25,26], although the rash is sometimes present at birth, which would make it difficult to implicate UV exposure in the aetiology [27]. Other manifestations include a vitiligo-like eruption in a black infant [28] and morphoea-like lesions [29].

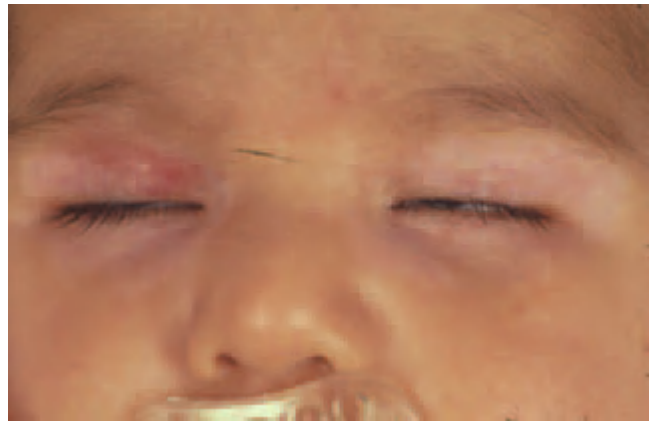

Fig. 56.37 Typical 'raccoon' eyelid lesions in neonatal lupus erythematosus.

The rash improves over the first few months of life and has usually resolved without scarring by 12 months of age. Occasional patients exhibit residual telangiectasiae [30], dyspigmentation or atrophy [24].

Cardiac. Complete heart block occurs in approximately 60% of white patients [5], although it may be less common in Japanese patients [31]. Associated features may also include pericardial effusions, pleural effusions, ascites, intrauterine growth retardation and hydrops fetalis [32]. Up to 50% will require pacing in the neonatal period and others will require a pacemaker at a later date [33]. Dilated cardiomyopathy occurs in up to 20%, and has a significant mortality in the first year of life [33].

Haematological. Thrombocytopenia may occur in up to 20% of cases [30,34], is transient and does not usually require treatment, although it has been associated with petechial and purpuric lesions. Neutropenia, haemolytic anaemia and aplastic anaemia have also been reported [35,36].

Hepatic. Hepatomegaly and splenomegaly have been reported in NLE [37], with histological changes of 'neonatal hepatitis' and, on occasions, fibrosis. Cholestasis has also been reported [37,38]. A recent study showed hepatobiliary disease in 19 of 219 patients with NLE, and in three this was the only finding [39].

Miscellaneous. Case reports have associated NLE with pneumonitis [6], haemochromatosis [40], aseptic meningitis [41], myelopathy [42], transient myasthenia gravis

[43], hydrocephalus [44], spastic paraparesis [30,45] and chondrodysplasia punctata [46].

Treatment

Cutaneous lesions. Skin disease is often mild and requires no treatment. Sun avoidance should be advised and low-potency topical steroids may be of benefit [5,33]. Persistant telangiectasiae have been reported to respond to the tunable dye laser [47].

Cardiac. Up to 50% may require pacing in the newborn period, and others may require pacemaker insertion at a later date [32]. There is little information with regard to whether CHB and its consequences can be prevented or treated *in utero*. One study reviewed outcomes in pregnancies of mothers with Ro antibodies who had received systemic steroids during pregnancy [48]. When steroids had been given during the first 16 weeks of pregnancy, no conduction defects occurred, suggesting that they may have possibly suppressed disease initiation during this period of gestation. Corticosteroids administered after the first 16 weeks, however, were not beneficial and did not reverse established complete heart block. Another study compared outcome in fetuses whose mothers were treated with oral corticosteroids at various stages during pregnancy. Although there was no improvement in established complete heart block, the treated group showed less progression from first- to second-degree block to complete block and some improvement in pleural effusions, ascites and hydrops [31]. Anecdotally, a mother with the HLA-DR3 phenotype, high titres of Ro/SS-A and La/SS-B antibodies and an existing child with neonatal lupus, delivered a healthy infant after plasmaphoresis three times weekly and systemic steroids during gestation [41].

Haematological. Most resolve spontaneously without treatment.

Hepatic. Most resolve spontaneously without treatment.

Pregnancy. A pregnant patient who is known to have Ro/SS-A or La/SS-B antibodies should be made aware of the possible problems, and their obstetrician alerted. The risk of NLE in a Ro/SS-A positive mother without connective tissue disease or a previous history of NLE is probably low [33,49]. The risk rises, however, with the presence of maternal lupus and the presence of the HLA-DR3 haplotype in the mother [8], and one study has suggested a risk of 1 : 60 for a woman with lupus and 1 : 20 if Ro/SS-A antibodies are also present [50]. However, another study suggests the risk of non-cardiac NLE in these groups to be 3% in the former and up to as high as 32% in the latter [51], although the risk is lower (and non-quantifiable) for CHB. The risk of NLE in a pregnancy in a mother who has already had a child with NLE has been reported as 25% [52] or 50% [5].

Prognosis

Infant. Although follow-up data are limited, some children have gone on to develop SLE in later life [3,53,54] and one child developed a CNS vasculopathy at the age of 17 years [55]. Follow-up is therefore advised.

Mother. Although mothers are often asymptomatic at the time of the birth, some may go on to develop an autoimmune disease, usually SLE or Sjögren's syndrome, and follow-up is therefore advised [52].

Laboratory investigations [1]. Laboratory investigations are frequently necessary to confirm the diagnosis, although even after extensive investigations it may be impossible to be entirely dogmatic, in view of the overlap of the manifestations of connective tissue diseases. Anaemia, of some degree, is found in approximately 75% of patients and is brought about by deficiency of iron, haemolysis or renal failure. The serum iron is usually low and may rise after corticosteroid therapy [2]. A positive Coombs' test can occur in the absence of haemolytic anaemia, and was present in 15% in a series of cases seen by the authors. Pure red cell aplasia has been reported [3]. Although leukopenia, specifically a lymphopenia, is a characteristic feature of the condition, and a white cell count of below 5000/mm^2 occurs in more than 33% of patients, leukocytosis may occasionally be found. The platelet count is reduced in approximately 20% of cases and is usually below 40 000/mm^2 in patients presenting with thrombocytopenic purpura. Thrombocytopenia may appear only during exacerbations or be a mild persisting feature [4]. Hyposplenism may occur [5]. The ESR is raised at some time in nearly 90% of patients; the C-reactive protein (CRP) is usually normal in the absence of infection, but some patients have a normal ESR throughout. The plasma viscosity may be raised, although initially thought unreliable, a more consistent assay is now being more widely used as an indicator of activity [6]. Serum globulins are frequently raised, with a rise in the gammaglobulin usually, although α_2-globulin may be elevated and the albumin decreased. IgE antibodies may be raised [7,8], particularly in patients with arthritis. False-positive serological tests for syphilis are found in approximately 25% of patients [9] and an atypical 'beaded' pattern of fluorescence of the *Treponema pallidum* antigen occurs when sera from certain patients are tested in the fluorescent treponemal antibody absorption (FTA-ABS) test [10]. Rheumatoid factor occurs in approximately 40%. Thrombosis occurs with the lupus anticoagulant (see p. 56.69), but occasionally haemorrhage results from other haematological abnormalities [11]. The lupus anticoagulant is one of a number of antiphospholipid antibodies that may be found in up to 50% of patients with SLE. As well as thrombosis, CNS disease is strongly related to the presence of these antibodies [12].

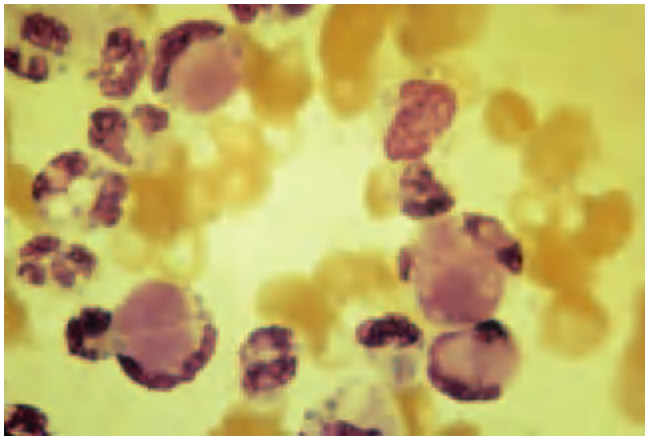

Fig. 56.38 Lupus erythematosus cells: the phagocytosed nuclear material is homogeneous and displaces the polymorph nucleus to one side.

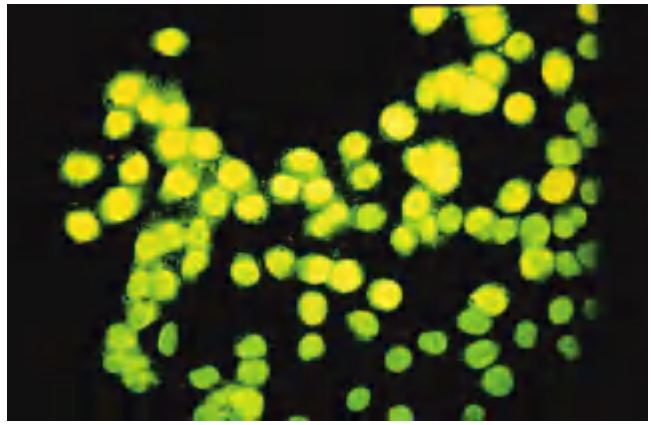

Fig. 56.39 Homogeneous type of antinuclear factor demonstrated on Hep-2 cells.

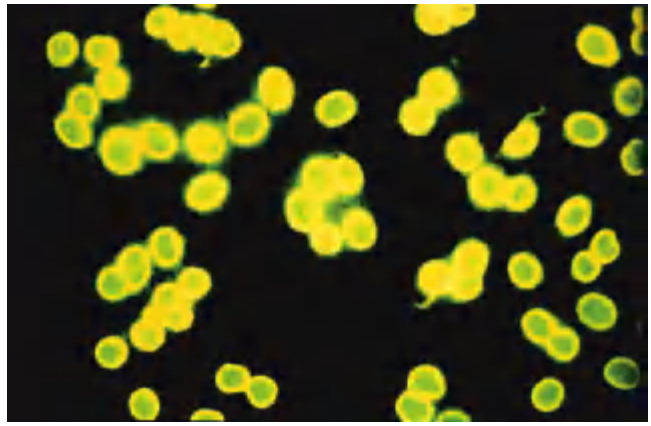

Fig. 56.40 Peripheral type of antinuclear factor demonstrated on Hep-2 cells.

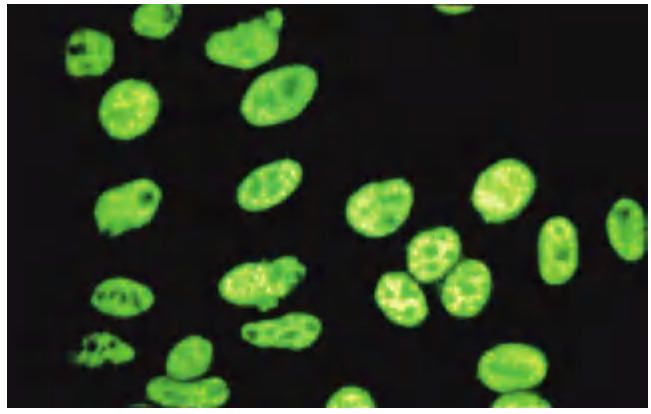

Fig. 56.41 Speckled type of antinuclear factor demonstrated on Hep-2 cells.

The LE cell phenomenon, first described by Hargraves *et al*. [13], is the basis for the LE cell test, which is positive in over 80% of patients. LE cells are polymorphonuclear leukocytes which have ingested nuclear material from degenerative white cells, in the presence of an antibody to deoxyribonucleoprotein (the LE cell factor) (Fig. 56.38). Sometimes, large masses of nuclear material are found extracellularly and, with surrounding leukocytes, form rosettes. LE cells, if present in large numbers, are highly suggestive of SLE, but the occasional LE cell is sometimes demonstrated in other conditions, including chronic DLE, systemic sclerosis and rheumatoid arthritis [14]. A positive LE cell test is a feature of drug-induced LE; LE cells were demonstrated in 60 out of 66 patients with procainamide-induced lupus [15]. The LE cell test has now been superseded by tests for antinuclear factors and anti-DNA antibodies.

One or more antinuclear antibodies can be detected by fluorescent antibody techniques in over 80% of cases. The incidence depends on the substrate used. Most British laboratories now use human cell lines for antibody testing, particularly Hep-2 cells derived from a human laryngeal cell line. This produces a reduction in the proportion of patients said to be antinuclear factor negative. Previously, the standard substrate was rat or mouse liver. Using rat liver, four staining patterns can be demonstrated [16], representing four systems of antinuclear antibodies (Figs 56.39–56.42).

1 In the *homogeneous pattern*, produced by antinucleohistone, the nuclei are stained all over

2 The *speckled pattern* shows minute points of fluorescence scattered all over the nucleus, the antigens being saline-soluble proteins

3 The *nucleolar pattern* shows uniform staining of each nucleolus

4 Sera containing anti-DNA antibody give rise to the fourth *peripheral or membranous pattern* [16,17], in which staining occurs at the periphery of the nucleus.

These staining patterns are produced by separate antibodies, but more than one antibody may be present in

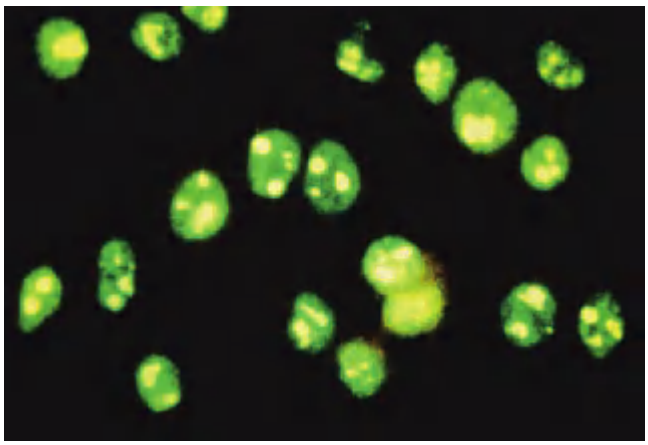

Fig. 56.42 Nucleolar type of antinuclear factor demonstrated on Hep-2 cells.

a single serum, usually in different titres. No particular antibody is specific for any disease. Discrepancies in the incidence between series probably depend on differences in techniques and the substrate used.

Homogeneous antinuclear factor (which is the same factor as the LE cell factor, although the fluorescent antibody test is more sensitive than the LE cell test) is more than twice as common as the speckled factor, but antinucleolar antibody is only occasionally found. The peripheral factor is present in high titre in more than 50% in the active phase of the disease [18], and is infrequent in other diseases. The so-called shrunken peripheral pattern is thought to be associated with a poor prognosis and a high incidence of renal disease [19]. It may appear 10–15 days before an exacerbation of the disease and be associated with a fall in serum complement [20]. In a series of 63 cases of SLE seen by the authors, one or more antinuclear factors were demonstrated in 55 patients (87%). Homogeneous staining was present in 46 cases, speckled staining in 18 and nucleolar staining in five. Titres up to 1 : 32 000 occur, but the titre frequently bears no relation to the activity, progress or duration of the disease. A high titre (over 1 : 64) of antinuclear factor(s), in a patient with symptoms and signs of a multiple system disorder, suggests the possibility of SLE or systemic sclerosis, and almost certainly excludes polyarteritis nodosa or cutaneous vasculitis. Any person in apparently good health found to have a high titre of antinuclear factor should be followed-up for years, as there is a considerable likelihood of developing LE or systemic sclerosis. A low titre (less than 1 : 16), in the absence of clinical symptoms and signs, can be ignored [21].

When Hep-2 cells are used as substrate, as well as being more sensitive to the presence of antinuclear antibody, further patterns can be identified [22]. These include centromere staining (see p. 56.109) associated with the CREST syndrome and in 6% of patients with SLE, homogeneous, peripheral (specific to SLE), fine and coarse speckles and a ground-glass appearance produced by Scl-70 antibody (see p. 56.109) found in systemic sclerosis. There are also several patterns of nucleolar staining: homogeneous, speckled and clumpy. The full clinical association of these antibodies has not been determined.

Circulating antibodies to DNA are almost always present in active disease [23,14] and may occur in the absence of antinuclear factors [24], although this is very uncommon using Hep-2 cells. Their demonstration by the Farr technique is the most specific aid to diagnosis, and levels often correlate with disease activity, although DNA antibodies should not be the only criterion [25]. Radiolabelled DNA is incubated with the test serum and any DNA–anti-DNA complexes formed are precipitated by 50% ammonium sulphate. Comparison of the radioactivity in the supernatant and precipitate gives the so-called DNA-binding activity. Values above 30% are abnormal. The level was raised in 83% of patients with SLE and in 100% of those with active disease. A rise in the index may precede an exacerbation of the disease, and levels fall with remission [26]. Normal values are found in drug-induced LE and in other disorders in which antinuclear antibodies occur. A high binding capacity is associated with poor prognosis and renal disorder [16]. The peripheral staining pattern of antinuclear antibody does not correlate with anti-DNA antibodies or with disease activity [27].

Several other antibodies occur in patients with SLE. Patients with antihistone antibodies have a lower incidence of renal and CNS disease, alopecia, anaemia and decreased complement [28]. Antibodies to soluble cellular antigens include anti-Sm antibody, which is found in 15–25% of patients and appears to be specific for the disease, occurring particularly in patients with renal disease, CNS disease and vasculitis. Anti-RNP antibodies occur in 25% of patients [29], but are characteristic of mixed connective tissue disease (see p. 56.116). It has been reported that titres correlate with disease activity [30].

Anti-Ro [31] antibody occurs in 30% of patients who have an increased tendency to photosensitivity [32,33], renal disease, Sjögren's syndrome and rheumatoid factor, as well as being a marker for neonatal lupus (see p. 56.53). It is also found in SCLE (see p. 56.24). Anti-Ro is an antibody to an RNP derived from RNA polymerase III-transcribed hY RNAs with a protein component that appears to be the main target. Two different proteins, one of 60 kDa and another of 52 kDa, react with most positive sera. The 60-kDa protein predominates in SLE, the 52-kDa in Sjögren's syndrome [34]. Patients with anti-Ro antibodies are more likely to have HLA-B8 and -DRw3 [35]. Anti-La, an antibody to another RNP product of RNA polymerase III, is present in 10–15% of patients, often with Sjögren's syndrome and with anti-Ro antibody. Although several different antibodies occur in the same patient, they fluctuate independently, and the antibody profile may

alter over the years. The only characteristic pattern of antibody appears to occur in the LE–erythema multiforme syndrome [36], in which there is speckled type of antinuclear factor, a specific precipitating antibody (originally designated SjT but now thought to be anti-La) and rheumatoid factor. This syndrome is occasionally found in cases of systemic as well as DLE, in which it was originally described (see p. 56.14). In cases associated with SLE, homogeneous antinuclear factor is also usually present.

Cryoglobulins may be found in 11% of patients. Cryoglobulinaemia may precede the manifestations of SLE by many years [37]. Cold agglutinins occur in 6%. Serum complement is frequently low [38], especially in patients with active nephritis. A decrease in levels may precede clinical evidence of an exacerbation of disease, and return to normal with remission but, in general, estimations of CH50, C3, C4 and circulating immune complexes are rarely helpful in assessing disease activity [39]. Other possible indicators of disease activity include β_2-macroglobulin [40] and serum IFN [41]. Increased levels of plasma anaphylatoxins (C3a) may predict exacerbations [42]. The intracutaneous injection of DNA solution, which has been advocated as a skin test [43], is not specific. Occasionally, circulating anticoagulants may be demonstrated [44,45]. Factor II may be absent and return with steroid therapy [46].

Inherited deficiencies of the major complement components occur with SLE [47], usually as autosomal recessive traits [48]. These include C1 [49], C2 [50] and C4 [51], as well as C5–C9. The most common is homozygous C2 deficiency in which SLE occurs in one-third of patients. Clinically, the lupus-like syndrome in C2 deficiency shows a low incidence of renal disease, low incidence and low titres of anti-DNA antibodies, infrequent occurrence of immunoglobulin and complement deposits in the skin, and frequent anti-Ro antibodies [46]. Isolated C1q deficiency has also been reported [52], and there is an association between C1-esterase inhibitor deficiency and SLE [53]. Patients may be helped by danazol [54]. Hereditary angio-oedema and SLE were found in the mother of twin boys who had DLE and angio-oedema, and this was associated with low C1 inhibitor and C4 levels [55]. Antibodies to Australia antigen can be demonstrated in 25% of cases [56]. Serum CRP levels are usually normal or only slightly elevated. A level higher than 60 mg/L suggests the presence of superimposed infection [57]. A number of soluble cytokines or their receptors may be found in serum of patients with SLE, and may correlate with disease activity: intercellular adhesion molecule-1 (ICAM-1) [58], TNF receptor [59] and IL-10 [60]. There is differential overexpression of heat-shock proteins in patients with differing patterns of systemic involvement [61]. Urinary levels of neopterin [62], or of IL-6 [63], may also be useful to monitor disease activity.

Antinuclear antibody-negative SLE [1,2]. Patients originally described under this title have many similarities with patients suffering from SCLE (see p. 56.24). Because the cutaneous involvement is usually the predominant feature, many patients present initially to dermatologists. Clinically, a non-scarring malar flush, oral ulceration and photosensitivity, with papulosquamous or annular lesions on the face, trunk and arms, are prominent, but arthritis, serositis, renal disease and haematological involvement are less frequent than expected in SLE. In approximately 5–10% of patients with SLE, antinuclear factor cannot be demonstrated using standard substrates such as rat or mouse liver. This is a problem in less than 1% if Hep-2 cells are used. These patients frequently have anticytoplasmic antibodies. Over 60% of patients have anti-Ro antibodies and approximately one-third have anti-La antibody (anti-La rarely occurs without anti-Ro). Twenty-five per cent have antibodies to single-stranded DNA. There is no difference in the histology of the skin between antinuclear-negative and -positive cases. Immunoglobulins and complement are found at the dermal–epidermal junction in 70% of patients, but are rare in the non-light-exposed uninvolved skin. Topical steroid therapy may be helpful, but oral antimalarials and steroids may be required. Approximately 10% of patients eventually become antinuclear factor-positive, although the pattern of anticytoplasmic antibodies does not alter.

Assessment of disease activity. A number of attempts have been made to devise definitions of disease activity, accompanied by scoring systems using combinations of clinical and laboratory parameters to allow comparative and longitudinal studies. Global measures such as European Community Lupus Activity Measure (ECLAM) [1], Systemic Lupus Erythematosus Disease Activity Index (SLEDAI) [2] and the more detailed British Isles Lupus Activity Grading (BILAG) [3] are useful in the context of clinical trials in patients with active systemic disease. However, none is specifically designed for the assessment of patients who most concern dermatologists, and do not grade skin disease in any meaningful way.

Association with other diseases. SLE can occur concurrently with rheumatoid arthritis [1], and may present with polymyalgia in elderly patients [2]. Systemic sclerosis and SLE may occur in the same patient [3], and the demonstration of immunoglobulins at the dermal–epidermal junction may be helpful in confirming the presence of both diseases [4]. SLE occurs with lichen sclerosus and with 'en coup de sabre' morphoea [5], and linear and plaque morphoea [6]. Sjögren's syndrome and SLE occur together [7–9] but the former is usually mild, and is unlike secondary Sjögren's syndrome occurring with rheumatoid arthritis. Patients with hyperglobulinaemic purpura may have antinuclear factor; this condition may, in certain cases, have features of SLE [10]. The finding of LE cells in young females with liver disease has already been mentioned. SLE can follow primary biliary cirrhosis [11], and may occasionally occur in association with necrotizing angiitis [12] and giant cell arteritis [13]. Patients who have LE and psoriasis often have anti-Ro antibodies [14].

Myasthenia gravis may follow SLE [15], and SLE may follow thymectomy for myasthenia gravis [16] or be associated with a thymoma [17]. Myasthenia gravis, thymoma and pemphigus may occur together in patients with SLE [18], and heterozygous C2 deficiency associated with angio-oedema, myasthenia gravis and SLE also occurs [19]. Angio-oedema resulting from C1-esterase deficiency can be associated with SLE [20], and protein S deficiency can occur in these patients [21].

SLE has been reported with Hashimoto's thyroiditis and pernicious anaemia [22]. It was associated with seminoma of the ovary in one case. Removal of the tumour led to an apparent permanent cure of the LE [23]. Lymphatic leukaemia or Hodgkin's disease has followed SLE [24], and lymphoma has been reported [25]. Amyloidosis [26] can develop in SLE, and in one case this led to adrenal insufficiency and was followed by malignant lymphoma [27]. The presentation with haemolytic anaemia [28] or thrombocytopenic purpura [29] is well documented, and overt SLE may appear after splenectomy for 'idiopathic thrombocytopenic purpura'. If this occurs, it is likely that the thrombocytopenia is an early manifestation of SLE. It may also occur in association with thrombotic thrombocytopenic purpura [30], pernicious anaemia [31], von Willebrand's disease [32], myelofibrosis [33,34], selective IgA deficiency [35], erythroleukaemia [36], red cell aplasia [37], monoclonal gammopathy and multiple myeloma [38], biclonal gammopathy [39], myelofibrosis [39], hyperviscosity syndrome [40], Whipple's disease [41] and ulcerative colitis [42]. SLE also occurs with pemphigoid [43] and cicatricial pemphigoid [44], pemphigus [45], dermatitis herpetiformis [46], linear IgA disease [47], epidermolysis bullosa dystrophica [48], porphyria cutanea tarda [49] (although the association has not been confirmed) [50], and occasionally with porphyria variegata or acute intermittent porphyria [51–53]. The disease has been reported in patients with Sweet's syndrome [54], Klinefelter's syndrome [55], hypoparathyroidism [56], partial lipodystrophy [57], relapsing polychondritis [58], pyoderma gangrenosum [59] and Kikuchi's disease [60]. In one case it has been associated with retroperitoneal fibrosis [61], and in another with eosinophilic fasciitis and retroperitoneal fibrosis [62]. It uncommonly occurs with gout [63] and sarcoidosis [64]. An unusual syndrome of breast hypertrophy, erythema annulare centrifugum, generalized melanoderma and immunodeficiency to viral warts has been associated with SLE [65]. Twelve per cent of patients with SLE have warts, which is a higher incidence than in a control population [66]. Senear–Usher syndrome (pemphigus and LE) has been associated with internal malignancy [67], but an overall increased incidence of malignancy in SLE is debatable. Malignancy occurred in 4.7% in one series [68]. Epidermodysplasia verruciformis occurs presumably as a result of immunodeficiency or prolonged treatment with corticosteroids [69]. Among other rare associations are Kaposi's sarcoma [70] and Kawasaki disease [71].

The relationship to DLE is discussed on p. 56.2. Patients with persistent false-positive serological tests for syphilis [72] may later develop SLE.

Kikuchi's disease and SLE. Histiocytic necrotizing lymphadenitis was first described independently by Kikuchi

Fig. 56.43 Erythematous facial plaques in Kikuchi's disease.

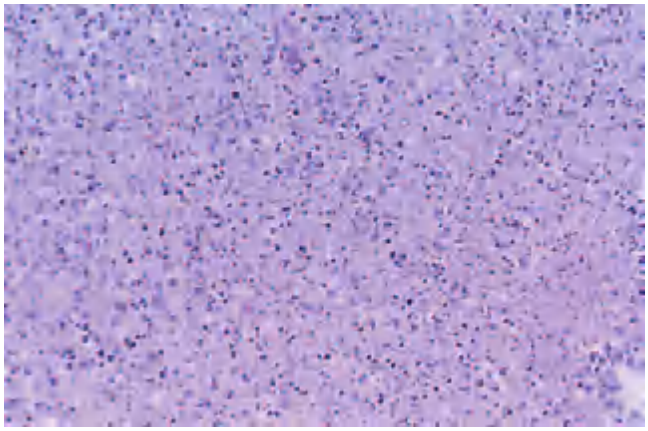

Fig. 56.44 Histiocytic necrotizing lymphadenitis (Kikuchi's disease). Lymph node. (Courtesy of Dr W. Merchant, Leeds General Infirmary, Leeds, UK.)

[1] and Fujimoto *et al.* [2] from Japan in 1972. Cases are predominantly female, but it can occur in males, and can occur at all ages. Usually, patients present with lymphadenopathy, frequently cervical, although other nodes can be involved. Fever, weight loss and night sweats are found in the more severely affected cases. There may be leukopenia and elevation of the ESR. Skin changes occur in 30% of patients [3]. They are all non-specific and include multiple indurated red papules on the back and arms [4], erythematous plaques resembling lymphoma, erythema and acneiform eruptions on the face (Fig. 56.43), and morbilliform, urticarial and rubella-like eruptions elsewhere. The oropharynx may be red or ulcerated.

Histology of the skin shows oedema of the papillary dermis, with a patchy perivascular infiltrate in the dermis and subcutaneous fat. The infiltrate consists of histiocytes containing nuclear debris and small lymphocytes. The nuclei of the histiocytes may be deformed. The lymph nodes show focal or complete loss of follicular architecture, with necrosis of cortical and paracortical areas (Fig. 56.44). The extensive infiltrate consists of small lymphocytes, immunoblasts, macrophages and so-called plasmacytoid T cells [5]. Neutrophils are rarely seen, a feature that may help to distinguish this condition from SLE. The natural history is for spontaneous healing in a few months but it can be fatal as a result of heart failure brought about by microscopic myocardial necrosis [6]. There was a 3.3% recurrence rate in one series [7]. In most cases, no treatment is required, but a course of prednisolone may speed resolution. Various triggers have been incriminated, including the human herpesvirus 6 [8], parvovirus B19 [9], Epstein–Barr virus [5], dengue virus [10] and infection by *Yersinia enterocolitica*, *Toxoplasma*, cytomegalovirus and human immunodeficiency virus (HIV) [11], and rupture of a silicone breast implant [12]. The condition is occasionally associated with SLE. It may precede SLE [13], may be the presenting feature of SLE [14] and, rarely, SLE may precede it [15]. The association was found in two of 108 patients with Kikuchi's disease studied by Dorfman [16], and two of eight patients studied by El-Ramaki *et al.* [17]. It has occurred with DLE in a case encountered by the authors, and may be associated with other cutaneous manifestations of lupus [18]. Other associated conditions include Still's disease [19,20] and Sweet's syndrome [21]. In addition to SLE, the disorder can occur with lymphoma, tuberculous lymphadenitis, viral lymphadenitis, infectious mononucleosis and drug eruptions.

Differential diagnosis. The conditions mentioned in the above section must be differentiated from LE. Many patients suspected of having a connective tissue disease may, even after investigation, present problems of categorization. The criteria for SLE of the ARA (1982) are shown in Table 56.3 [1]. The presence of four or more of the 11 manifestations, serially or simultaneously, is compatible with SLE (96% sensitive, 96% specific).

Other features, such as cutaneous LE lesions of any type, diffuse alopecia, involvement of the scalp or mucous membranes, preferably confirmed by histopathology, or direct immunofluorescence, may be helpful.

Several practical points are important. The ESR need not be elevated. In patients at Leeds, 15% followed up for at least 5 years have never had an ESR above 20 mm in the first hour. Several of these have had high titres of antinuclear factor, raised levels of anti-DNA antibodies and lowered serum complement. Diagnosis thus depends upon the association of features rather than on any specific abnormality. The demonstration of a high titre of antinuclear factor is important. In the acute phase, the membranous types of antinuclear factor may be present as well as a raised level of anti-DNA antibody, anti-Sm antibody and a reduction in the serum complement. In the authors' experience, the presence of antinuclear factor in high titre almost certainly excludes polyarteritis nodosa and other arteritic disorders. When a raised ESR, raised serum globulin, leukopenia and evidence of renal disease are added, the diagnosis becomes highly probable. It is important to remember that antinuclear factor is not always present in SLE, and in such cases alopecia, Raynaud's phenomenon and oral ulceration commonly occur [2]. The demonstration of immunoglobulins in the dermal–epidermal junction of uninvolved as well as involved skin may be very helpful (see p. 56.34). The combination of IgG and IgM at the dermal–epidermal junction of involved and uninvolved skin, raised DNA binding, antinuclear antibody in a titre of more than 1 : 64 and decreased C3 or C4 is highly suggestive of SLE [3]. In drug-induced LE, anti-DNA antibodies are absent, serum complement is normal and globulin is not found in the uninvolved skin. Acute febrile neutrophilic dermatosis (Sweet's syndrome) may mimic SLE when a 'butterfly rash' is associated with fever, myalgia, arthralgia, hepatosplenomegaly, renal disease and hyperglobulinaemia [4].

Prognosis [1]. The course of SLE is very variable [2]. Acute fulminating cases are much less common than subacute cases, which smoulder on for many years. Mortality rates have declined in both England and Wales in the 10-year period 1974–83 [3] and in the USA [4]. Although, in pre-steroid days, 52% of patients in one series [5] died within 2 years, in another series 54% of patients survived 11 years [6], compared with controls, of whom 97% survived a similar time. In 1977, an overall 5-year survival of 91% was reported [7], and 98% in another series in 1978 [8], although a 5-year survival of only 88% was reported from a rheumatological clinic in 1990 [9]. Approximately three-quarters will now survive 15 years [10]. Survival is related to organ involvement and to frequency of exacerbations [11]. Of those without renal involvement, 84% survive 15 years, compared with 57% whose kidneys are affected [10]. Spontaneous remissions, sometimes lasting 10–20 years, occurred in 35% of Dubois and Tuffanelli's [12] patients, the longest being 26 years. Serological as well as clinical remission occurred in 4% of 305 patients [13]. Exacerbations are more frequent in the first 5 years of the disease [14]. Pregnancy does not affect long-term survival. Prolonged survival is associated with an increased risk of atherosclerosis, avascular necrosis and neuropsychiatric dysfunction [15]. In elderly people the presentation is insidious and the clinical course is relatively benign. Renal disease and serological abnormalities are less frequent, and arthritis, with subcutaneous nodules, and pleuropericarditis are more prominent in elderly people [16].

The better prognosis of the more recent series is a result, not only of the administration of corticosteroids, but also of earlier diagnosis, the avoidance of stress and drugs such as sulphonamides, and the control of infections by antibiotics. The cause of death is frequently progressive renal failure, occasionally with anuria. Secondary infection, particularly bronchopneumonia, was a much more common cause of death in the pre-antibiotic era, although infection may still be more important than renal failure.

The high infection rate is not caused solely by steroid [17] or antimetabolite therapy. Spontaneous peritonitis caused by Gram-positive bacteria is a complication of lupus nephritis treated with corticosteroids [18]. Unusual infections such as pneumococcal epiglottitis have been reported [19]. There is an increased risk of *Salmonella* bacteraemia [20] and rapidly fatal pneumococcal septicaemia [21]. Repeated skin infections may be a presenting feature. Cellulitis of the periorbital area caused by *Staphylococcus aureus* and group A haemolytic streptococci has been reported [22,23]. Neisserial infections may also occur [24]. Death may result from vasculitis of the CNS in patients presenting with convulsions, psychoses and paralysis. Patients with CNS lesions and psychosis have a poor prognosis. Deaths from CNS involvement become more important in the later stages of the disease [25]. Others may die from heart failure or the side effects of therapy [26].

A bimodal pattern of mortality has been described [27], but not confirmed, in black patients [28]. Patients who die early in the disease die from active LE, including renal involvement, receive large doses of steroids and have a high incidence of infection. Those who die later have relatively inactive disease, long duration of steroid therapy and a high incidence of atherosclerotic heart disease and myocardial infarction [11]. Nevertheless, it is the authors' experience that death from infection is common, even in long-standing cases. The maximum disease activity occurs early, and patients rarely develop new organ involvement after the first few years [8,14]. Late reactivation of SLE can occur [29].

Although the disease is much more common in females, the prognosis is worse in males [30–33]. Males are more likely to develop renal failure [34]. Although race and ethnic origin have been claimed not to influence prognosis [35], increased mortality has been noted in Asians [36] and black people [37], probably in part because of socioeconomic conditions. The degree of renal involvement is probably the most important factor in prognosis. Patients with nephrotic syndrome at the onset of nephritis do badly and may die within a few months, but development later in the disease does not have an adverse effect. Patients with albuminuria may survive on small doses of steroids for many years, and the overall prognosis of patients with renal involvement is not as bad as early studies suggested. Patients with cutaneous lesions of DLE and laboratory abnormalities have the same prognosis as uncomplicated cases of DLE [38]. Patients with arteritis, antiphospholipid syndrome, thrombocytopenia, haemolytic anaemia and CNS involvement have a poorer prognosis than those whose illness mainly involves the joints. There appears to be no increased risk of malignancy [39], although earlier reports suggested this might be so [40,41].

Genetic counselling. The clinical genetics of lupus has been reviewed [1]. Approximately 5% of first-degree relatives of patients may have or may develop lupus. The risk is doubled if there are two affected first-degree relatives, and this risk is even greater if further family members are affected. The risk for female relatives is greater than for males and may also be increased for those with hyperglobulinaemia or antinuclear antibodies. Mothers with anti-Ro and anti-La antibodies may have children with neonatal lupus and heart block. When a child has neonatal lupus or CHB, the risk of a subsequent child having heart block is approximately 25%.

Treatment [1–3]. The aim is to try to maintain optimal function with the minimum of therapy. SLE is an episodic disease, and treatment must be tailored to the patient's requirements. Morale must be maintained. In acute cases, and during severe exacerbations, bed rest is required. Undue exposure to the sun should be avoided and patients should be advised to wear broad-brimmed hats, to cover the 'V' of the neck and the arms, and to use a sunscreen preparation. Mental stress, physical overexertion and secondary infection should be avoided. There seem to be few problems with menopausal women on hormone replacement therapy [4]. Drugs may be required for symptomatic treatment but should be kept to a minimum. However, the danger from infection is great, and antibiotics should not be withheld for fear of causing an exacerbation. Death can occur from *Salmonella* infection [5]. Estimation of CRP may be helpful; if raised it suggests infection. Dapsone may be helpful for urticarial lesions [6], bullous eruptions [7] and for thrombocytopenia [8].

Hypertension must be treated, and while it is generally agreed that hydralazine can be used safely in most patients with SLE [9], there are now better modern alternatives including angiotensin-converting enzyme inhibitors and α-blockers. Diuretics may be required for the nephrotic syndrome or cardiac failure, and anticonvulsants for epilepsy. Chlorpromazine is a good sedative for psychosis. Aspirin may be very useful, particularly in patients with joint manifestations. There is an increased risk of aspirin hepatoxicity in SLE [10]. Indometacin may also be of benefit in cases with arthritis. Ischaemic necrosis of bone may be best treated early by core decompression [11].

Corticosteroids are required in acute cases, and should be given in adequate regimens. Prednisolone 60 mg/day is the steroid of choice initially. It is rare for higher dosage to be needed. Once the condition appears to be under control, the dosage may be reduced gradually, until a maintenance dosage of approximately 5–15 mg/day is reached. A single dose daily, given in the morning [12], produces fewer side effects and does not impair the therapeutic response.

Not all patients require steroids, especially if there is no internal organ involvement [2]. It is important to assess the patient's progress by their general well-being and relief of symptoms, rather than by strict attention to laboratory abnormalities [13]. The ESR and DNA antibodies are no guide to the adequacy of therapy; the titre of antinuclear antibodies often persists unchanged despite clinical remission. Anti-DNA antibody and serum complement levels may be helpful in predicting exacerbations [14]. Low C3 often indicates severe renal disease. There is some evidence that a return of serological abnormalities to normal is followed by a prolonged remission [15], but exceptions indicate that serological data alone cannot be used as a basis of therapy.

Some fulminating cases have been treated with massive doses of steroids but the advantages of such therapy rarely outweigh the risks. There is no evidence that a very high dosage of corticosteroids is beneficial in CNS disease [16]. Steroid-induced psychosis is less common than cerebral lupus, but both can occur in the same patient [16]. Prolonged high dosage of corticosteroids (e.g. prednisolone 60 mg/day for 6 months) is said to improve renal lesions more than small suppressive doses [17,18]. This improvement of survival is not seen in patients with raised blood urea before the onset of therapy. There is no evidence that steroids are prophylactic and that prolonged therapy will prevent the development of new features. No single test can reliably indicate the degree of activity [19]. Steroid myopathy can occur with high doses: serum enzymes are usually normal but urinary creatine is increased [20]. Myopathy may take up to 4 months to improve on reducing therapy.

In mild cases, the administration of chloroquine or hydroxychloroquine may allow the dosage of steroids to

be reduced, but the reduction may not be clinically meaningful [21]. Antimalarials are less useful than in DLE, and may be dangerous for long-term therapy. They may have a place in patients with photosensitivity. Pregnancy is not contraindicated, as healthy live babies have been delivered by women on antimalarial therapy throughout pregnancy [22].

Immunosuppressive drugs have been used for patients not responding to corticosteroids or to act as steroid-sparing agents [23]. It has been concluded that azathioprine adds nothing to high-dose prednisolone treatment in mild or moderate renal disease [24]. Another controlled trial, comparing azathioprine plus prednisolone with prednisolone alone, did not show any significant difference in the number of deaths, renal or extrarenal manifestations, serum complement levels, DNA antibodies, LE cells, antinuclear antibody titres, or Coombs' antibodies, or any evidence of a steroid-sparing effect [25]. Sudden withdrawal may be followed by relapse [26]. Cyclophosphamide may be a more effective immunosuppressant, but it is more toxic than azathioprine. Most but not all trials have suggested that it may be useful in SLE [27–30], although not all support routine use. Nevertheless, pulsed therapy with cyclophosphamide may be useful for renal disease and is as effective as pulsed methylprednisolone [31]. Triple therapy with prednisolone plus azathioprine and cyclophosphamide had no therapeutic advantage over prednisolone and azathioprine [32].

Chlorambucil has been found to be helpful by some [33,34], but not by others [35]. An extensive trial [23] involving 53 patients has shown excellent results with a combination of prednisolone and chlorambucil in the treatment of diffuse lupus glomerulonephritis when compared with 110 patients treated with prednisolone alone, prednisolone and azathioprine, or prednisolone and cyclophosphamide. There are still some reservations about this combined therapy.

Methotrexate 7.5 mg/week has improved steroid-resistant patients [36], and patients without renal or CNS involvement [37], and 10–20 mg/week is useful for mucocutaneous lesions [38].

The long-term risk of malignancy must be considered whenever immunosuppressive drugs are used. Cyclophosphamide has been associated with bladder cancer [39], acute non-lymphocytic leukaemia and solid tumours. Mesna may reduce urotoxic side effects, but 50% of patients develop rashes which may be confused with an exacerbation of SLE [40]. Reticulum cell sarcoma [41] and non-Hodgkin's lymphoma [42] are hazards of azathioprine therapy.

Ciclosporin has been used in resistant cases in a dosage of 3–5 mg/kg, but four of 16 patients had a flare during treatment and three discontinued treatment because of side effects [43]. Pulse therapy with methylprednisolone 1 g given intravenously in 500 ml normal saline over 4 h on 3 successive days to in-patients may be helpful in individuals who are not controlled by oral prednisolone and immunosuppressives [44]. Double-blind trials have indicated that any initial improvement may not be maintained [45]. Given monthly it may prevent deterioration in renal function in patients with nephritis [46].

Plasmapheresis of 2 L/day for 3–4 days each week over a period of 2–3 weeks may be helpful in a small number of patients with a high level of immune complexes, whose condition is deteriorating despite other therapy, but controlled trials have not been convincing [47], and plasmapheresis may even be detrimental [48]. Any benefit lasts only approximately 2–3 weeks. Plasmapheresis may be useful in managing life-threatening complications such as fulminating vasculitis or CNS disease [49]. Intravenous gammaglobulin 1 g/kg/day for 3 days improved four out of five patients. The effect lasts 4–6 weeks [50]. Provisional studies of extracorporeal photochemotherapy have shown improvement in a few patients, and treatment was not associated with any side effects [51]. Anticoagulants may be required for patients with lupus anticoagulant or anticardiolipin antibodies who have thrombotic episodes. Danazol 400–600 mg/day may help patients with premenstrual exacerbations [52], and sometimes has a marked effect on thrombocytopenia [53]. Oral levamisole, in a dosage of 150 mg three times daily has been found helpful by some [54], but not by others [55]. Antilymphocyte and antithymocyte antisera may help patients with nephritis not responding to either corticosteroids or azathioprine [56]. Although thymectomy has been carried out for SLE, this cannot be advocated as a satisfactory method of treatment, and in some patients SLE has actually followed thymectomy and myasthenia gravis. Acute anuric renal failure may respond to dialysis, corticosteroids and heparin [57]. SLE remains clinically inactive in patients undergoing dialysis for chronic renal failure [58]. Renal transplantation should be considered for terminal lupus nephritis. Disease activity and exacerbations decrease [59]. There may be no recurrent lupus nephritis in the allograft [60]. The risk of failure of allograft function is increased when there is serological evidence of disease activity [61].

A new and surprising therapeutic approach is that although UV light, especially UVB, can exacerbate SLE, it has been found in a controlled trial that exposure to UVA-1 (340–400 mm) at a dosage of 60 kJ/m^2 three times weekly reduced disease activity, reduced the need for medication and decreased antibody levels [62]. A low-fat, high marine oil diet (eicosapentaenoic acid: max EPA 20 g/day) modified disease activity in 27 patients in a placebo-controlled trial over 3 months [63].

The lupus anticoagulant, anticardiolipin antibodies and the antiphospholipid antibody syndrome [1,2]

The lupus anticoagulant was first described in SLE [3], but it also occurs in drug-induced SLE, other connective tissue diseases, polymyalgia rheumatica/giant cell arteritis (where 40–50% of patients may have antibodies [4]) and carcinoma and lymphoma [5]. It may be induced by infection, including that caused by Epstein–Barr virus [6] and varicella [7]. It also occurs as the causative abnormality of the primary antiphospholipid (Hughes') syndrome [8,9], although a small proportion of those classified as having the primary syndrome will progress to lupus or a lupus-like syndrome [10].

The lupus anticoagulant is only one of several antiphospholipid antibodies, which include the anticardiolipin antibody demonstrated by ELISA. IgG anticardiolipin antibody has been found in 23% of patients with SLE [11], and is associated with similar clinical features to those seen with the lupus anticoagulant [12–15]. The presence and titre seem to depend on disease activity and decrease with treatment, particularly when of IgM type. In a study of healthy blood donors, anticardiolipin antibodies and the lupus anticoagulant were found in 4–6% of 499 donors, mainly young females [16].

The features associated with the lupus anticoagulant are caused by an acquired immunoglobulin (IgG or IgM), identified by prolonged activated partial thromboplastin and kaolin clotting times, which cannot be corrected by normal plasma. There may also be IgA antiphospholipid antibodies [17]. There are now a number of methods for detecting the abnormalities. These have been reviewed [18], and include assessment of the extrinsic pathway of coagulation [19]. These antibodies are directed against a range of phospholipids, including cardiolipin. The route by which thrombosis is induced remains unclear, but some antiphospholipid antibodies interact with a complex of phospholipid and β_2-glycoprotein-I to inhibit factor XII activation, platelet activation and prothrombinase activity [20]. The antibodies are found in 14% of patients with SLE, half of whom have thrombotic episodes [21] in leg, renal, hepatic [22], cerebral or pulmonary vessels. The lupus anticoagulant has been associated with Libman–Sacks endocarditis [23], chorea [24], labile hypertension, epilepsy, myelitis, myocardial infarction, valvular heart disease, haemolytic anaemia, retinopathy [25] and Addison's disease [26]. The presence of a lupus anticoagulant may also be related to avascular necrosis of bone [27]. Rarely, patients develop vascular occlusions in multiple organs [28]. This catastrophic variety may be fatal. There is also a syndrome in which a severe reduction in clotting occurs because of a different set of antiphospholipid antibodies—the haemorrhagic lupus anticoagulant syndrome [29].

Cutaneous lesions [30] include thrombophlebitis, purpura and ecchymoses, livedo reticularis, leg ulcers, cutaneous necrosis [31], gangrene and subungual splinter haemorrhages [32]. Histologically, non-inflammatory thrombosis of small dermal blood vessels can be demonstrated, but necrotizing vasculitis is not a feature [33]. Thromboses in the placenta lead to fetal death, and may recur in subsequent pregnancies. Thrombocytopenia also occurs. All women with SLE who have recurrent abortions and thrombotic episodes, or who are biological false-positive reactors, should be screened for the lupus anticoagulant, as treatment with prednisone 40–80 mg/day and aspirin 75 mg/day may result in successful pregnancy [34]. One patient with repeated fetal loss was successfully treated with intravenous human gammaglobulin [35]. Full anticoagulation (international normalized ratio (INR) greater than 3), with or without aspirin, appears to be the most effective therapy in the non-pregnant patient [36]. The presence of the antibodies without clinical features is not an indication for either steroid therapy or anticoagulation.

Scleroderma [1]

Sclerosis of the skin occurs in a variety of conditions, such as dermatomyositis and LE, and invariably occurs as part of the cutaneous manifestations of systemic sclerosis, which is described elsewhere. However, the term 'scleroderma' should strictly be confined to sclerosis of the skin, either localized or generalized, occurring in patients as the only or prominent feature. In such circumstances it is better to use the term 'morphoea'. There has been much discussion and confusion about the relationship of morphoea to systemic sclerosis (see below), but the two conditions, despite certain similarities, are best considered as distinct entities.

Localized morphoea

SYN. LOCALIZED SCLERODERMA; CIRCUMSCRIBED SCLERODERMA

Definition. A disorder of unknown cause in which there is localized sclerosis of the skin. The condition may be subdivided clinically into the following types [1–3]:

1 Circumscribed plaques
2 Morphoea profundus/subcutaneous (deep)
3 Bullous morphoea
4 Linear morphoea
5 Frontoparietal lesions (en coup de sabre), with or without hemiatrophy of the face.

Aetiology. The cause of morphoea is unknown. A number of studies, however, have shown *in vitro* abnormalities in fibroblasts from patients with morphoea. These include fibroblast promotion of migration of mononuclear leukocytes across endothelial cell monolayers [1], increased platelet-derived growth factor and receptor expression [2] and increased transforming growth factor-β (TGF-β) receptor expression [3], which may lead to increased connective tissue growth factor (CTGF) gene expression and ultimately fibrosis [4,5]. That morphoea is an immunologically mediated disease also gains support from studies that have found increased levels of circulating cytokines in patients with morphoea. These include IL-2 receptor [6,7], IL-6 receptor [8], soluble CD4 and CD8 [9], CD23 [10], CD30 [11], TNF-α [12], soluble vascular cell adhesion molecule-1 (VCAM-1) and E-selectin [13], antiendothelial cell antibodies [14] and antibodies to fibrillin 1 [15]. That they may be involved in disease activity is supported by some studies, which have found increased levels of, for instance, soluble IL-2 receptor in active but not inactive disease [6,7], although such findings are by no means uni-

versal. Additional support for an autoimmune aetiology is the occurrence of scleroderma-like lesions in chronic graft-versus-host disease, and an association with idiopathic thrombocytopenic purpura [16].

Experimental exchange of Thiersch grafts between normal and affected sites resulted in rapid transformation of the normal graft to morphoea and vice versa [17]. Trauma may be a triggering factor [18,19] and may precede the onset by many months. Immobilization has also been reported as a cause [20]. Morphoea has also occurred after bacillus Calmette–Guérin (BCG) vaccination [21], following varicella [22], injections of vitamin K [23] and after antitetanus vaccination [24]. There are several reports of morphoea occurring at the site of previous radiotherapy [25,26]. Recently, surgical trauma has been reported as a stimulus for the development of lesions after arteriovenous fistula formation [27] and rhinoplasty [28]. Hormonal factors may influence the disease: morphoea may develop during, or be exacerbated by, pregnancy, but the influence of the menopause is less clear.

Infection with borrelial organisms has been implicated in the aetiology of morphoea, some central European studies suggesting a relationship between morphoea and acrodermatitis chronica atrophicans, a disease induced by infection with *Borrelia burgdorferi* [29–31]. These studies found raised levels of antibodies against this organism in patients with morphoea compared with controls, and described the presence of viable organisms in biopsies from morphoeic lesions. In addition, using the polymerase chain reaction, *Borrelia* DNA has been found in skin biopsies from patients with morphoea [32]. However, other studies [33–37] have shown no evidence of *Borrelia* antibodies or DNA in morphoea of patients from Scandinavia, Germany, Spain or America. A recent review [38] has suggested that the reason for these contradictory findings is that either *Borrelia* infection is not the cause of morphoea or that a subset of morphoea is caused by a special species of *Borrelia* present in some parts of Europe and Asia but not in the USA and other parts of Europe.

The genetic influence on morphoea is unclear. A familial incidence has been noticed [39], and localized and systemic scleroderma has been noted in monozygotic twins [40]. Some cases of the frontal type appear to have a genetic basis [41], but there are no significant HLA associations [42]. There is an increase in the incidence of organ-specific autoantibodies in patients and relatives [43]. Morphoea has been associated with phenylketonuria, and improvement has occurred with a low-phenylalanine diet, but excretion of phenylalanine and *o*-hydroxyphenylacetic acid in nine children with morphoea was normal [44].

Morphoea has been reported after therapy with a number of drugs. Morphoea-like plaques occurred in a patient on penicillamine therapy and remitted within a year of stopping treatment [45]. Cutaneous lesions have also been reported after therapy with bromocriptine [46], hydroxytryptophan and carbidopa [47,48], pentazocine [49,50], docetaxel [51], bleomycin [52,53] and after melphalan limb perfusion [54]. These localized lesions are in contrast with the systemic sclerosis-like reactions reported later in this chapter.

Although the clinical picture of morphoea is usually distinctive, and different from systemic sclerosis, the histology and histochemistry [55–57] of the skin are similar, and X-ray diffraction, historadiographical and electron microscope investigations [44,58–60] show no differences. Electron microscopy may show changes in the underlying muscle fibres in both conditions, but only in systemic sclerosis are endothelial changes found in the muscle capillaries [61]. Skin collagen may be increased in morphoeic plaques [62], possibly because of clonal overactivity of fibroblasts [63], but is decreased in the involved skin in systemic sclerosis [64]. The two disorders rarely occur together. Nail fold capillaroscopy may reveal abnormal capillaries in such patients [65].

Pathology (Fig. 56.45). The epidermis may be normal, or flattened and atrophic with loss of the rete ridges. At first the dermis is oedematous, with swelling and degeneration of the collagen fibrils, which become homogeneous and eosinophilic. There may be a scanty perivascular lymphocytic infiltrate. Cellular infiltrates of lymphocytes, plasma cells and macrophages, either perivascular or diffuse, occurred in 84% in one series, and there is some evidence that the infiltrate may precede fibrosis [1,2]. Later, the dermis is markedly thickened, with dense collagen and relatively few recognizable fibroblasts. The elastic tissue is reduced. The dermal appendages and dermal and subcutaneous fat are progressively lost. Some sweat glands may

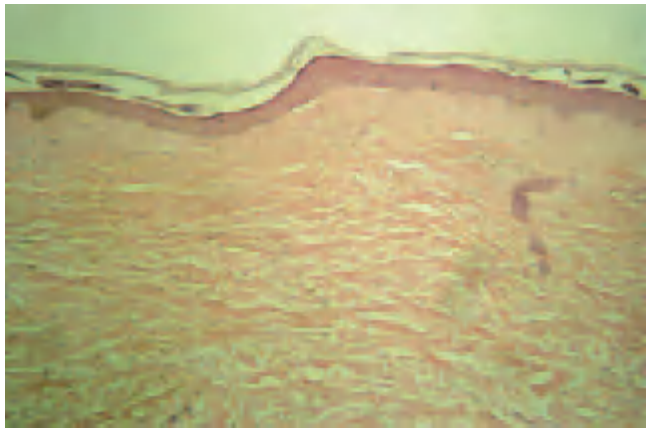

Fig. 56.45 Morphoea: slight atrophy of the epidermis with loss of dermal appendages and degeneration of dermal collagen.

survive, deep in the dense sclerotic mass. Small dermal blood vessels may show intimal thickening.

Immunohistochemistry shows that the main changes in morphoea consist of foci of intercollagenous staining for connective tissue antigens in the reticular layer of the dermis [3]. IgM and C3 are found at the basement membrane and in dermal blood vessels, particularly in more extensive and deeper lesions, but there is no relation to systemic disease [4]. The histological features are similar to those seen in generalized morphoea and in the skin in systemic sclerosis.

Incidence. All ages are affected, the peak incidence occurring between 20 and 40 years of age, although 15% begin below the age of 10 years [1,2], in which age group the linear lesions predominate. The female to male ratio is around 3 : 1 in most studies. Most linear lesions (75%) occur before the age of 40 years, whereas 75% of localized plaques arise between the ages of 20 and 40 years [2]. In one series, localized plaques occurred in 60 patients, with linear lesions in 33 and guttate in 13 [3], but in another series [2] there were more patients with linear lesions than with plaques. The condition is said to be rare in black people [3]. A recent epidemiological study of morphoea in the USA has found a female to male ratio of 2.5 : 1, an incidence of 2.7 in 10 000 and a prevalence at 80 years of age of 1 in 500 [4].

Clinical features

Plaque lesions. These occur as indurated areas of skin, which at first are faintly purplish or mauve in colour. After some weeks or months they lose their colour (Fig. 56.46), especially in the centre, and appear as thickened waxy areas, which are ivory in colour, with a characteristic lilac-coloured edge (Fig. 56.47). The surface is usually smooth and shiny but may be nodular [1]. The hairs are absent, and usually the area ceases to sweat. Vesicles, bullae [2] and haemorrhages may occasionally occur, and sometimes telangiectases may be seen. The plaque is attached to the deeper tissues and, if thick, may be hypoaesthetic. The lesions are round or oval, sometimes irregular, and vary in size from approximately 2 to 15 cm or more in diameter. They are usually multiple, and often bilateral, but asymmetrical. They occur on the trunk and limbs, face

Fig. 56.47 Localized morphoea on the foot: late stage but still showing lilac border.

Fig. 56.48 Localized morphoea: pigmentation usually occurs as the lesion resolves but may occur at the onset.

and genitalia. They are less commonly found in the axillae and perineum and around the nipples. Sometimes, plaques accompany linear lesions.

Although the onset of lesions is usually insidious, they can occasionally occur rapidly, with erythema and oedema. Sometimes they may be preceded by pigmentation (Fig. 56.48). In subcutaneous morphoea, induration is indistinct and the lilac ring is absent. Deep involvement of underlying structures in morphoea of the trunk is unusual, but occurs occasionally and may be followed by deep atrophy [3]. Obscure abdominal pain and migraine were features in approximately 15% of patients in one series [4], but usually any pain is limited to the skin lesions. One study detected abnormalities of the vertebral column in 47% of those X-rayed, with spina bifida occulta occuring in 20 patients. These findings were most common in those with linear lesions, occurring in 26 of these 108 patients [4]. Other studies have not, however, reported such findings.

It has been suggested that atrophoderma of Pasini and Pierini is a primary abortive form of morphoea [5] in which induration fails to occur.

Guttate lesions. In true guttate morphoea, the lesions are similar to, but smaller and more numerous than plaque lesions. Some cases may represent lichen sclerosus et atrophicus (white spot disease) rather than true morphoea. It has been suggested that these two diseases may have a similar pathogenesis [6] or coexist [7,8].

Bullous lesions. Peterson's classification [9], describes bullous morphoea as a distinct entity. However, blisters have been described in all types of morphoea and have been thought to result from lymphatic dilatation along with the release of major basic protein from eosinophils [10]. Others have suggested that, at least in some cases, the blisters represent the development of associated lichen sclerosus [11].

Subcutaneous morphoea/deep morphoea/morphoea profundus. Nodular [1], keloidal [12] or subcutaneous morphoea are variants of morphoea that exhibit differing amounts and depths of inflammatory changes and sclerosis. The term morphoea profundus was first suggested by Whittaker *et al.* [13], in 1989, to describe a solitary fibrotic plaque on the shoulder, back, neck or paraspinal area, which histologically showed fibrosis, hyalinization of collagen fibres and a deep dermal and subcutaneous inflammatory infiltrate. The overlying skin may be pigmented or hypopigmented. Osteoma cutis can develop within such lesions [14] and contracture of the flexor muscles of the finger has been reported in subcutaneous morphoea [15].

Linear lesions (Fig. 56.49) [16]. The essential features are similar to the plaque lesions, but the lilac ring is inconspicuous or only present at the advancing border. They are usually single and unilateral, although occasionally bilateral lesions occur. They can follow the lines of Blaschko [17]. The limbs are frequently affected, the legs more than the arms. They may also occur on the anterior aspect of the thorax, and sometimes the abdomen or buttocks are affected. Lesions involving one arm and one leg are usually homolateral. Rarely, half of the body (face, arm, trunk and leg) is involved [18]. Occasionally, a linear lesion on the leg is preceded by oedema of the limb. Lesions take the form of linear areas of induration, similar to those found

Fig. 56.49 Linear morphoea.

Fig. 56.50 Localized morphoea of the arm showing growth retardation.

in the plaques, but sometimes the condition may extend to involve the underlying muscles, or even bone, with resulting disturbances in growth in approximately 20% (Fig. 56.50) [19] and possibly severe flexion deformity [20,21]. The surface may show patchy hyperkeratosis. Usually, lesions occur along the length of the limb or around the trunk, but sometimes a band surrounds a limb

Fig. 56.51 Frontoparietal morphoea ('en coup de sabre').

or a finger, resembling ainhum [22,23]. The tissues distal to such a band may be oedematous and depigmented [19]. The fibrosis may spare areas within an otherwise linear lesion, producing 'skip' lesions.

Linear scleroderma has been associated with hypertrichosis [24], melorheostosis [25–27], and ulcerated dystrophic calcinosis cutis [28]. Nodular morphoea has been reported in a linear pattern [29].

Frontoparietal lesions (Fig. 56.51) *'en coup de sabre' (from its resemblance to a sabre cut), with or without hemiatrophy.* These lesions usually start with contraction and firmness of the skin over the affected area. Subsequently, an ivory irregular sclerotic plaque develops, sometimes with telangiectatic vessels coursing over it, together with hyperpigmentation at the edge. Eventually, a linear depressed groove appears on the frontoparietal region, extending into the scalp, producing a linear zone of alopecia, which may be preceded by bleaching of the hair. The groove may extend downwards into the cheek, nose and upper lip, and involve the mouth and gum. In severe cases, it extends as far as the chin and neck. The condition may affect the gingivae [30] and the jaw may also be involved, with alteration of the spacing and direction of the teeth [31]. The corresponding side of the tongue may be atrophic, although sometimes the lesion is in the midline of the tongue. Not infrequently, there is atrophy of the corresponding part of the face and cheek, with facial asymmetry, and this usually occurs within a year. The Parry–Romberg syndrome of hemifacial atrophy looks very similar, but there should be no cutaneous sclerosis at

any stage [32]. Rarely, frontoparietal lesions may be bilateral [33,34] or trilinear [35] and may follow Blaschko's lines [36]. Sometimes, there may be morphoeic plaques elsewhere on the body or evidence of linear morphoea on the extremities and trunk. Facial atrophy without frontoparietal morphoea can be associated with morphoea elsewhere. Ipsilateral wasting of the upper limb occurs in less than 10% of cases [37]. Total hemiatrophy of one side of the body can occur.

Contralateral or bilateral atrophy is rare. The bones of the skull can be involved and the EEG may show evidence of dysrhythmia, maximal over the affected area. Neurological abnormalities have been reported [38–40]. A variety of ocular lesions occur [41], including enophthalmos, involvement of the lids, oculomotor muscles, iris and fundus, and myopathy of the external eye muscles [42]. Atrophy of the nasal part of the iris and loss of cilia on the upper eyelid followed exactly the line of the skin lesions in one case [43]. Heterochromia of the iris also occurs [44]. 'En coup de sabre' morphoea has presented as unilateral eyelid oedema [45]. Ossification occasionally occurs [46].

Scleroderma in childhood [1–3]. Childhood onset occurs in 2–3% of all cases of scleroderma. Most present with morphoea-type lesions (particularly linear) although systemic sclerosis does occur. The clinical features are similar to adult cases but localized trauma a few months before

Fig. 56.52 Disabling pansclerotic morphoea of the fingers.

onset of morphoeic lesions occurs in one-quarter of childhood patients. Children are less likely to show serological abnormalities than adults, with antinuclear antibodies being found in only approximately one-third of those with localized disease. Scl-70 antibodies are found in children with systemic sclerosis, although much less frequently than in adults.

Disabling pansclerotic morphoea of children [4]. This is a rare severe mutilating form of morphoea involving the dermis, fat, fascia, muscle and even bone, usually starting before the age of 14 years. It may develop from linear morphoea. Superficial and deep cutaneous sclerosis involve the trunk and extremities, scalp and face, with sparing of the fingertips and toes (Fig. 56.52). There may be a claw deformity of the hands, and patients may walk on tiptoe because of contracture of the Achilles tendons (Fig. 56.53). Arthralgia and stiffness occur at the onset, and intense pain may be a problem, presumably because of involvement of cutaneous nerves [5]. Raynaud's phenomenon is not found, but a few cases have had oesophageal, pulmonary and periodontal changes. Flexion contractures, osteoporosis and other bone changes are frequent. The electromyogram and histology of muscle may be abnormal, but creatine phosphokinase is normal. Elevation of ESR, hypergammaglobulinaemia and eosinophilia are frequent. Treatment with PUVA [6], low-dosage UVA-1 [7] and ciclosporin [8] has been reported. The reponse is often poor, however, and in most patients the condition is progressive [9] and occasionally fatal [4].

Fig. 56.53 Disabling pansclerotic morphoea of the legs.

Associated lesions. Arthralgia, sometimes localized to the sclerodermatous extremity, unilateral Raynaud's phenomenon, a history of migraine and intermittent recurrent colicky abdominal pain are sometimes found [1]. Abnormal radiological appearances of the spine occurred in 47% of patients in one series, [1] particularly those with linear scleroderma. Spina bifida was found in 20 patients and was most common in patients with linear morphoea of the legs, lower abdomen and buttocks. Other abnormalities included sacralization of lumbar segments, the presence of six lumbar vertebrae, prolongation of transverse arches, scoliosis and kyphosis. Pain in the lumbar region, like that of a protruded lumbar intervertebral disc, was sometimes a feature. Rib abnormalities such as rudimentary or cervical ribs, torticollis, atrophic clavicle, absent pectoralis muscle, contracted pelvis, shortened ulna and deformities of the feet and toes have been reported [1], but other studies have not reported similar findings. Associated cutaneous abnormalities include warty, vascular or pigmented naevi, usually with linear morphoea on the same

side, café-au-lait spots, alopecia areata, vitiligo, generalized ichthyosis or pigmentation, dystrophy of the nails and hirsutism. Localized morphoea occurred in a pigmented area of Becker's melanosis [2]. Children may be intellectually precocious [1]. A variant occurring later in life, in which morphoea confined to the face and anterior part of the scalp is associated with tissue calcification, hair loss and beaking of the nose, has been reported [3]. Sclerotic panatrophy, disseminated granuloma annulare and morphoea have occurred in the same patient [4].

Occasionally, morphoeic lesions may occur in association with lesions of lichen sclerosus et atrophicus. Localized patches of morphoea may occur in patients with systemic sclerosis [5] and occasionally patients with localized patches of morphoea may later develop systemic sclerosis [1,6]. Although no systemic abnormalities were found in 27 autopsies on patients with localized morphoea [7], changes in the oesophagus, muscles and joints may occur in as many as 27% of cases [8]. The diagnosis of systemic sclerosis was confirmed at autopsy in a 71-year-old woman with two patches of localized morphoea on the front of the chest, who subsequently developed cardiac enlargement, pulmonary fibrosis and a dilated aperistaltic oesophagus [9]. Typical morphoeic patches on the skin and gastrointestinal radiological changes typical of systemic sclerosis were found in another patient [10].

Morphoea has occurred with DLE [11], mixed connective tissue disease [12] and eosinophilic fasciitis [13], and frontoparietal morphoea has been associated with SLE [14]. Morphoea has followed SCLE [15] and may also occur with dermatomyositis [16], carpal tunnel syndrome [17], nephritis [18], vitiligo [19], pemphigus [20], primary biliary cirrhosis [21] and myasthenia gravis [22]. The coexistence of morphoea, localized bullous pemphigoid and subcorneal pustulosis has been reported [23]. Elastosis perforans serpiginosa has also occurred with morphoea [24]. Localized scleroderma can follow augmentation mammoplasty [25] and linear oedema, nodularity and scarring, with hidebound skin, has been attributed to leaking of silicone into an arm [26].

There is no relationship between localized morphoea and internal malignancy [27], although systemic sclerosis has been associated with carcinoma of the lung, skin and liver [27,28]. The morphoea-like changes found in patients with carcinoid syndrome are thought to occur as a result of serotonin release by the tumour [28]. Squamous cell carcinoma has been reported in patients with long-standing pansclerotic morphoea [29] and in localized scleroderma in a patient treated with azathioprine [30].

Laboratory abnormalities. ESR and serum protein assays are usually normal, but eosinophilia may occur [1]. Anti-single-stranded DNA antibodies are more frequent in generalized morphoea (75%) and linear morphoea (53.3%) than in localized morphoea (27.3%) [2]. Antihistone antibodies have been detected in 32% of patients with linear morphoea and in 25% with localized morphoea [3]. They

do not correlate with the clinical features [4]. In children, a higher incidence of rheumatoid factor, compared with controls, has been found [5]. Hereditary deficiency of complement factor C2 is reported [6]. Organ-specific autoantibodies are more commonly found than in controls [7]. Thrombocytopenia responding to corticosteroid therapy has been reported in two patients [8]. Approximately 40% of patients with linear morphoea have positive antinuclear antibodies, and the presence of these antibodies (with homogeneous and nucleolar patterns), antibodies to single-stranded DNA and the presence of eosinophilia may indicate disease activity [9] and the late development of systemic complications [10]. Serum procollagen type 1 carboxy-terminal propeptide has been reported to be raised in 30% of patients with localized morphoea, correlating with the number of lesions. Levels are lower than in generalized morphoea and may be a useful indicator of disease activity [11]. Type 3 procollagen propeptide has also been reported to be raised [12]. However, others have not found these markers as useful. Ultrasound scanning has been reported as being helpful in monitoring the course of localized morphoea [13].

Prognosis. Plaque-like lesions tend to improve with time. The induration lessens and the lesions blend in with the rest of the skin, leaving a brownish stain, which may persist for a long time. The duration of activity is usually between 3 and 5 years, but some lesions last up to 25 years. It is common to find fresh lesions developing on new sites as other lesions resolve. Residual pigmentation persists for a long time in approximately one-third of patients. Linear lesions tend to persist for longer than plaque lesions, but on the whole improve with time. Calcinosis occasionally occurs in linear lesions, and sometimes requires surgical removal. Contractures may limit movement of joints and give rise to clawing of the hand. Unilateral atrophy of one or more limbs may occur. Facial hemiatrophy is usually persistent, but frontoparietal scleroderma may clear, and may be accompanied by regrowth of hair. In 63 of 88 children with morphoea, lesions resolved with minimal cosmetic disability [14]. Very rarely, patients with localized morphoea may subsequently develop classical systemic sclerosis [14,15]. It has been suggested that the presence of anti-Ku antibody may be a prognostic indicator of such progression [15].

Differential diagnosis. The diagnosis is usually not difficult, the insidious development of indurated plaques and bands in the skin, with or without hemiatrophy, being unlikely to occur in other conditions. If there is a lilac-coloured border diagnosis is easier. Reticulate lilac lesions with minimal induration can resemble cutaneous polyarteritis nodosa. Morphoeic lesions occur in sarcoidosis [16]. Lesions can start as a vascular blush, and may be mistaken for a macular vascular naevus. In the acute phase, the condition must be distinguished from scleroedema of Buschke, but in this condition the onset is much more acute, and the lesions may follow an infectious episode. Fading pigmented lesions are sometimes very difficult to diagnose, but the previous history of some induration in the area is usually helpful. Atrophic pigmented lesions resembling lesions of the atrophy of Pierini and Pasini (see Chapter 46) [17], occurred in 47% of the patients in one series [18]. Abdominal lesions may be confused with so-called lipodystrophia centrifugalis abdominalis infantilis (see Chapter 55) [19,20]. Atrophic morphoeic plaques can result from intramuscular injections of vitamin K [21] or subcutaneous corticosteroid injections [22]. Conditions producing pseudoscleroderma (see p. 56.83) may have to be considered. *Melorheostosis* is a rare condition presenting in adults with painful abnormalities of the skeleton and adjacent soft tissues, usually limited to a single limb. Linear endosteal bony densities of the long bones are seen on radiography, and resemble candle wax flowing along the affected bone. In children, the usual presentation is with asymmetrical contractures of a limb, occurring in association with thickening of the overlying skin and fascia, and distal vascular problems exacerbated by attempted surgical correction of the orthopaedic problem, including angiomas and arteriovenous malformations [23]. It is suggested that the distribution of these lesions represents the sclerotome, or the areas of the body supplied by a spinal sensory nerve, and that skin and muscle involvement occur in the relevant dermatome and myotome [24]. The cutaneous lesions are almost certainly a part of the developmental abnormality, rather than coexisting linear morphoea [25].

Treatment. As the expected natural history is towards spontaneous resolution, the condition may be allowed to take its natural course, if uncomplicated. If intervention is required, localized treatment with topical or intralesional steroids may be helpful [26]. More recently, calcipotriol has been shown to inhibit the growth of morphoea fibroblasts *in vitro* [27], and has proved beneficial when used topically *in vivo*, both alone [28] and in combination with UVA-1 in children [29].

Numerous systemic agents have been reported to be helpful in morphoea (on the basis of case reports or small open studies), including phenytoin [30], *p*-aminobenzoate [31], griseofulvin [32], etretinate [33], vitamin E [34], chloroquine and hydroxychloroquine [35]. Tranilast was reported as helpful in a boy with linear morphoea and contractures [36], and plasmapheresis was helpful (in combination with systemic corticosteroids) in three patients with localized scleroderma and antinuclear antibodies [37]. Topical photodynamic therapy was been reported as being helpful in five patients with localized disease [38].

Systemic corticosteroids have been found to be helpful in an open trial [39], although they are probably only

beneficial in the inflammatory stage of the disease [26]. D-penicillamine has been reported as helpful in open trials [40–42] in regimens of 2–5 mg/kg/day, with or without pyridoxine 20 mg/day. However, there is a risk of renal damage [40]. Ciclosporin was found to be helpful in open studies in localized morphoea [43,44]. Oral calcitriol, in regimens of 0.5–0.75 μg/day, has been reported as helpful in a small study [45], but a recent double-blind placebo controlled trial did not confirm this [46]. In recent years, UVA irradiation, both alone at low [47–50], medium [51] and high doses [52], as bath or oral photochemotherapy [53–56], and in combination with calcipotriol [29], has been reported as helpful. None of these studies, however, was a randomized double-blind controlled trial. Low-dose methotrexate has proved useful in widespread morphoea [57,58] and in localized morphoea in children when used in combination with systemic corticosteroids [59].

Physical therapy in the form of physiotherapy may be helpful in preventing joint deformities and contractures and in maintaining joint movement and muscle strength. It may also help to prevent sclerosis secondary to lymphoedema in the limbs of patients with linear morphoea [26]. Surgical intervention for the relief of contractures [60], the lengthening of limbs and the correction of deformities may have to be carried out in certain cases. Various plastic surgery techniques can help patients with 'en coup de sabre' morphoea [61–65] and those with ossification [66]. For those patients in whom the sclerotic processes have extended into the jaw to involve the teeth, dental treatment may be required.

Generalized morphoea

SYN. GENERALIZED SCLERODERMA

Definition. A rare condition in which idiopathic sclerosis of the skin occurs in a widespread manner. It usually starts on the trunk and is not associated with systemic disturbances.

Fig. 56.54 Generalized morphoea showing diffuse tightness of the skin of the chest.

Aetiology. The aetiology is unknown. The most frequent age of onset is between 30 and 40 years, and lesions start between the ages of 11 and 50 years in 80% of patients [1]. Approximately three females are affected for every male. The occurrence of generalized morphoea and localized morphoea in two sisters has been reported [2].

Pathology. This is identical to that of localized morphoea. It has been suggested that in the early stages an inflammatory infiltrate of lymphocytes, histiocytes and plasma cells is found, primarily in the subcutaneous tissue. Later, the subcutaneous tissue is replaced by hyalinized connective tissue and this is responsible for the induration of the skin. Direct immunofluorescence shows changes in approximately one-third of cases, with IgM in the basement membrane and IgM and C3 in the dermal blood vessels being the most frequent findings. Similar changes may occur less frequently in linear morphoea.

Clinical features (Fig. 56.54). The onset is usually insidious, and the patient notices the development of plaques resembling those of localized morphoea. A lilac-coloured border surrounding the indurated ivory-white shiny lesions is usually seen in the early stages. The plaques are commonly much larger than those seen in localized morphoea, being many centimetres in diameter. Usually, plaques start on the trunk and gradually increase in size, with the development of new plaques over the first year or two. The main areas involved are the upper trunk, breasts, abdomen and upper thighs. The arms may also be involved, and in some cases the hands resemble those seen in the tumid phase of systemic sclerosis, with spindling of the fingers, binding of the skin to the underlying tissues and semiflexion of the hands and fingers. The legs, face, neck and scalp may also be involved. Scarring alopecia can result from involvement of the scalp. In some cases, the whole of the body may be involved from the top of the

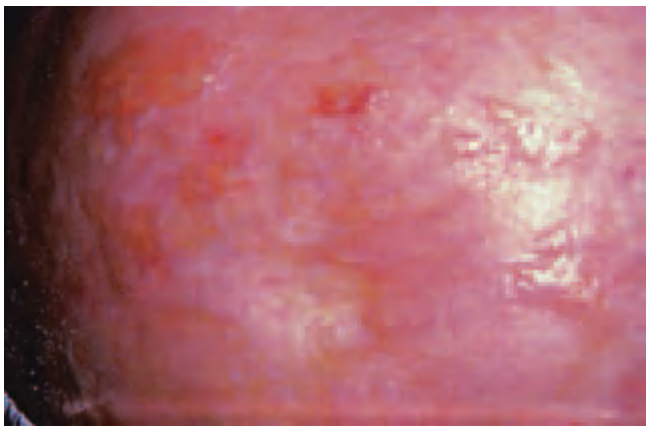

Fig. 56.55 Bullous lesions in generalized morphoea.

head to the feet, although this occurred in only one out of 44 cases in one series [1]. If the chest wall is markedly involved there may be difficulty in breathing because of constriction of the thorax. The intercostal muscles may also be involved, and death may result from respiratory failure [3]. The face is expressionless, the skin being shiny, often brown, and indurated. Telangiectasia of the face is not a feature, and although mouth opening may be restricted, the radial furrowing of systemic sclerosis is not seen. Raynaud's phenomenon occurs occasionally but is not a characteristic feature. Sometimes, especially after trauma, the hands may develop whitlows, but there is no atrophy as seen in systemic sclerosis. The tissues of the trunk and limbs sometimes show a brawny non-pitting oedema. Bullae may develop in localized areas, particularly on the abdomen (Fig. 56.55). Nodular lesions may also occur [4], and multiple keloids may be the first manifestation of the disease [5]. Acral myofibromas have been reported [6]. If the condition is generalized, it may be impossible to see any area showing a lilac border. Pigmentation is common, and in some patients may be generalized. Keratoses and calcinosis can occur.

Contractures occur in limbs, which become thin and hard. Some patients complain of considerable soreness in the acute phase, especially of the trunk and breasts. Joint pains occur in approximately 50% of patients, particularly in the fingers, wrists, elbows and knees. Definite rheumatoid arthritis may be found. Very occasionally, severe contractures, atrophy and infection may be associated with intractable pain in the limbs, and amputation may be required. Squamous cell carcinoma may develop in lesions of over 20 years' duration [7,8].

Sometimes generalized morphoea may develop as an extension of localized morphoea or be associated with lesions of lichen sclerosus et atrophicus [9]. Subcutaneous morphoea [10] seems to be more inflammatory than generalized morphoea of the dermis, and may respond to anti-inflammatory agents. Such cases may be more likely to develop mild systemic involvement and have eosinophilia. Generalized morphoea has been associated with polymyositis and the sick sinus syndrome [11] and necrotizing vasculitis [12].

Laboratory investigations. Investigation for systemic disease is usually negative. Eosinophilia, elevated ESR and hypocomplementaemia occasionally occur. Anti-single-stranded DNA antibody occurs, but anti-double-stranded DNA antibody is rare. Serum procollagen type 1 carboxy-terminal propeptide may be a useful index of activity. Levels are higher than in localized morphoea [13]. Scl-70 antibodies are rarely found.

Differential diagnosis. The following points help to distinguish morphoea from systemic sclerosis. Raynaud's phenomenon is uncommon in generalized morphoea and is almost universal in systemic sclerosis. The distribution of the lesions also differs. In generalized morphoea, the trunk is more frequently involved, whereas the face, hands and, to a lesser extent, the feet, are most commonly involved in systemic sclerosis. Generalized morphoea usually slowly improves over the years. Scleroedema of Buschke is usually a more acute and less widespread disorder. Morphoea must also be distinguished from the various conditions described below under 'pseudoscleroderma'. Generalized morphoea may have to be distinguished from eosinophilic fasciitis (see p. 56.90).

Prognosis. Some improvement is usually seen in the course of 3–5 years, but the disease may last for many years and one patient still showed changes 33 years after diagnosis [1]. In most cases, the skin slowly softens and the pigmentation decreases. With time, the tendency to ulceration, with trauma and blistering, decreases. Although some patients may be severely disabled by the immobility associated with the sclerotic changes and contractures, others with widespread sclerosis may remain surprisingly active. Patients usually remain in good health.

Treatment. The general measures outlined previously for the treatment of localized disease are just as important for patients with generalized disease.

A number of the systemic agents may also help generalized disease including systemic steroids, penicillamine, antimalarials and low-dose methotrexate. In addition, individual case reports suggest a role for agents such as sulfasalazine [14], salazopyrin [15], grenz ray treatment [16] and extracorporeal photochemotherapy [17]. Initial reports suggested a role for oral calcitriol but a recent double-blind study has not confirmed this.

An increasing body of literature suggests that ciclosporin may be helpful for generalized morphoea [18,19], although controlled studies are lacking. It must be used with care, as side effects are common. Severe renal disease

may result, although the latter is perhaps more likely in patients with active systemic disease [20,21]. As for localized disease, perhaps the modality with the greatest body of literature supporting its use is UVA phototherapy and photochemotherapy, although it must be stressed that none of these studies was controlled.

Pseudoscleroderma

Sclerosis of the skin may be seen in several conditions other than morphoea or systemic sclerosis [1]. Scleroedema of Buschke is usually triggered by a febrile illness and comprises non-pitting induration of the face, neck, shoulders, arms and sometimes trunk. Scleromyxoedema also presents with thickening and tethering of the skin and is usually associated with a circulating paraprotein.

Scleroderma-like changes are sometimes seen in porphyria cutanea tarda [2,3] and in phenylketonuria [4,5], when they usually appear in the first year of life. Irregular indurations appear first in the muscles and subcutis of the thighs and buttocks, and later the changes extend to the trunk and proximal parts of the limbs. Contractures, especially of the legs, are characteristic. Histology shows proliferation of histiocytes and fibroblasts in the connective tissue stroma, atrophy of the skin appendages and an inflammatory infiltrate. Improvement in the skin lesions occurs with exclusion of phenylalanine from the diet. In older children, the lesions and histology resemble morphoea. Two mentally retarded siblings with phenylketonuria had morphoea and atrophoderma of Pasini and Pierini, respectively [6], suggesting that these conditions may be related.

Scleroderma-like lesions have been observed in cases of muscle glycogenosis with an undetermined enzyme defect [7]. Induration and atrophy occur in the skin and muscles in the first few months of life. The proximal parts of the limbs are involved early and contractures occur, particularly in the legs, giving a characteristic bent-knee gait. Mental retardation may be a feature.

The scleroderma-like lesions of primary systemic amyloidosis, with or without multiple myeloma, may be difficult to distinguish if not accompanied by nodular and papular lesions, particularly about the shoulders and neck, and by macroglossia. Primary localized cutaneous amyloidosis occurs in systemic sclerosis [8]. Pseudoscleroderma also occurs in multiple myeloma [9] and paraproteinaemia [10].

Acrodermatitis atrophicans, a disease found in central and eastern Europe, resembles localized morphoea (see Chapter 46).

Sclerosis of the legs is found in patients with the carcinoid syndrome [1,11,12] and atrophy of the acral parts in Werner's syndrome [1], but these disorders should be distinguished by their other manifestations. Progeria, acrogeria and poikilodermatous epidermolysis bullosa [13] are other rare conditions in which scleroderma-like lesions occur. Sclerosis of the skin occurs in the GEMSS syndrome (*g*laucoma, lens *e*ctopia, *m*icrospherophakia, *s*tiffness of the joints and *s*hortness due to increased production of normal collagen [14]) and in Moore–Federman syndrome (short stature, stiffness of joints, characteristic facies).

The skin is oedematous and indurated in hypothyroidism, and atrophic changes in the skin in postpartum hypopituitarism may resemble scleroderma [1]. Pseudosclerodermatous changes may also be seen in rheumatoid arthritis [15], and in patients with long-standing diabetes mellitus in which limited joint mobility, termed cheiroarthropathy, is associated with thickening of the skin. The changes are most marked in the hands [16].

Occupational scleroderma

Vinyl chloride disease [1–4]

One to six per cent of polyvinyl chloride (PVC) workers, particularly reactor cleaners, develop coldness, stiffness, numbness, burning pain and discoloration of the fingers and hands, and to a lesser extent the feet, on exposure to cold. Other symptoms include loss of energy, loss of libido, impotence, dyspnoea and feeling light-headed, with irrational laughter and whistling. The skin of the hands, forearms, face and trunk may be thickened. The hands show mottled pink, purple or white areas. The terminal phalanges are shortened and bulbous, and the nails are curved. Telangiectases occur on the face, resembling those of systemic sclerosis, and there may be difficulty in opening the mouth, although radial furrowing and pigmentation are not features. Usually, it is possible to distinguish between classic systemic sclerosis and vinyl chloride disease [5]. Parotitis [6], hepatomegaly and splenomegaly occur. X-rays show erosion of the tufts of the terminal phalanges and thinning of the other phalanges of the fingers and toes. Erosions also occur in the metatarsals, pelvic bones, clavicles and bones of the arms and legs. Nail fold capillaroscopy shows changes similar to those seen in systemic sclerosis. Narrowing of digital arteries and hypervascularity of the digital tufts are seen on arteriography.

Histologically, there is thickening and separation of collagen fibres and fragmentation of elastic fibres in the dermis. Immunohistology reveals an immune-complex vasculitis with deposits of IgG, complement and fibrin in the media of small- and medium-sized arterioles [7]. Other immunological features include low levels of non-organ-specific autoantibodies, polyclonal hyperglobulinaemia, cryoglobulinaemia, cryofibrinogenaemia, *in vivo* complement activation and conversion, reduced T cells and moderate B-cell proliferation. Anticentromere or anti-Scl-70 antibodies cannot usually be demonstrated [8], although a patient who presented with 'pneumoconiosis' and systemic sclerosis features 10 years after exposure did have a positive ANA and Scl-70 antibodies [9]. Thrombocytopenia, abnormal platelet aggregation, abnormal liver function tests, raised serum creatine phosphokinase indicating muscle involvement, patchy defects of pulmonary ventilation and perfusion, hepatic fibrosis and oesophageal varices also occur.

The prognosis is unknown, and many men have not improved after removal from exposure. There is no effective treatment. Angiosarcoma of the liver is a serious complication. If the level of exposure to vinyl chloride monomer in PVC manufacturing plants is kept below five parts per million, further cases of vinyl chloride disease should not occur. A genetic susceptibility is shown by an increase in HLA-DR5 in all patients and of -B8 and -DR3 in those severely affected [8]. Acro-osteolysis has also been reported in a worker not exposed to vinyl chloride [10].

Scleroderma-like lesions resulting from perchlorethylene, trichlorethylene and organic solvents

A disorder, resembling vinyl chloride disease, has been reported after exposure to perchlorethylene, a solvent used in dry cleaning of clothes [11,12]. Acrocyanosis and acrosclerosis were associated with polymyopathy and hepatic damage. Some of the features, including the presence of speckled antinuclear factor and favourable response to prednisone, were suggestive of 'mixed connective tissue disease'. Exposure to trichlorethylene may be associated with scleroderma [13–16], possibly after even a single prolonged exposure. Of patients with systemic sclerosis in an eastern European series, 28% had suffered significant exposure to organic solvents [17]. Similarly, an Italian study has confirmed an aetiological role of exposure to solvents in scleroderma [18]. A man who used trichlorethylene for cleaning metal also had peripheral neuropathy, Raynaud's phenomenon, impotence, gynaecomastia, hepatomegaly, lymphadenopathy and pigmentation [16]. He was probably a case of

Crow–Fukase (POEMS) syndrome. In a Japanese series, generalized morphoeic lesions, similar to those found in occupational scleroderma, were found in nine of 115 patients with systemic sclerosis. Seven had been exposed to organic solvents before the onset of Raynaud's phenomenon. Some had visceral changes of systemic sclerosis [19]. The same authors induced sclerotic skin changes in mice by the intraperitoneal injection of napththa, *n*-hexane and hexachlorethane. A sclerodermatous syndrome consisting of cold sensitivity, restrictive lung defect, peripheral neuropathy, oesophageal dysfunction, labile hypertension and monoclonal paraproteinaemia has been reported in a man who had worked with many solvents. These included benzene, toluenes, toluidines, xylenes, xylidenes, aniline compounds, and ethanolamine and its derivatives [20]. Solvents recorded in other reports include isopropylalcohol, ethyl acetate, naphthalene, trimethylbenzene and turpene derivatives [21]. Systemic sclerosis occurred in two workers handling *meta*-phenylenediamine [22].

Scleroderma-like lesions resulting from pesticides

Sclerodermatous changes can occur in workers handling pesticides. Substances possibly incriminated include chlordane, heptochlor, malathion, parathion, DDT, sodium dinitro-orthocresolate and 7-chlorocyclohexane [2,23,24]. Raynaud's phenomenon occurs, but there is no evidence of involvement of internal organs. Hyperkeratosis of palms and soles with sclerodactyly of the fingers and toes has been reported in a weed sprayer with chloracne [25].

Scleroderma-like lesions resulting from epoxy resin

Six Japanese men exposed to the vapour of epoxy resins in the production of transformers for television sets developed scleroderma-like skin changes and erythema, with fatigue, loss of weight, myalgia and arthralgia [26]. The histological changes were those of scleroderma, but there was no definite evidence of systemic involvement. A hardener—1,1′-*bis*(3-methyl)-4-amino(cyclohexyl)methane—was thought to be the cause. Improvement occurred when the men stopped work, and the disorder resolved completely within 5 years without any internal organ involvement developing [27]. One patient developed systemic sclerosis sine scleroderma after exposure to epoxy resin [28].

Silicosis and scleroderma

The association of silicosis and scleroderma has been reported in Italy [18], in South African coal mines [29] and in coal mines in other countries where silica is present [30–33]. Men in other occupations, such as sandblasters and quarrymen, may be affected. Because of the occupational risk, the condition occurs predominantly in men, particularly those suffering from silicosis. In East Germany, 93 of 120 male patients with systemic sclerosis had suffered long-term silica exposure, and 49 had coexisting silicosis [34]. The lung changes frequently precede the scleroderma. Visceral manifestations resembling those of systemic sclerosis occur in approximately half of cases, and antinuclear factor can be demonstrated in one-third. In these cases, the clinical and immunological changes are indistinguishable from those found in systemic sclerosis without any environmental exposure [35]. Systemic sclerosis-like syndromes may follow exposure to urea formaldehyde foam insulation [36].

Iatrogenic scleroderma

Scleroderma-like changes resulting from bleomycin [1,2]

Cutaneous fibrosis with acrocyanosis, acrosclerosis, pigmentation, hair loss, flexion contractures and ulceration occurs in patients treated with the antitumour agent bleomycin. Pulmonary fibrosis is a prominent feature. Remission occurs some months after withdrawal of the drug. Cisplatin can cause similar changes.

Scleroderma resulting from other drugs

Carbidopa [3], pentazocine [4], cocaine [5] and appetite suppressants [6] have all been implicated in the development of sclerodermatous disease.

Scleroderma induced by silicone or paraffin implants (human adjuvant disease) [7]

Skin sclerosis, sometimes resembling morphoea, occurs at the site of injection of silicone for cosmetic breast surgery. It may act by the release of silica. Sometimes, more widespread connective tissue disease resembling systemic sclerosis [8], mixed connective tissue disease, SLE, rheumatoid arthritis, primary biliary cirrhosis, Sjögren's syndrome [9] or eosinophilic fasciitis [10] occurs. Paraffin injections may be a more important factor than silica in causing systemic sclerosis-like disease [11]. A causal link between silicone breast implants and autoimmune diseases seems to have been discounted [12].

'Toxic oil' epidemic syndrome [1,2]

In 1981, in certain areas of Spain, the ingestion of rapeseed oil denatured with aniline caused a multisystem disease affecting 18 000 people. The most prominent pathological feature was a widespread non-necrotizing intimal vasculitis in practically every organ [3]. The early phase, lasting 2–3 months, consisted of atypical pneumonia, gastrointestinal and neurological symptoms and a pruritic rash. The rash involved the limbs, abdomen and trunk, and resembled a viral exanthem lasting approximately 5–20 days. Occasionally, palpable purpura or erythema multiforme occurred. Eosinophilia was always present, antinuclear antibodies were frequently found, and elevation of IgE and abnormal liver function tests could be demonstrated in one-third of cases. Histology showed dilatation of blood vessels, and an inflammatory exudate including eosinophils in the dermis. Three to four months after the onset, 10% of patients developed a transitory eruption consisting of multiple yellowish or brownish papules of all areas except palms and soles. Five to six months after the onset, patients, mainly women, developed a neuromyopathy, and either localized or gen-

eralized morphoea or a disorder resembling systemic sclerosis, with dysphagia, oesophageal changes and occasionally renal involvement. Sicca syndrome and pulmonary hypertension were prominent features in some cases. Histology of the skin showed dermal infiltration and sclerosis with interfibrillar mucin deposits, but immunology was negative.

Most patients recovered to some extent, although 50% had persistent symptoms when reviewed in 1984 [4]. The cause is unknown. An immune reaction to an unknown antigen seems likely. HLA typing showed an increased incidence of HLA-DR3 and -DR4 in females with chronic disease [5].

Graft-versus-host disease [1–5]

Definition. Graft-versus-host disease (GVHD) occurs when immunocompetent cells from a donor recognize and react against 'foreign' tissue antigens in an immunocompromised host. Originally reported following bone marrow transplantation (regularly used in the management of leukaemias, lymphoma, immunodeficiency and inborn errors of metabolism), GVHD is now recognized to occur following transfusion of non-irradiated blood, after maternofetal transfer of lymphoid cells, and following peripheral blood stem cell transfer [6]. Post-transfusion-related GVHD is an uncommon but potentially fatal complication of transfusing blood between immunologically related individuals. It appears that transfused white blood cells are not recognized as foreign, and react against host tissue. The reaction seems to depend on heterozygosity of class I antigens. The two recognized forms of the disease are acute and chronic.

Incidence. Even using prophylactic therapy to prevent its occurrence, GVHD occurs in approximately 50% of patients receiving successful marrow allografts for various disorders, including immunodeficiency diseases, aplastic anaemia, acute leukaemia and radiation exposure, despite careful histocompatibility matching [7]. The frequency is the same in those receiving peripheral blood stem cell grafts [8]. It has recently become clear that the typical acute form of the syndrome can also occur after syngeneic (identical twin) or autologous bone marrow grafting, in which genetically identical material is transplanted, and may occur in approximately 10% of such cases [8].

Aetiology [4,9]. Billingham described the original criteria for the development of a graft-versus-host reaction in 1966:

1 Genetically determined histocompatibility differences between donor and recipient

2 Immunocompetent cells in the grafted tissue able to recognize foreign histocompatibility antigens in the host and to react against them

3 Inability of the host to recognize and react against the grafted tissue.

It is clear from animal experiments [10,11], as well as the occurrence of typical GVHD in human syngeneic transplants, that criterion **1** is no longer an essential prerequisite for the development of the acute form of the syndrome. GVHD in this situation occurs because of MHC class II differences. It usually only occurs after the withdrawal of immunosuppression [12].

A similar syndrome occurs in recipients of IL-2 and lymphocytes activated by this stimulating lymphokine given as treatment for widespread malignancy. Cells activated by this technique are non-specifically cytotoxic, capable of self-reactivity and may have the features of NK cells. In animal models, and in humans, HLA-DR-bearing Langerhans' cells are reduced in the acute form of the disease, and T cells directed against these cells are found. In addition, IFN production by activated T cells induces HLA-DR expression on keratinocytes, making them targets for a similar reaction [13,14]. The risk of developing GVHD may be related to cytokine gene polymorphisms [15].

A possible hypothesis is suggested by Ferrara [16]; immunologically competent donor T lymphocytes are not destroyed in the host because they are not recognized as foreign. Activated T cells release IL-2, IFN and probably other lymphokines. IL-2 activates cytotoxic cells (probably NK cells), and HLA-DR-bearing epidermal cells and Langerhans' cells may be specifically attacked, giving rise to acute GVHD. The same, or similar, cells recognize any persisting malignant cells in the host, and it is suggested that graft-versus-leukaemia reactions explain the lowered incidence of recurrence of the original malignancy in patients with GVHD. However, there are some criticisms of the theory of T-cell-mediated cutaneous pathogenesis, mainly that early graft-versus-host reactions do not show T-cell infiltration of the skin [17]. In addition, successful treatment of GVHD is accompanied by the induction of apoptosis in T cells and some epidermal cells. This suggests that a failure of programmed cell death may be a feature of pathogenesis [18]. Nevertheless, the use of T-cell-depleted marrow for grafting reduces the incidence of GVHD and prevents HLA-DR expression on keratinocytes,

but unfortunately the failure rate of the transplant is markedly increased.

Pathology [19]. For acute GVHD, the cutaneous histological changes have been graded for severity.

Grade I Basal cell vacuolation with or without mononuclear cell infiltration

Grade II Solitary epidermal cell necrosis, surrounded by mononuclear cells

Grade III Regional epidermal cell necrosis with bullae

Grade IV Toxic epidermal necrolysis

Less severe histological grades may be impossible to differentiate from drug-induced reactions. At an immunocytochemical level, the earliest (preclinical) changes are an increase in dermal macrophages expressing α_1-antichymotrypsin. In grade I disease, there is keratinocyte HLA-DR and ICAM-1 expression, and in the later stages, $CD25^+$ T cells, L1 antigen-positive keratinocytes, and VCAM-1^+ macrophages are increased [20].

In chronic GVHD, histological changes are lichenoid, or resemble scleroderma. IgM may occur at the dermal–epidermal junction, with granular deposits of IgM, IgA and C3 in the walls of dermal vessels. There is associated microvascular disease mediated by cytotoxic T cells [21].

Clinical features [1,2]. Acute GVHD usually occurs within 60 days of a bone marrow transplant, and most often after 7–12 days. Mild fever is followed by a faint red maculopapular rash on the hands, feet, face and forehead. This spreads to the trunk and limbs, becoming deeper in colour. Desquamation or even toxic epidermal necrolysis follows. Bullous and ulcerated forms are described [3], and a follicular pattern may indicate more severe disease [4]. Hepatitis (indicated by raised bilirubin and alkaline phosphatase) and bloody diarrhoea resulting from enteritis are other features and, in severe cases, death occurs by the 21st day. In the original cases, it was rare to have liver and gut involvement without cutaneous pathology, and skin biopsy was the simplest reliable test for diagnosis. However, the introduction of T-cell depletion as a prophylactic measure has changed the pattern of disease so that skin disease may be mild, while liver and bowel disease may be severe. Thus, the value of skin biopsy has been questioned [5]. Clinical stagings for each organ system, and grading for the overall clinical picture, have been proposed [6].

Chronic GVHD may be localized (Fig. 56.56) or generalized, and principally involves the skin and the liver. The former occurs in 10% of patients as hyperpigmented nodular areas, which may be guttate, and eventually soften and atrophy. The early phase of generalized GVHD generally appears up to the 100th post-transplant day and usually, but not always, follows acute GVHD. Initially, a slowly progressive erythematous rash on the face, palms and soles becomes lichenoid, with changes resembling lichen planus in the oral mucosa [7]. Lichenoid changes may be limited to the nails [8]. Later, scleroderma-like changes occur, which are sometimes widespread and disabling. The condition resembles systemic sclerosis, with tightening of the skin of the face, hands and feet. Autoantibody changes similar to those found in systemic sclerosis may occur [9]. Disease may be localized to the extremities and associated with a polyneuropathy [10].

Fig. 56.56 Localized eroded sclerotic graft-versus-host disease.

Oesophageal changes and subcutaneous calcification may occur. Morphoea-like changes have been reported [11]. Eruptive violaceous vascular tumours on the legs may occur [12]. Reticulate patchy hyperpigmentation and, less commonly, hypopigmentation, poikiloderma, vitiligo (which may be total [13]), erythema, atrophy, alopecia, multiple follicular papules, deep ulcerations of the buttocks and legs, and dystrophic nail changes are other features [14]. Panniculitis may occur [15]. Gastrointestinal symptoms, a Sjögren-like syndrome [16], polymyositis [3], abnormal liver function tests, primary biliary cirrhosis [17] and other organ changes occur [3].

That there may be some interaction between viral infections and minor histocompatibility differences in the pathogenesis of chronic GVHD is suggested by the development of scleroderma-like skin changes in areas affected by measles in a patient 8 months after bone marrow transplantation [18]. Similarly, pathogen-free transplanted animals do not develop GVHD until given bacteria or endotoxin, and patients nursed in laminar flow isolation remain disease-free until they are removed from this environment [19].

Treatment. Prophylactic use of ciclosporin [20,21], methotrexate and prednisolone [22] and, in particular, combinations of these agents [23], has reduced the incidence of acute GVHD. None of these regimens has produced a definite reduction in the incidence of chronic GVHD, and recent studies indicate no benefit in 24-month rather than 6-month ciclosporin therapy in this situation [24]. T-cell depletion by using anti-T-cell receptor antibodies is successful in reducing the frequency of acute GVHD when used with post-transplant ciclosporin [25]. Combination therapy appears to be better at preventing GVHD than monotherapy, but overall survival is unchanged in younger patients because of higher leukaemic relapse. Older patients survive longer on combination therapy (methotrexate with ciclosporin or T-cell depletion) [26]. Intravenous IgG may help to prevent GVHD, but its value is unconfirmed [27]. Granulocyte colony-stimulating factor, used to enhance engraftment may reduce the incidence of GVHD [28].

Once the disease is established, treatment with high-dose corticosteroids or ciclosporin is of value symptomatically, and antilymphocyte globulin may be of additional benefit [29], particularly if combined with tacrolimus [30]. Treatment with prednisone and azathioprine for at least 9–12 months helps generalized chronic GVHD in one-third of patients [31], but complications are common, and survival may be reduced by the addition of azathioprine. Thalidomide, used in both low dosage (100 mg/day) and high dosage (400 mg/day) has been of value, but may result in severe cutaneous ulceration [32,33]. PUVA therapy [34], UVB [35], UVA-1 [36] and extracorporeal photophoresis [37] may be of benefit, even in severe disease [38,39]. Most recently, infliximab, the monoclonal anti-TNF therapy, has been used successfully [40].

Prognosis. Forty to fifty per cent of patients with chronic GVHD are dead within 10 years of developing the disease. Mortality is caused both by the disease itself, and by severe superinfection, related, at least in part, to the immunosuppressive effects of treatment. Recurrence of the original disease is also a problem. Patients who develop chronic GVHD after the acute form, those with the lichenoid type of eruption, and those with significant liver disease have a worse prognosis, with 80% mortality at 10 years [41]. Persistent thrombocytopenia is also an adverse sign [23].

Eosinophilic fasciitis [1–8]

SYN. SHULMAN'S SYNDROME

This scleroderma-like syndrome appears to be a distinct entity, although some have suggested that it is an early variant of systemic sclerosis [2,9] or linear scleroderma [10], or that it may occur in conjunction with other connective tissue disease [11]. It occurs in children and adults, more commonly in males than females. The clinical features are the acute onset of pain, swelling and tenderness of the distal part of the limbs, which become indurated. There is limitation of movement of the feet and hands. Occasionally, the face or abdomen can be affected, and there may be superficial blistering and haemorrhage. A relationship to strenuous exertion or trauma has been suggested. Twenty-nine per cent of 52 patients showed lesions of localized morphoea at some stage [12]. Raynaud's phenomenon is rare, there is limited evidence of involvement of internal organs such as occurs in systemic sclerosis, and no history of a previous infection to suggest scleroedema. Blood eosinophilia up to 30% is a striking feature, occurring in approximately 70% of cases [13]; it is associated with elevation of the ESR and hyperglobulinaemia, but these are not present in all cases. Rarely, aplastic anaemia and thrombocytopenia occur [7]. Antinuclear antibodies cannot be demonstrated and serum complement levels are normal. Cytokine production by mononuclear cells is enhanced but the pattern is of mixed Th1 and Th2 [14]. Histologically, there is dermal sclerosis, with inflammation and fibrosis of the fat and deep fascia. The fascia is thickened and infiltrated with lymphocytes, plasma cells, histiocytes and eosinophils. IgG and C3 deposits can be demonstrated in the deep fascia. Clinical improvement and disappearance of eosinophilia follows corticosteroid therapy, but spontaneous remission has been reported. Methotrexate may be useful [15].

An eosinophilic fasciitis-like syndrome occurs after recent ingestion of L-tryptophan [16,17]. In addition to the usual features of fasciitis, there is muscle weakness and elevated muscle enzyme levels. Enhanced type I procollagen gene expression in the skin has been demonstrated [17]. Myalgia, eosinophilia, dyspnoea, oedema, arthralgia, neuropathy and rashes occur in the eosinophilia–myalgia syndrome [18,19] which can also be precipitated by tryptophan [9]. Cutaneous manifestations include localized and generalized morphoeic lesions and urticarial and papular lesions [20].

Connective tissue panniculitis (see Chapter 55)

This term has been used [1] for focal nodular or atrophic linear or plaque-like lesions on the face, upper trunk or extremities, which histologically show lymphocytic panniculitis with caseation necrosis. The lesions may respond to chloroquine.

REFERENCE

1 Winkelmann R, Padilha-Goncalves A. Connective tissue panniculitis. *Arch Dermatol* 1980; **116**: 291–4.

Relapsing eosinophilic perimyositis [1]

This rare disorder is in the spectrum of eosinophilic myositis, and is characterized by inflammation within the perimysium (and often epimysium) without necrosis, as opposed to polymyositis and eosinophilic myositis in which necrosis and inflammation occur in the endomysium.

Clinically, patients may present with episodic swelling of the muscles, fatigue and fever. Skin lesions include blotchy erythema over the swollen muscles and erythematous papular lesions of the palms. There is peripheral blood eosinophilia and hyperglobulinaemia, but the muscle enzyme levels are normal or only slightly elevated. Histologically, there are perimysial eosinophilic infiltrates.

The aetiology is unknown. The prognosis is good, although the patient should be followed up in case of the development of lymphoproliferative disease. Most patients respond to moderate doses of steroids or indometacin.

Systemic sclerosis [1,2]

SYN. PROGRESSIVE SYSTEMIC SCLEROSIS; SYSTEMIC SCLERODERMA; ACROSCLEROSIS

Definition. Systemic sclerosis is a multisystem disorder characterized by the association of vascular abnormalities, connective tissue sclerosis and atrophy, and autoantibodies (see p. 56.95 for diagnostic criteria) [2].

The name progressive systemic sclerosis was coined by Goetz in 1945. In most cases, the disease is not 'progressive' and this term is now omitted by most authors [2–5].

Incidence. Systemic sclerosis is a rare disorder, with an incidence between 2.3 and 10 per million population [6–8]. The prevalence rates in a British study were 13 per million males and 48 per million females, although these are probably minimum figures [9], and there may be considerable regional variations, possibly as a result of environmental factors [10]. Figures from South Carolina are much higher (67–265 in 100 000) [11]. The ratio of females to males is between 3 and 6 : 1 [8,9,12]. The peak onset is in the fourth decade in females and usually later in males;

however, overall, 85% of patients present between the ages of 20 and 60 years [8]. In men, the condition appears to be more common among coal miners and those who work in dusty trades, and it has been suggested that silicosis may be a predisposing factor [13]. It occurs in all races, but seems to be less frequent in Asians [14]. There is evidence that black women with systemic sclerosis are more likely to develop diffuse disease at a younger age and have decreased survival compared with white women [15].

Aetiology [1]. The aetiology of systemic sclerosis is unknown. The presence of vascular symptoms in virtually all patients, the fact that these may predate the development of classic fibrotic change, and the presence of markers of vascular damage (e.g. elevated von Willebrand factor antigen levels [2,3]), suggest that the vasculature, in particular the endothelial cell, is the initial target in this disease. Vascular abnormalities are not limited to the clinically abnormal skin [4]. Damage to the endothelial cell may initiate the fibrotic process, either through the effects of ischaemia or via growth-modulating mediators released from platelets and inflammatory cells. However, the pathological changes in the internal organs do not always seem to be directly related to changes in the small blood vessels of the same area.

There is clear evidence of endothelial injury and death [5], and the primary pathology in vascular endothelium appears to be a fibromucinous change [6]. Serum from patients with the disease is cytotoxic to endothelial cells, either directly [7] or by antibody-dependent cellular cytotoxicity [8], but patients' serum has no effect on unstimulated release of prostacyclin [9], although stimulated release may be impaired [10]. The influence of sera from affected patients on angiogenesis varies with the phase and type of disease, being stimulatory in early limited disease, but inhibitory in chronic diffuse disease [11]. Damage to endothelium is followed by vascular occlusion resulting from thrombus formation, and tissue ischaemia follows. Abnormalities in various blood components contribute to this tissue anoxia: red cell deformability is reduced [12], platelet aggregation to collagen may be specifically enhanced [13] and *in vivo* markers of platelet activation are increased [14]. Levels of fibrinogen, von Willebrand factor antigen (possibly indicating the degree of vascular damage) [15] and other plasma proteins are also raised, contributing to increased plasma viscosity, further reducing microvascular blood flow. Anticardiolipin antibodies are present in more severely affected subjects, and may cause endothelial cell damage [16].

The associated fibrosis in systemic sclerosis is caused by the increased accumulation of collagen. Scleroderma fibroblasts synthesize more collagen than those from normal controls [17,18], and collagenase activity is normal [19]. The deposited collagen is similar in composition to that deposited in other fibrotic disorders, with a normal ratio of type I to type III collagen [19]. The cause of this excessive production is unknown: both intrinsic overactivity and excessive stimulation of fibroblasts may occur. Fibroblast function is modified by endothelial cell products released in a cell culture system [20]. Small collagen fibres are increased, and the response of systemic sclerosis fibroblasts to most mitogens is normal, or reduced, indicating overstimulation [21]. Raised levels of growth factors, both platelet-derived [22] and non-platelet-derived [23], support this suggestion. In addition, glycosaminoglycan synthesis is increased in fibroblasts from patients with the disease, and is stimulated by a mononuclear cell product (possibly IL-1) [24], although other mononuclear cell products can inhibit collagen overproduction [25]. Other connective tissue proteins, including tenascin, are increased [26]. However, there is evidence for an expanded clone of overactive fibroblasts in systemic sclerosis [27], possibly derived from fibroblasts from the deeper dermis [28,29]. There is also an excessive response of fibroblasts to TGF-β [30], to platelet growth factors [31] and to serum from patients with the disease [32]. TGF-β may have a role both in fibroblast stimulation and in endothelial inhibition [21]. There is a failure of the inhibitory feedback of the amino-propeptide of type I collagen on the fibroblasts [33]. Soluble cytokine receptors [34]

and serum levels of adhesion molecules [35] are raised, and reflect disease activity. Circulating anticollagen antibodies to collagen types I and IV occur in patients with systemic sclerosis [36], but these appear to be inversely related to the severity of the disease. They occur in approximately half of British patients and in at least one relative in over 80% of their families. It has been suggested that serotonin hypersensitivity may be a factor in both the vascular and fibrous changes of the disease [37]. Abnormal metabolism of, and responses to, serotonin and tryptophan may contribute to both fibrosis and vascular abnormalities [38]. Raised numbers of mast cells in affected skin may similarly contribute.

Autoimmunity. It is not clear whether autoimmunity, indicated by the presence of antinuclear and other antibodies, is a primary abnormality or occurs because of cellular damage. A role for immune factors in endothelial injury is suggested by the presence of antiendothelial cell antibodies in 30% of patients [1,2], the ability of endothelial cells to act as a modulator of immune responses [3] and the finding of an IgM vasculopathy in acute-onset systemic sclerosis. Furthermore, circulating immune complexes occur in over 50% of cases [4], but their significance is unknown.

There is also evidence of abnormal cellular immunity. Patients with systemic sclerosis show leukocyte migration inhibition to a variety of autologous, homologous and heterologous antigens [5]. However, the development of delayed cutaneous hypersensitivity is normal [6]. Patients have a deficiency of circulating T lymphocytes [7]

and impaired lymphocyte transformation in response to phytohaemagglutinin (PHA) [8]. Both these features are related to the severity of the disease and the degree of visceral involvement, and also to an increased incidence of HLA-B8 [9]. The haplotype B8/DR3 is associated with decreased cellular immunity [10]. Helper cells [11], T cells possibly activated by raised levels of IL-2 [12] and NK cells are increased [13], and suppressor cells decreased [14]. These T-cell changes are more marked in later stage generalized disease. Patients with extensive disease have reduced antibody-dependent cytotoxicity, PHA-induced T-cell cytotoxicity [15] and NK-cell cytotoxicity to Chang liver cells [16], although others have found enhanced NK activity [17]. Some patients with systemic sclerosis develop a delayed cutaneous reaction to autologous leukocytes [18]. Sclerodermatous changes may occur after allogeneic bone marrow transplantation (see p. 56.87).

Genetic factors. Despite the rarity of familial cases of systemic sclerosis [1–4], abnormalities of the serum immunoglobulins [5] and the high incidence of antinuclear factor in first-degree relatives of patients with systemic sclerosis [6], together with an increased incidence of HLA-B8 in the more severe cases [7], suggest that genetic factors play a part in the aetiology. Clinical and immunological subsets may be genetically determined, but to date there appears to be no clear relationship between HLA, autoantibodies and clinical manifestations [8]. Chromosomal abnormalities have been described in patients with the disease [9,10] and in their relatives, and a serum factor may be responsible for this abnormality. HLA-DR typing shows an increase in DR2, DR3 and DR5 [11]. There is an association between the B8-DR3-DR52-DQB2 haplotype and the development of pulmonary fibrosis [12]. Patients with mild disease have raised DR2 and DR5 and anticentromere antibodies. No relationship between HLA type and Scl-70 antibodies has yet been demonstrated. In identical twins discordant for the disease, autoantibodies [13], T-cell abnormalities and abnormal fibroblast response to mononuclear cell stimulation were found only in the affected twin [14].

A recent intriguing hypothesis suggests that transfer of fetal cells to the mother or vice versa during pregnancy may result in microchimerism, which has been demonstrated in higher frequency in systemic sclerosis [15]; this may then stimulate a unique immune response.

The age distribution of the disease suggests that the susceptible genotype is probably characterized by a single inherited dominant allele on the X chromosome, explaining the female predominance, together with autosomal factors. Initiation would depend on the occurrence of specific random events believed to be somatic mutations in lymphoid stem cells [16], producing 'forbidden' clones of lymphocytes. These synthesize cellular autoantibodies that are pathogenic, damaging endothelial cells. After a variable latent period, damage to tissue occurs. Antinuclear factors are the result of the disease. Normal defence mechanisms (more efficient in females) may be inhibited by precipitating factors such as silica or other environmental hazards. The pattern of organ involvement may be related to particular forbidden clones that are active, or to local tissue differences.

Other factors. There is no evidence of a chemical cause, although cocaine has been suggested as a trigger in some cases [1]. The role of silicone gel prostheses used for breast augmentation has been much discussed, but there is now agreement that there is no relationship between this procedure and the development of systemic sclerosis [2,3]. Physical trauma appears to precipitate the disease in genetically predisposed individuals [4], who may have the allele HLA-DR52 [5]. Virus-like particles have been observed by electron microscopy in striated muscle [6], and acid-fast bacilli, closely allied to mycobacteria, have been found in skin biopsies [7] in systemic sclerosis, but their significance is not known. Glucose-tolerance curves may suggest latent diabetes [8]. A prolongation of sensory chronaxia has been found in both normal and abnormal skin [9], and it has been suggested that the condition is a primary abnormality of the central autonomic nervous system. Reciprocal skin grafting has shown that if sclerodermatous skin is placed in a normal bed, it remains sclerodermatous, and if clinically normal skin is placed in a sclerodermatous area it becomes sclerodermatous [10]. Thus, in systemic sclerosis, the skin involvement is generalized or irreversible, in contrast with morphoea, in which the disorder is localized and reversible.

Diagnosis. The criteria for diagnosis have been established by the Subcommittee for Scleroderma Criteria of the ARA [1] and are generally accepted. Patients should have either:

1 Scleroderma proximal to the digits, affecting limbs, face, neck or trunk—this is the single major criterion; or
2 At least two minor criteria, consisting of:
(a) sclerodactyly
(b) digital pitted scarring
(c) bilateral basal pulmonary fibrosis.

These criteria have 97% sensitivity and 98% specificity, and difficulty arises principally in males who have a sclerodermatous condition brought about by occupational exposure to, for example, silica or vinyl chloride. These patients often fulfil two minor criteria, and indeed share many characteristics, both clinical and immunological, with true systemic sclerosis [2].

Classification of systemic sclerosis. There have been many attempts to classify the disease [3–6]. Most recently, a simplified classification has been proposed [7]. In this system, patients are classified as having diffuse cutaneous systemic sclerosis (dSSc), or limited cutaneous systemic sclerosis (lSSc). The distinction is made principally on the basis of the extent of cutaneous involvement, but also includes certain other clinical and immunological features (Table 56.9). This system appears satisfactory because systemic involvement, which determines the prognosis of the disease, is less frequent in patients with limited cutaneous disease.

Table 56.9 Classification of systemic sclerosis.

Diffuse cutaneous systemic sclerosis
Short interval (< 1 year) between the onset of Raynaud's phenomenon and the development of skin changes
Truncal and peripheral skin involvement
Tendon friction rubs
Pulmonary fibrosis, renal failure, gastrointestinal disease, myocardial involvement
Capillary drop-out visible in nail folds
Scl-70 antibody-positive
Anticentromere antibody-negative
Limited cutaneous systemic sclerosis
Long history of Raynaud's phenomenon
Limited skin involvement (peripheral only)
Calcification, telangiectasia, late onset of pulmonary hypertension
Capillary dilatation visible in nail folds
Anticentromere antibody-positive

Pathology [1]. It is important to realize that this widespread disease does not involve all organs in any patient: in certain cases it may be limited to one or two organs. Even when changes are present in an organ, the distribution of these changes is by no means uniform. Although a striking abnormality in systemic sclerosis is the sclerotic change in tissues such as the heart, lungs, submucosa and muscularis of the gastrointestinal tract, widespread vascular lesions may be a prominent feature of certain cases. The digital arteries may be severely involved, and changes of endarteritis may be seen in the lungs, heart, gastrointestinal tract, muscle and kidney. Infiltrations of inflammatory cells, particularly lymphocytes, may occur in the joints, mucosa and submucosa of the gastrointestinal tract, and in striated muscle.

In the skin, the dermis shows hyalinization of the collagen, often with associated abnormalities of elastic tissue and reticulin. The changes may be slight and difficult to detect unless the histological technique is excellent. In particular, standard fixatives must be used if hyalinization of the collagen is to be assessed. In severely involved skin, the epidermis and its appendages are usually atrophic, with loss of the rete ridges. Sometimes, there is hyperkeratosis, and the dermis shows variable degrees of homogenization of the collagen, and occasionally a light dermal lymphocytic infiltrate. In the tumid or 'inflammatory' phase in the fingers, the dermis may show a striking infiltrate, with lymphocytes predominating. Cellular infiltrates of lymphocytes, plasma cells, fibroblastic-type cells and macrophages, either perivascular or diffuse, occurred in 49% of patients of one series [2], but there was no correlation with serum serological abnormalities. Electron microscopy has shown that both T and B lymphocytes are present in the infiltrates [3], although most are activated helper T cells. Hyalinization and intimal thickening of the blood vessels may occur, but fibrinoid change is uncommon. Evidence from electron microscopy [4] and the normal distribution of cutaneous enzymes, acid mucopolysaccharides and other ground substances, together with the absence of any abnormal gammaglobulin, fibrinogen or albumin, using fluorescent antibody techniques, suggests that the alterations in dermal collagen are the result of a simple increase in the number of fibrils. Quantitatively increased fibrillogenesis, with an increased proportion of thin fibrils of type III collagen [5] in the dermis, has led some authors [6] to conclude that qualitative and quantitative disturbances in mesenchymal ground substances may play an important part in the increased formation of qualitatively normal collagen fibrils in scleroderma [7]. Further evidence that the ground substance is the tissue mainly involved has been provided by the finding of a normal concentration of water and hydroxyproline in the dermis [8]. Some authors believe that the main alterations in the skin in systemic sclerosis take place in the subcutaneous tissue and not in the dermis [9]. It is suggested that the replacement of subcutaneous tissue by connective tissue is the cause of the induration of the skin.

Histology, histochemistry, immunopathology and electron microscopy of depigmented areas of skin show changes similar to those found in vitiligo [10]. The digital vessels frequently show intimal and medial thickening, which may be so gross as to almost occlude the vessel (Fig. 56.57); this accounts in certain cases for gangrene of the fingers. Occasionally, fresh thromboses may be seen. Similar but less marked changes are found in the digital arteries of the toes, and the vessels of the leg may also show intimal thickening, which results in ischaemia and gangrene. The intimal thickening is very similar to that seen in the peripheral vascular obstruction that occurs in rheumatoid arthritis. Thromboses of major arteries can also occur [11], and reduction of local tissue fibrinolytic activity can be demonstrated in the involved vessels. Giant cell granulomatous necrosis of the intima of vessels and fat in nodular lesions of the skin has been described [12].

Immunoglobulins and complement may be demonstrated by fluorescent antibody techniques at the dermal–epidermal junction in telangiectases, but not in the indurated skin without telangiectasia [13]. Biopsies should not be taken from telangiectatic areas. The main immunohistological changes in the skin in systemic sclerosis consist of foci of intercollagenous staining for connective tissue antigens in the reticular layer of the dermis [14]. The absence of immunoglobulin and complement from the dermal–epidermal junction may be useful in distinguishing systemic sclerosis from SLE, in which the major changes are at the dermal–epidermal junction. Patients who have both systemic sclerosis and SLE have

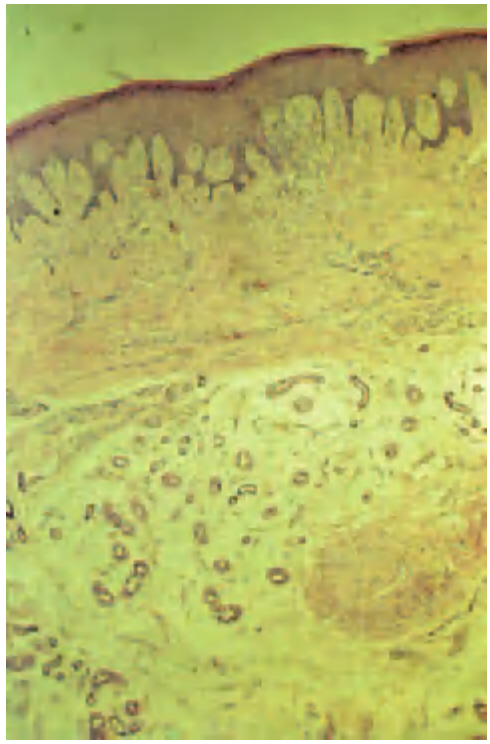

Fig. 56.57 Systemic sclerosis: section of finger showing thickened dermis with hyalinization of the collagen and almost complete occlusion of a digital vessel.

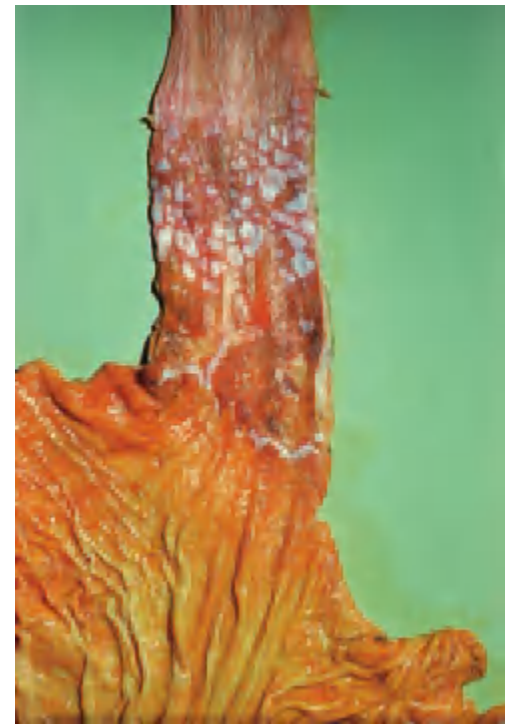

Fig. 56.58 Pearly white plaques in the oesophagus in systemic sclerosis, giving a cobblestone appearance.

deposits of immunoglobulin and complement at the dermal–epidermal junction in involved and uninvolved skin as well as changes in the dermal collagen. Patients with scleroderma as part of 'mixed connective tissue disease' have positive immunofluorescence at the dermal–epidermal junction [15].

The gastrointestinal tract is frequently involved. The oesophagus may show areas of epithelium looking like pearly white plaques, giving a cobblestone appearance (Fig. 56.58). Microscopically, subepithelial fibrosis is the most common finding, but fibrosis may also occur in areas of muscular atrophy. The smaller arteries may show endarteritis, and some cellular infiltration also occurs. In the duodenum, jejunum, ileum and colon there is a patchy disappearance of muscle, especially of the circular layer, with replacement by fibrous tissue. The subserosal and submucosal tissues may also be thickened and fibrosed. Vessels in these areas may show sclerosis and intimal fibrosis.

Pathological changes in the lungs may be seen, even in the absence of symptoms or radiological signs of pulmonary involvement and even in the presence of normal pulmonary function. Progressive diffuse alveolar fibrosis occurs with obliteration of capillaries and alveolar spaces, but is preceded by an inflammatory alveolitis [16,17]. In other cases, hyaline degeneration and fibrosis of alveolar walls result in the disappearance of the alveolar parenchyma and of the capillaries. Rupture of the thinned alveolar walls gives rise to cysts that are lined by cuboidal or columnar epithelium, which may be ciliated. Electron microscopy [18] may show thickening of the alveolar–capillary basement membrane. Arterial lesions in the lungs take the form of concentric thickening of the intima by loose myxomatous tissue and, later, sclerosis. In certain cases, the vessels may be almost completely occluded. Neoplastic change is a rare complication of the pulmonary abnormalities in systemic sclerosis. Various types of neoplasm have been reported [19,20], including malignant pulmonary adenomatosis, alveolar cell carcinoma, adenocarcinoma, oat cell carcinoma and squamous cell carcinoma.

The heart may show no change macroscopically, although showing widespread histological changes. The major coronary arteries are usually patent. Pericarditis, sometimes with effusion, is not uncommon, and sometimes the myocardium shows considerable streaky or focal fibrosis. Occasionally, the mitral or tricuspid valve is involved [21], and Libman–Sacks type of non-bacterial endocarditis has been reported [22]. Histologically, the myocardium may show focal or diffuse fibrosis, associated with degeneration or atrophy of some of the muscle fibres. Occasionally, smaller arteries and arterioles show thickening of the walls. Sometimes, an aneurysm of the myocardial wall develops, and the aorta may show

adventitial fibrosis with a focal necrotizing panaortitis and valvulitis.

Involvement of the kidneys used to be the most common cause of serious morbidity and mortality, but this is now uncommon, probably because of the early and improved control of hypertension. In one of the first pathological studies, renal lesions were found in 74% of patients at autopsy [23], and in 90% in another series [24]. It has been suggested [25] that a triad of intimal proliferation of the small intralobular arteries and arterioles, fibrinoid necrosis of the walls of the afferent arterioles and sometimes the glomerular loops, together with cortical infarction characterizes renal lesions in systemic sclerosis. Vascular luminal occlusion may occur, particularly in patients with renal crisis [26]. These changes are not always found, and there are probably no absolutely specific features. Other changes include a mucoid appearance of the intimal thickening of the proximal part of the intralobular arteries. Hypercellularity of the glomeruli and fibrinoid necrosis of the basement membrane of the glomerular tufts may be found. The tubules may be atrophic and surrounded by increased connective tissue, or be dilated and full of hyaline eosinophilic material. A hyaline droplet nephrosis may occur. In the more chronic cases, glomerular hyalinization and interstitial fibrosis predominate. Immunohistological techniques [27] show thickening of the glomerular capillary basement membrane and alteration in the reticular tissue of arterioles associated with deposits of fibrin and very occasionally with the presence of IgG and C3.

The liver is usually normal in systemic sclerosis, although mild fibrosis of the portal tracts and around the bile ducts can occur. The gall bladder may be fibrosed. The spleen may show fibrinoid necrosis of arterioles and endarteritis obliterans, and endarteritis is also found in the adrenals, mammary glands, pancreas, uterus and ovaries.

Histological changes in the muscles are similar to, if not identical with those of dermatomyositis. Muscle fibres show varying degrees of degeneration, such as loss of cross-striations, hyalinization of bundles, vacuolation and splitting, with interstitial and focal infiltration of lymphocytes. Later, sclerosis develops and the vessel walls may be thickened. There may also be some thickening of the endomysium and perimysium. The thyroid [28] and parathyroid [29] glands may be involved in the fibrotic process, and the thymus may show cortical atrophy [30].

Widening of, and vascular changes in the periodontal membrane of the teeth occur.

The CNS is rarely involved, but occasionally there may be thickening of the walls of vessels in the white matter, and meningeal lymphocytic or granulomatous infiltrates. Peripheral neurological involvement is characterized by increased collagen deposition in the epi- and perineuria, and intimal thickening of the vasa nervorum [31].

Natural history. In the majority of patients, the onset is with Raynaud's phenomenon, although this may have been present for many years, and the cutaneous changes occur after an interval. This is much shorter in males—in whom it is usually under a year—than in females, in whom it is usually approximately 5 years, but may be as long as 30 years [1]. Occasionally, Raynaud's phenomenon and cutaneous sclerosis are noticed at the same time, and sometimes Raynaud's phenomenon may follow the onset of cutaneous or other manifestations, or be absent. The risk of anyone with Raynaud's phenomenon developing systemic sclerosis is relatively small, although it seems to be greater in males than in females [2]. Sclerodactyly may be found in approximately 10% of patients with Raynaud's disease, but systemic sclerosis occurs in approximately 4% of patients with this combination [3]. The differentiation between severe Raynaud's disease and early systemic sclerosis is difficult, but may be aided by nail fold capillaroscopy and the presence or absence of autoantibody [2]. The main cause of mortality used to be renal disease, but recent studies show a preponderance of cardiovascular problems, with coronary and cerebrovascular events [4]. In addition to the microvascular changes described, it is now apparent that large vessel changes similar to atherosclerosis are also increased in systemic sclerosis [5].

Clinical features. The earliest feature is usually, but not invariably, Raynaud's phenomenon. Other early presenting symptoms and signs include swelling of the hands in approximately 15% of patients, swelling of joints, ulceration of the fingers, whitlows and even gangrene. Occasionally, the diagnosis may be made in a patient presenting with leg ulcers or calcinosis cutis. With the increased availability of laser treatments, some patients' first presentation is for treatment of telangiectasia. Less common early symptoms include gastro-oesophageal reflux and dysphagia; constipation, diarrhoea and abdominal pain are usually late features.

Cutaneous changes. The hands and face are the most frequently involved, but the changes may extend proximally to involve the forearms and upper arms, usually but not always in a continuous fashion. The fingers may be oedematous and swollen, and the skin feels tight and has a shiny appearance. With increasing severity, the skin becomes immovable or hidebound. The clinical impression of thickness and toughness of the skin is enhanced because of binding down of the skin to deeper structures. The collagen content is decreased but the density is normal [1]. Sometimes, the chest becomes tight, shiny and pigmented. The facial appearance in a well-developed case is characteristic. The forehead is smooth and shiny, the skin is bound down and hard, the lines of expression are smoothed out and the nose becomes small and pinched (Fig. 56.59). The mouth opening is constricted and radial furrows appear, giving a pursed appearance (Fig. 56.60). The lower eyelids cannot be depressed by the fingers to show the conjunctivae, because of atrophy of the tissues. Very rarely, periorbital oedema can occur [2]. Small matlike telangiectases are frequently found on the face. Sometimes, the changes on the face are minimal and detected only by an astute observer after the diagnosis has been suspected because of other changes. Mandibular atrophy can occur (Fig. 56.61). Chondrodermatitis nodularis helicis was found in three of 21 patients with limited cutaneous disease [3].

Just as the face may be involved to a greater or lesser extent, the hands may also show great variability in their appearance (Fig. 56.62). Sometimes, in the early stages, only a little atrophy can be seen. Occasionally, the fingers and hands are swollen and rather tumid, and there is

Fig. 56.60 Systemic sclerosis: restricted mouth opening.

Fig. 56.62 The hands in systemic sclerosis: oedematous phase.

Fig. 56.63 Systemic sclerosis: healed ulceration of the fingertips.

difficulty obtaining full extension. The terminal phalanges may be bulbous. Later, however, the changes are easily recognized. Atrophy occurs first in the pulps of the fingers, and small painful ulcers are formed, which heal leaving depressed scars (Fig. 56.63). Pitted scars occur in over one-third of patients, not only on the tips of the fingers but also in a linear distribution on the ulnar border of the thumb and radial borders of the index and middle fingers, as well as the dorsa of the fingers over the joints [4]. Later, sclerosis of the overlying skin of the fingers develops, giving the fingers a smooth shiny tapered appearance, with the nails curving over the atrophic phalanges. Later still, the nails become very small and the whole of the distal part of the finger atrophies. The nail folds may show ragged cuticles. Pterygium inversum unguis-like changes are sometimes found [5]. Slow-healing whitlows and paronychia are common, and ulcers may also occur over the knuckles. Later, the atrophy and sclerosis extends to involve the whole hand, which is held in semi-flexion, full extension of the fingers and metacarpal joints being impossible. Gangrene of the fingers is not uncommon, and

Fig. 56.64 Systemic sclerosis: 'cobblestone' appearance on the dorsum of the hand.

Fig. 56.65 Systemic sclerosis: pigmentation of the abdomen.

may occur surprisingly early in the disease. It does not necessarily indicate a poor prognosis. Digital arteriography confirms narrowing of the digital arteries [6].

Telangiectases are often found on the palms and on the rest of the hands. Calcium deposits occur in the skin of the fingers and hands, and may break down to discharge chalky material. Calcinosis may also be found around the elbow, where the olecranon bursa may be involved. Erythema may be seen on the thenar and hypothenar eminences. Hyperkeratotic plaques over the phalanges may indicate amyloid material deposited in the dermal papillae [7]. Multiple small papules of lymphangiectasia may occur in 'hidebound' skin because of obstruction of lymphatic channels by the sclerosing process (Fig. 56.64) [8]. Ivory-coloured subcutaneous nodules 3–20 mm in diameter occur rarely on the trunk and limbs. Histology shows fibromatous changes [9] or fibrinoid necrosis [10].

Similar, although less severe changes occur on the feet, and not infrequently the tips of the toes become black with incipient gangrene. The feet become encased in tight firm skin with mottled patches of pigmentation and atrophy. These changes may extend up the legs and be present on the thighs.

In a series of patients at Leeds, changes on the hands occurred in 95% of cases, on the face in 90%, beneath the clavicles in 30% and on the feet in 15%. The changes on the face, hands and feet tend to be progressive, but changes on the trunk have been seen to regress over the years. Dilated nail fold capillaries visible without a lens occur in approximately 10% of patients and, occasionally, heliotrope cyanosis around the eye suggests a diagnosis of dermatomyositis. There is some evidence that the degree of nail fold capillary dilatation correlates with the severity of organ involvement [11], but this has not been confirmed [12]. Nail fold capillary abnormalities have been correlated with Raynaud's phenomenon, digital pitted scars and low finger temperature [13]. Using wide-field microscopy, the capillaries are enlarged and distorted. There is loss of capillaries with disruption of the capillary bed in approximately 90% of patients. These features may indicate those patients with Raynaud's phenomenon who will go on to develop systemic sclerosis [14,15], but do not distinguish between different connective tissue diseases [16]. Transient nodules resembling erythema nodosum occasionally occur; the histology of these shows panniculitis and endarteritis.

Telangiectases varying from 2 to 20 mm in diameter, blanching on pressure and refilling from several different foci, occur in 75% of patients. They are found mainly on the face, lips, mouth, upper trunk and hands, but may extend as far as the upper thighs. These mat-like telangiectases are not absolutely diagnostic of systemic sclerosis. Pigmentation occurs in approximately 50% of the patients, most frequently on the face, and to a lesser extent on the legs, thighs, lower abdomen (Fig. 56.65), axillary folds and dorsa of the hands. Occasionally, the pigmentation is so gross as to lead to a suspicion of Addison's disease [17], and sometimes gives a mottled appearances. Dense warty pigmentation in the axillae can resemble acanthosis nigricans [18]. Leg ulcers occur in 40% of patients and are difficult to heal. Livedo reticularis [19] and small white areas of atrophie blanche develop around the ankles, even without ulceration. These features can occur in patients without hypertension. A case has been reported of large soft cystic lesions over the interphalangeal joints of both hands. Aspiration revealed mucoid material, and the histology suggested focal mucinosis [20]. Rarely, papular and nodular mucinosis may occur and may be a presenting feature [21]. Lesions resembling acrokeratoelastoidosis have been described [22].

Systemic sclerosis without skin involvement [1–4]. Although skin lesions and Raynaud's phenomenon usually precede systemic changes, there is no doubt that occasionally the situation is reversed. In these cases, diagnosis may be difficult until the disease has progressed further to give characteristic changes in other organs.

Calcinosis. Weber [1] described calcinosis in scleroderma long before Thibierge and Weissenbach [2], whose names are usually associated with the syndrome. Calcification in systemic sclerosis occurs most commonly (25%) in the fingers, especially on the palmar aspects of the terminal phalanges. It is less common than absorption of the phalanges, but sometimes occurs in the absence of any radiological bone change. Digital calcification is approximately 10 times as common in females as in males. Calcification also occurs in the soft tissues around the iliac crests, alongside the spine between the vertebrae, around the knees, on the dorsa of the feet and around the elbows. Occasionally, ulceration of superficial nodules occurs, with discharge of chalky material. Deposits tend to be of considerable size and less diffuse than the calcification seen in the muscles of healed dermatomyositis. Calcification may occur in the internal organs. A suggestion that warfarin may inhibit and reverse calcification requires confirmation [3].

Bone changes. Absorption of the terminal phalanges is a feature of both systemic sclerosis and Raynaud's phenomenon, but systemic sclerosis is the only condition in which phalangeal absorption is associated with calcinosis (Fig. 56.66) [1]. Approximately 70% of patients show absorption, which may be minimal and only involve one terminal phalanx, or be gross and involve several phalanges, including the middle or even proximal phalanges. An erosive arthropathy, with 'pestle and mortar' deformity of the distal interphalangeal joints, resembles that seen

Fig. 56.66 Systemic sclerosis: terminal absorption of the phalanges and calcinosis.

in psoriatic arthropathy [2]. It must also be distinguished from gouty arthritis [3]. Pain in the temporomandibular area and a grinding sensation on chewing may be associated with bone resorption of the angle of the mandible [4] and zygomatic arches [5]. Other bone changes in systemic sclerosis include an increased intraosseous deposition of calcium [6,7] and osteopoikilosis, a rare condition in which multiple small islands of dense bone occur at the epiphyses and metaphyses [8–10]. Osteolysis also occurs in the distal end of the radius and ulna, humerus [11], acromioclavicular joint, ribs and cervical spine [12]. Avascular necrosis of the head of the femur, presumably resulting from vasculitis, has been described [13,14].

Pulmonary involvement. Lung involvment predominantly represents diffuse pulmonary fibrosis associated with diffuse disease or pulmonary hypertension, which is more associated with limited disease or CREST syndrome [1]. Symptoms may develop only some time after the lung disease, so they are a poor predictor of lung involvment. Dyspnoea on exertion is usually the first symptom, and this may progress until the patient is distressed even at rest. Cough, usually without sputum, is also a common symptom, and may be troublesome at night, suggesting aspiration; haemoptysis is rare. Cyanosis and occasionally finger clubbing may occur in patients with severe involvement, and these signs may indicate cor pulmonale. Recurrent episodes of pneumothorax, pleurisy, pulmonary effusion and pneumonia are less common features. Considerable loss of weight may also be a prominent feature at this stage. The earliest change consists of diffuse reticular shadowing extending from the cardiac borders to the peripheral and basal parts of the lungs, usually in the lower lung fields. Sometimes, nodular changes are seen, and occasionally the apices are involved (Fig. 56.67). Cystic changes are frequent. The cysts are usually small, but if extensive the appearances are those of 'honeycomb lung'. Pneumothorax may occur [2]. Pulmonary calcification has rarely been reported [3,4], as has telangiectasia [5].

Fig. 56.67 Pulmonary involvement in systemic sclerosis: nodules are prominent, particularly in the upper zones, and there is some reticulation in the lower zones.

Pulmonary function is frequently abnormal when radiology shows no abnormality [6]. A sensitive test of pulmonary function is the estimation of diffusing capacity (transfer factor); this test is impaired in 75% of patients. The DL_{co} may give an indication of survival, if it is less than 40% there is a 10% 5-year survival, compared with 75% if it is greater than 40%. Pulmonary involvement is more frequent in more severe and rapidly progressing disease, especially in males [7], but occurs in the CREST syndrome [8], and may precede cutaneous changes [9]. The presence of antihistone and antitopoisomerase (Scl-70) are associated with pulmonary fibrosis [10]. Small-airway disease may precede measurable impairment of gas diffusion [11]. In severely affected cases, the vital capacity and maximum breathing capacity are both abnormal. Serial observations of pulmonary function may be helpful [12]. Pulmonary hypertension, sometimes severe, can occur, and does not necessarily correlate with tests of pulmonary function [1]. It is not yet possible to say whether impairment of pulmonary diffusion is caused by vascular changes or thickening of the alveolar wall and interstitial tissue. Pulmonary hypertension tends to be progressive and fatal, although new therapeutic options are available.

Lung radiography may be normal in the face of symptoms and abnormal lung function, so the investigation of choice for pulmonary fibrosis is high-resolution CT scan, which is non-invasive. One series showed that high-resolution CT was 24% more accurate than radiography in demonstrating minimal evidence of fibrosing alveolitis [13]. The role of bronchoalveolar lavage is still debatable, but in expert centres it may provide additional information.

Involvement of the gastrointestinal tract. Macroglossia has been reported [1]. The oesophagus is involved in approximately 75% of all patients and is the most frequent part of the gastrointestinal tract to be affected. Oesophageal manometry and radionuclide transit are better than radiography for showing motor abnormalities [2,3], although the changes are non-specific [4]. Although dysphagia is usually regarded as being the predominant symptom, this is not correct, as symptoms of oesophageal reflux are twice as common. The typical radiological appearance is that of an atonic dilated oesophagus, which contains air in the resting state (Fig. 56.68). Oesophageal dilatation and abnormal peristalsis do not necessarily occur together. Stricture of the lower end of the oesophagus occurs in just over 10% of patients, is not necessarily related to gastro-oesophageal reflux or hernia, and can occur without any symptoms of dysphagia. Dysphagia is much more commonly the result of loss of propulsive activity in the oesophagus, and may occasionally be related to candidal overgrowth [5]. Hiatus hernia occurs in approximately 25% of patients. It is important to remember that approximately four out of every 10 patients with radiological changes have no symptoms. Carcinoma of the oesophagus has been reported [6,7]. Occasionally, dysphagia may be localized to the neck because of thickening of the pharyngo-oesophageal muscles [8].

Oesophageal aperistalsis has been reported in SLE and Raynaud's syndrome [9,10], but whenever aperistalsis is found systemic sclerosis must be suspected. Diffuse spasm may be detected by oesophageal manometry in approximately 5% of patients with systemic sclerosis [11].

The stomach shows dilatation and lack of peristalsis in approximately 6% of cases. Involvement of the stomach may be more common in Asians [12]. Carcinoma of the stomach has been reported [13]. Bleeding can occur from telangiectasia in all parts of the gastrointestinal tract, especially the stomach [14]. Systemic sclerosis is one cause of gastric antral vascular ectasia—the so-called watermelon stomach, because of the striped appearance on endoscopy. Gastric bleeding may occur at any time and may precede other signs of systemic sclerosis [15].

The duodenum shows changes of dilatation and lack of peristalsis in approximately one-third of patients. This does not appear to be a result of excess collagen deposition [16]. The changes are most pronounced in the second and third parts. Duodenal ulceration has been reported, but is probably not significant in comparison with its incidence in the normal population.

Intestinal involvement is infrequently noted in patients who have no relevant symptoms, but colicky abdominal pain and abdominal distension, with a pattern of distended loops visible through the abdominal wall, together with diarrhoea or, alternatively, constipation, may lead to a clinical diagnosis of obstruction, and death may follow from paralytic ileus. Volvulus of the small intestine may occur [17]. There may be bleeding from telangiectases. Radiological changes consist of dilated loops of bowel, with impairment of peristalsis and segments of normal or narrowed intestine. Strictures are rare. Jejunal sacculation has been reported [18,19]. Radiological changes occurred in approximately 10% of patients in the Leeds series, but others [20] found changes in 57%. Intestinal motility studies may be useful in determining changes in the small bowel [21]. If the abdomen is opened, distended loops of bowel may be seen showing a blue-grey serosal surface with numerous dilated lacteals. Small intestine involvement, determined by jejunal biopsy, small bowel radiology and tests for bacterial overgrowth and malabsorption, occurs in 55% of patients [18].

Steatorrhoea, malabsorption of glucose, calcium, vitamin B_{12} and folic acid may occasionally occur. It is important to remember that malabsorption of one or more of these substances may occur in the presence of normal fat absorption. Osteomalacia or skin changes have not been seen as the result of malabsorption. Excessive enteric loss of protein is sometimes a feature [22]. There is evidence [18] that bacterial overgrowth in the intestinal lumen as a result of stagnation because of abnormal peristalsis is a major cause of malabsorption in systemic sclerosis, and this may be corrected by therapy with tetracycline. Intestinal permeability is normal [23]. Pancreatic function is abnormal in 15% of cases [24], and death may occur from pancreatic necrosis [25].

Pneumatosis cystoides intestinalis may complicate small intestine involvement [26]. Patients present with recurrent acute or subacute intestinal obstruction [27] and rupture of cysts can cause pneumoperitoneum [28]. Treatment with respiration of high concentrations of oxygen has been successful [29].

The colon is frequently involved. In the Leeds series it occurred in 43% of cases. The patients may complain of constipation or diarrhoea. The most striking radiological change is the presence of wide-mouthed diverticula, best demonstrated on post-evacuation roentgenograms (Fig. 56.69). They usually occur on the inferior surface of the transverse colon and in the descending colon, which may be dilated and atonic; occasionally, the appearance may resemble that of ulcerative colitis [30]. Perforation of colonic diverticula [31] may result in death from peritonitis. Volvulus has been reported [32]. Colonic telangiectasia with consequent iron-deficiency anaemia may occur [33]. The mucosa of the colon has been described as being pale, dry and rather rigid on sigmoidoscopy [34], but this must be very uncommon. Anorectal pressure measurements show abnormal motility in 74% of patients [35]; symptoms are very much less common. Rectal prolapse and faecal incontinence may result. Primary exudative ascites has been reported [36].

Hepatic involvement. The liver is usually normal in systemic sclerosis, although cirrhosis and portal hypertension are occasionally found. It is by no means substantiated that such fibrosis is caused by systemic sclerosis. Bleeding from oesophageal varices may occur [1]. Systemic sclerosis has been reported in 17% of patients with primary biliary cirrhosis [2,3]. Ascites can occur without liver disease [4].

Cardiac involvement [1,2]. The resting ECG is abnormal in approximately 50% of cases, and cold-induced changes also occur [3]; however, the changes may be the result of other causes. Abnormalities of rhythm occur and these include paroxysmal atrial tachycardia, atrial fibrillation and flutter. Partial or complete heart block is not uncommon. In addition to abnormalities of rhythm, ECG may show bifid P waves and T-wave changes, indicating atrial or ventricular myocardial involvement. The conduction system seems to be relatively spared in systemic sclerosis and the high incidence of conduction disturbances may be the consequence of damage to the working myocardium [4]. Dyspnoea may be present but pain in the chest is not a prominent feature. Pericardial involvement occurs and is usually asymptomatic [5]. Mitral valve prolapse occurs more frequently in a number of connective tissue diseases, including systemic sclerosis, than in normal controls [6]. Other valvular abnormalities are rare [7]. Coronary reserve is reduced [8]. General enlargement of the heart, left-ventricular hypertrophy or a triangular outline are the most frequent radiological abnormalities. Radionuclide scanning [9], echocardiography [10], and 24-h ECG monitoring [11] are useful in the detection of abnormalities of the myocardium.

Renal involvement. Pathological changes in the kidney used to lead frequently to serious clinical problems, but the management of hypertension, and in particular the introduction of modern drugs such as inhibitors of angiotensin-converting enzyme (ACE), have revolutionized this aspect of the disease. Slight proteinuria is considered to be the most common clinical feature, often early in the disease. Proteinuria occurred in 36%, hypertension in 24%, azotaemia in 19% and malignant hypertension in 7% of one series [1]. One or more markers were found in 45% of patients. Approximately 40% of patients show dis-

turbances of creatinine clearance. Nephrotic syndrome is increasingly rare [2]. Approximately 8% of patients with renal involvement develop malignant hypertension [3]. This may develop rapidly in the course of a few weeks, with headaches, nausea, vomiting and deterioration of vision in a patient whose renal function has previously been normal. Prior to 1971, survival beyond 1 year was unusual, the usual survival being 1–3 months. The prognosis, even with renal crisis, has improved dramatically since the introduction of ACE inhibitors (see p. 56.114). Although renal involvement has an adverse effect on survival in systemic sclerosis, patients with mild impairment of renal function may live for years.

Muscle involvement [1,2]. Muscle weakness may occur, and differentiation from dermatomyositis may be difficult, especially if there is a heliotrope appearance and oedema of the eyelids, and dilatation of the nail fold capillaries. In one series [3], the two diseases could not be distinguished in 36 of 727 patients. Muscles of the forearms and hands are affected as well as the proximal muscles. Creatine phosphokinase elevation and excessive creatinuria correlate well with muscle weakness. Electromyography is abnormal in 50% of patients early in the disease and in 93% in late stages [4], and histological changes are present in approximately 40%. MRI and spectroscopy can be useful non-invasive monitors of disease activity [5]. There does not appear to be any evidence that systemic sclerosis occurs as a cutaneous marker of internal malignancy, although carcinoma of the lung may develop in patients with pulmonary involvement [6].

Tendon involvement. Leathery, palpable and audible friction rubs occur over the limbs and tendons [7] in approximately 25% of cases. Rupture of the extensor tendons of the hand has been reported [8]. The tendon was infiltrated with amyloid.

Joint involvement [1–3]. Arthritic pain is not uncommon in the early stages of systemic sclerosis, and sometimes rheumatoid arthritis is the initial diagnosis made. Radiological changes indistinguishable from rheumatoid arthritis occur, especially in the hands, but there are no specific changes ascribable to systemic sclerosis. They include periarticular osteoporosis, joint-space narrowing, erosions and, rarely, avascular necrosis [4], erosions of long bones [5], bone ankylosis [6] and erosive osteoarthritis.

Dental changes (see Chapter 66) [1]. Widening of the periodontal membrane because of fibrosis, with thickening of the vessel walls, occurs in approximately 30% of cases (Fig. 56.70). Usually the whole root is involved. Anterior

Fig. 56.70 Widening of the periodontal membrane in systemic sclerosis.

as well as posterior teeth are affected, and the lamina dura may or may not be abnormal. Thickening of the periodontal membrane is not related to the duration of Raynaud's phenomenon, calcinosis, involvement of internal organs, antinuclear factor or prognosis. Thickening of the periodontal membrane is not diagnostic of systemic sclerosis and is also found in periapical infection. Widening of the periodontal membrane in only one tooth is usually a result of such infection.

Osteolysis of the mandibular angle and coronoid process occurs with equal frequency [2], and these osteolytic areas may fracture [3]. A patient who had multiple external and internal root resorptions for which all the teeth were removed was successfully treated with osseointegrated implants [4].

Central nervous system [1,2]. The nervous system is involved in fewer than 10% of cases [3], although asymptomatic involvement may be more common [4], and others have found involvement in 40% of patients, which can be associated with ulceration of the skin [5]. Neuropathy has been reported [6,7]: autonomic neuropathy may not be uncommon [8,9]; trigeminal neuropathy presents with numbness and pain in the face [10], and occurs in 4% of patients [11]. Of 22 cases with chronic trigeminal sensory neuropathy, nine had systemic sclerosis [12]. It is unilateral at first but later becomes bilateral. Other cranial nerves may be involved [13]. Carpal tunnel syndrome and meralgia paraesthetica may occur. Local anaesthetics may have an abnormally prolonged action [1]. Subacute combined degeneration is the result of vitamin B_{12} deficiency caused by malabsorption secondary to involvement of the small intestine by systemic sclerosis [14]. Spinal cord compression may occur because of soft-tissue calcification [15]. The EEG is not specific. Sensory chronaxia is prolonged in both abnormal and normal skin. Such prolongation in normal skin does not occur in any other condition apart from tabes dorsalis [16]. Impotence has been reported as an initial manifestation of the disease [17,18].

Eye changes. Tightness of the lids, diminished tear secretion, keratoconjunctivitis sicca and shallow fornices are specific ophthalmic changes [1]. Sjögren's syndrome occurs in 15% of cases. Retinopathy, with haemorrhages, exudates and cytoid bodies may occur with a relatively low blood pressure, and has been attributed to direct vascular involvement by systemic sclerosis [2]. Fluorescein angiography shows vascular abnormalities in the choroid in 50% and in the retina in 10% of patients [3]. Central retinal vein occlusion has been reported [4].

Laboratory investigations. Anaemia may be found in patients with renal failure, gastrointestinal bleeding or malabsorption. The ESR is raised in approximately half of patients, as is the serum globulin level. Elevation of gammaglobulin occurs more frequently than elevation of α_2-globulin. Other acute-phase reactants are usually normal, although there are defects in the acute-phase response

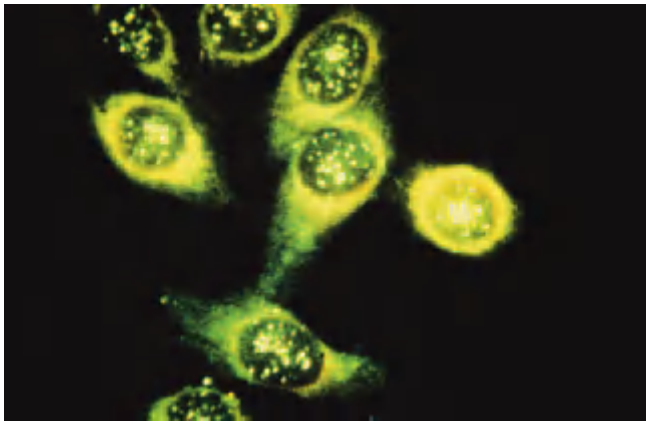

Fig. 56.71 Anticentromere antibody demonstrated on Hep-2 cells.

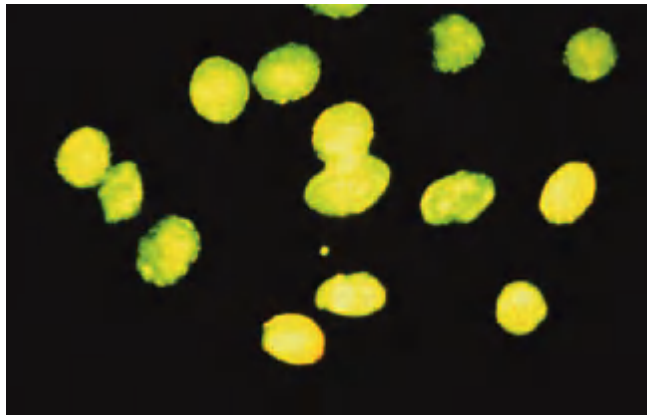

Fig. 56.72 Scl-70 antibody demonstrated on Hep-2 cells.

to some stimuli [1]. False-positive serology occurs in approximately 5%. Cold agglutinins may be found in 25% of cases. The Coombs' test is usually negative, although Coombs'-positive haemolytic anaemia and pancytopenia have been reported [2]. Circulating anticoagulant has been demonstrated in one case [3], but was not found in 24 patients at Leeds [4]. Anticardiolipin antibodies are found in 25% of cases overall, and occur more frequently in those severely affected [5]. Cryoglobulins are only rarely detected. Cryofibrinogenaemia has been held responsible for ulceration and gangrene of the fingers in some cases. Rheumatoid factor is present in approximately 30% of patients. Serum complement levels are usually normal. LE cells may be demonstrated in 8% of patients. Sometimes, SLE may occur in association with systemic sclerosis [6,7], but the presence of LE cells in systemic sclerosis does not necessarily imply coexistent SLE. Antinuclear antibodies have been demonstrated in 78% of patients using rat liver [8], and in 97% using Hep-2 cells [9] as substrate. Using Hep-2 cells, both speckled and homogeneous types occur, and nucleolar patterns—speckled, homogeneous and clumpy—are demonstrated more frequently than in other diseases. Centromere staining, resulting from an antibody that reacts with the kinetocore of metaphase chromosomes, occurs in 40–70% of milder (or CREST) cases [9,10] who have longer duration of disease and little renal involvement (Fig. 56.71). Anticentromere antibodies may be present in patients with Raynaud's phenomenon before the clinical features of systemic sclerosis appear. They seem to be indicative of a favourable prognosis [11]. They also occur in 6% of patients with SLE (including drug-induced lupus) [12], 6% of patients with mixed connective tissue disease, 17% of patients with primary biliary cirrhosis and systemic sclerosis [13], 11% of patients with primary biliary cirrhosis alone and 5% of patients with morphoea [14]. A diffuse 'frosted glass' staining of nuclei of Hep-2 cells is caused by Scl-70 antibody, a precipitating antibody to topoisomerase I, which is unique to systemic sclerosis and occurs in approximately 20% of patients, particularly those with lung involvement (Fig. 56.72) [10,15]. Higher frequencies are described, even in patients with acrosclerosis alone [16]. Scl-70 and anticentromere antibody occur together in 5% of cases [17], but when occurring alone may define separate subsets of the disease. There is no relationship between Scl-70 and disease survival [18]. Scl-86 is a related antigen [19]. Other antibodies occur, presumably indicating immunological subsets, and include antibody to centriole [20,21], anti-Jo-1 [22] and anti-Ro/SS-A [23]. More intensive investigation of autoantibodies may reveal additional subsets of the disease [24]. Several patterns of nucleolar staining have been described [25]. A homogeneous pattern was associated with polymyositis/scleroderma overlap, a clumpy pattern with diffuse cutaneous systemic sclerosis and a speckled pattern with localized cutaneous systemic sclerosis. Anti-DNA antibodies are not found [26]. Anti-IgE antibodies occur [27]. Other precipitating antibodies to saline extracts of human tissue [8] may be found in 15% of patients. Anti-smooth-muscle and antiendothelial antibodies have been reported [28,29]. Antineutrophil cytoplasmic antibodies occur in 9% [30] and antihistone antibodies in 42% [31]. The latter was more frequent in patients with cardiac and renal involvement. Serum type III procollagen peptide concentrations are raised and reflect disease activity [32,33]. Urinary excretion of 5-hydroxyindole-acetic acid is normal, as is thyroid function.

Variations. Patients with calcinosis, Raynaud's phenomenon, sclerodactyly and telangiectasia may form a separate entity known as CRST syndrome [1], or CREST syndrome if oesophageal (esophageal) involvement is included. This is unlikely to be a separate syndrome, distinct from systemic sclerosis [2]. The variability of expression and course of the authors' series of patients with systemic sclerosis suggests that this type of case is only a subgroup of systemic sclerosis. This has been confirmed by other workers [3,4]. However, the delineation of this group of patients emphasizes that the diagnosis of systemic sclerosis does not always imply such a poor prognosis as has hitherto been considered.

The suggestion that 'systemic scleroderma' should be divided into two groups—diffuse scleroderma and acrosclerosis—remains to be confirmed [5]. The former, a relatively small group, can be distinguished from acrosclerosis in that the sex distribution is equal, the age of onset is later, Raynaud's phenomenon is absent, cutaneous sclerosis is the usual presenting feature, the sclerosis of the skin is usually generalized rather than acral, and the course is more rapid and fulminating, with death in a few years. However, both types show similar visceral involvement and laboratory abnormalities, and some patients with acrosclerosis have a short course, and Raynaud's phenomenon is not invariable. Occasionally, acute diffuse scleroderma may be much more benign than expected [6]. These two groups are probably clinical variants of systemic sclerosis. A more recent attempt at subdivision of the disease into diffuse and localized forms has met with more agreement (see p. 56.95) [7].

Systemic sclerosis in childhood. Systemic sclerosis occurs in childhood, and the clinical features resemble those seen in adult cases. Raynaud's phenomenon is less frequent and renal disease is rare [1]. The course of systemic sclerosis in childhood is said to be slower, and the disability and visceral involvement less severe than in adults [2], but fatal cases have been reported [3]. The problem has been reviewed in depth [4].

Involvement of the genital tract [1]. Vaginal dryness, ulcerations and dyspareunia are significantly more frequent in patients with systemic sclerosis when compared with controls. Frequency of sexual intercourse and sexual satisfaction is decreased, and the menopause may be early.

Pregnancy [1]. Systemic sclerosis usually remains unchanged during pregnancy, but postpartum renal failure and peripheral gangrene have been described [2]. Severe renal, pulmonary or cardiac disease in the mother may be an indication for termination of the pregnancy [3], and such complications may occur late in pregnancy. ACE inhibitors may be of value for hypertension in pregnancy, although there are potential risks to the fetus [4]. There is conflicting evidence regarding the incidence of abortion and stillbirth [5,6]. Fertility may be impaired.

In some cases, pregnancy seems to precipitate the disease.

Associations. Sometimes, systemic sclerosis occurs in association with other conditions, particularly those considered to have some autoimmune features. Usually, it is possible to differentiate between the diseases, but occasionally there is clinical and immunological overlap. The relationship to SLE and dermatomyositis has already been mentioned. Immunohistology of involved and uninvolved skin is of value. Sjögren's syndrome, the most common features of which are dryness and atrophy of the conjunctiva, cornea and buccal mucosa, together with arthritis, occurs with systemic sclerosis in approximately 17–20% of patients [1,2], and resembles the primary form of Sjögren's syndrome [3]. Extensive investigation reveals at least one abnormal test of the sicca syndrome in all cases [4]. Salivary flow is normal, but deficient in IgA [5]. Antibodies to Ro and La are useful markers of the presence of Sjögren's syndrome in systemic sclerosis [6], occurring in 60% of cases [7]. Other muscle disorders that have been reported in association with systemic sclerosis include polymyositis [8], myasthenia gravis [9] and muscular dystrophy [10]. Pathological features of systemic sclerosis are sometimes found in patients with polyarteritis nodosa [11–13], but there is not the same clinical or immunological overlap as seen with SLE. Temporal arteritis has been reported [14,15], and the condition has also occurred with malignant atrophic papulosis (Degos' syndrome) [16], thrombophlebitis and cryofibrinogenaemia. The association with Hashimoto's thyroiditis is rare. Unsuspected hypothyroidism may occur [17]. Systemic sclerosis is one of the disorders that are sometimes associated with congenital agammaglobulinaemia and IgA deficiency [18]. It may occur with autoimmune haemolytic anaemia [19], autoimmune neutropenia [20], thrombocytopenic purpura [21], microangiopathic haemolytic anaemia [22], urticaria pigmentosa [23], pemphigus vulgaris [24], monoclonal gammopathy [25], primary biliary cirrhosis [26,27], nodular hyperplasia of the liver [28], coeliac disease [29], pseudoxanthoma elasticum [30], elastosis perforans serpiginosa [31], lymphoma [32] and multiple sclerosis [33]. Reversible myasthenia gravis may occur on treatment with penicillamine [34].

Differential diagnosis. Well-developed cases of systemic sclerosis presenting with Raynaud's phenomenon and typical cutaneous changes on the face and hands are easy to recognize. Generalized morphoea may sometimes cause confusion. However, Raynaud's phenomenon is less common in the latter, and the distribution of the skin changes is different in so far as generalized morphoea involves the trunk, as well as the limbs. Systemic involvement is unusual, although not unknown, and the course is usually towards improvement over the years.

Localized morphoea should present little difficulty, although occasionally morphoeic patches may be seen in systemic sclerosis, and systemic lesions may occasionally be found in morphoea [1–3]. Sometimes, patients with localized morphoea may later develop systemic sclerosis. Morphoeic lesions were seen in 6.7% of Japanese patients with systemic sclerosis [4]. Patients with atrophoderma of Pasini and Pierini may progress to systemic sclerosis [5]. Acrosclerotic skin changes occasionally occur in SLE and dermatomyositis. Cold blue hands with inability to extend the fingers has been reported in bisalbuminaemia [6]. The pigmentation of systemic sclerosis may be confused with Addison's disease [7,8]. Cutaneous changes resembling systemic sclerosis have been reported in an unusual type of porphyria with features of erythropoietic protoporphyria and hepatic cutaneous porphyria [9]. A case of primary amyloidosis presenting as scleroderma has been described [10]. There is no Raynaud's phenomenon in familial sclerodactyly [11].

The stiff-skin syndrome [12] or congenital fascial dystrophy [13] is a rare condition presenting in childhood, in which stone-hard indurations of the fascia and dermal collagen occur. There is no systemic involvement, and the resulting disability is permanent. Patients with sclero-myxoedema—a variant of lichen myxoedematosus—may resemble systemic sclerosis but there is no Raynaud's phenomenon or systemic involvement apart from the characteristic slow paraprotein in the serum. The POEMS (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M* protein, *s*kin changes) or Crow–Fukase syndrome also shows a monoclonal paraprotein among a large number of potential features, including diffuse hyperpigmentation, scleroderma, hypertrichosis and lymphadenopathy, as well as the features indicated by its acronym. Of these patients, 50% have multiple myeloma [14]. Differentiation from systemic sclerosis relies on the presence of neuropathy and gammopathy [15,16].

Raynaud's phenomenon, firmness of the skin of the fingers, radiological absorption of the terminal phalanges and thickening of the walls of dermal arteries occur in workers engaged in the polymerization of vinyl chloride (see p. 56.82). The cutaneous changes of systemic sclerosis may resemble acrogeria (see Chapter 46), but the latter dates from birth. The condition may have to be distinguished from leprosy if a peripheral neuropathy is present [17]. Up to 40% of insulin-dependent juvenile diabetics have contractures at the proximal interphalangeal joints, with thickening of the skin of the fingers (diabetic cheiroarthropathy) [18,19].

Prognosis [1–3]. The prognosis for this disorder is variable. Some patients die within a year or two and others live for many years, even those whose course may initially have been rapid with gangrene of the extremities. Males have a poorer prognosis than females [2,3], although in a recent series [4] the reverse was true. Overall, there is a fourfold increase in mortality in patients with systemic sclerosis. Patients with extensive skin and visceral involvement have a poorer prognosis [5], as do approximately 20% with rapidly progressive disease [6]. Pulmonary involvement is permanent; patients with 60% or greater reduction in pulmonary diffusing capacity have a 5-year survival of less than 10% [7]. Renal involvement is also an adverse factor, although some patients live for years. Patients with telangiectases and calcinosis have the same prognosis as other patients. Those with changes confined to the hands have a good prognosis [8]. Five-year survival varies between series from 34 to 80%, the difference probably depending on the proportion of females. Cumulative survival rate in one series [9] was 80% at 2 years, 50% at 8.5 years and 30% at 12 years. There is no relation to the presence or type of antinuclear factor. Patients with depression of T cells and decreased cell-mediated immunity [10], and with histocompatibility type HLA-B8, appear to have extensive disease and a poor prognosis [11]. The usual causes of death are from intercurrent infection, respiratory failure, cardiac failure, renal failure sometimes with malignant hypertension, and perforation of the gastrointestinal tract. Occasionally, patients with pulmonary involvement develop carcinoma of the lung [12], but the association of isolated cases of carcinoma of the thyroid, ovary, cervix, brain, oesophagus, stomach, breast [13], lymphoma and leukaemia with systemic sclerosis may be fortuitous [14]. Occasionally, the two diseases occur simultaneously and a rare improvement of systemic sclerosis with treatment of the malignancy has been observed [15]. Localized radiotherapy for solid malignant tumours in patients with systemic sclerosis has been noted to exaggerate the cutaneous and internal fibrotic reaction in the irradiated areas [16].

Treatment. Symptomatic management of the patient is very important. There is no specific treatment, and no therapy is known to alter the course of the disease. Corticosteroids in low dosage may give a feeling of increased well-being and reduction of articular symptoms, and in these cases maintenance on a low dosage of prednisolone, such as 5 mg once or twice daily, is justified. Larger dosage will be required for patients with associated LE. There is no evidence that corticosteroids retard the progress of the disease in any way, nor is there any real evidence that corticosteroids induce the onset of renal failure. Dexamethasone pulse therapy has been claimed to improve some patients [1]. It is important to advise the patient to keep as warm as possible, particularly in the winter months, and suitable work may have to be found

to allow this. A light job in a warm atmosphere is ideal, and it is important to avoid even minor trauma of the hands. Electrically heated gloves are helpful [2], except in patients with incipient gangrene. Smoking should be discouraged [3]. There is no specific therapy for the skin, but applications of 0.025–0.05% tretinoin (Retin-A) have decreased perioral and facial tightening and creases [4]. Areas affected by calcium deposits may break down and heal with difficulty. Occasionally, deposits may have to be excised [5]. These techniques may be superseded by treatment with the carbon dioxide laser [6]. Treatment of digital calcinosis was successful in approximately two-thirds of cases. The average healing time was 6 weeks. Reconstructive surgery for sclerodactyly has sometimes given satisfactory results [7].

Vasodilators, such as oral reserpine [8], guanethidine [9], and particularly nifedipine 10–20 mg four times daily [10,11] and diltiazem [12], may improve the blood flow in the fingers. Ketanserin 20 mg twice daily to 40 mg three times daily may [13] or may not [14] be useful. Nifedipine may worsen oesophageal symptoms [15]. Prazosin 1 mg orally three times daily reduces the frequency and severity of vasospasm [16]. Simply warming the hands in hot water for 5–10 min produces considerable improvement in peripheral blood flow [17], and regular use of such a technique reduces the number and severity of attacks of Raynaud's phenomenon [18]. Intra-arterial reserpine is ineffective, and may have serious side effects [19]. Prostacyclin [20,21] and the synthetic prostacyclin analogue iloprost [22] are potent vasodilators and inhibitors of platelet aggregation, and have been found to be effective in decreasing the frequency, duration and severity of Raynaud's phenomenon, warming the hands, relieving pain and healing ischaemic ulcers. Earlier reports of the effect of prostaglandin E_1 have not been confirmed [23]. Infusion of prostacyclin via a central venous catheter over 72 h at a rate of 2.5–10 ng/kg/min produces improvement for approximately 8 weeks. Side effects include hypertension, headache, facial flushing, abdominal colic, nausea, vomiting and diarrhoea, and pain at the angle of the jaw at the beginning of mastication, disappearing within minutes. Similar results have been obtained by 5-h intravenous infusions given weekly for 3 weeks through a peripheral vein [24], a procedure that can be carried out on outpatients. Iloprost is useful in cases of incipient gangrene and digital ulcers [25]. Transdermal applications of these agents may be beneficial [26].

The use of intravenous low-molecular-weight dextran (Rheomacrodex) has been advocated [27], but controlled trials [28] have shown no consistent benefit, although in occasional patients there is healing of ulcerated fingertips. Renal failure and oliguria have followed this treatment [29]. Intravenous pentoxifylline may be of benefit in acute ischaemic lesions [30]. Cervical or lumbar sympathectomy may produce some improvement in the cutaneous circulation for a year or two, but there is no lasting benefit.

Penicillamine in regimens of from 500 to 1500 mg/day (mean 750 mg) given over approximately 2 years may decrease skin thickness, reduce the rate of further visceral involvement and improve the prognosis of patients if given early in their disease [31,32], particularly those with pulmonary involvement [33]. Other authors have found no benefit or no improvement in vascular or systemic complications, even if there is limited skin improvement [34]. In particular, progression of oesophageal disease continues [35]. Penicillamine therapy is associated with troublesome side effects [36]. In one study [37], the skin of 32% of patients improved but deterioration occurred in the same percentage. In patients known to be sensitive to penicillin, the risk of an immediate allergic reaction is low [38]. Colchicine (1 mg/day or higher for 6 days per week) has also been advocated [39], but found to be ineffective [33]. Isotretinoin in a dosage of 1 mg/kg may help cutaneous sclerosis [40], as may factor XIII given intravenously [41]. Plasmapheresis [42] and plasma exchange [43] combined with prednisone and cyclophosphamide have been used for patients with severe systemic sclerosis [42], with some clinical improvement and reduction of endothelial cell cytotoxicity. Extracorporeal photochemotherapy is encouraging but expensive. It has been shown to be more effective than penicillamine in decreasing clinical skin involvement and also safer in patients with disease of less than 4 years' duration [44]. Patients were treated for two consecutive days every 4 weeks for 6 months. It may be insufficient to control severe progressive disease with systemic involvement [45] and its use is controversial [46]. Azathioprine in a dosage of 150 mg/day has been subjectively helpful in approximately one-third of cases. Chlorambucil by mouth does not halt the progression of systemic sclerosis [47,48]. Intravenous 5-fluorouracil, given intermittently for 6 months, improved cutaneous and systemic features in an uncontrolled trial [49].

Ciclosporin may be of benefit [50,51]. It may improve skin induration but not visceral manifestations; adverse reactions, particularly nephrototoxicity, are frequent [52]. IFN-γ influences fibroblast behaviour *in vitro* [53]. It has reduced the skin score and improved blood gas analyses without any adverse effects over 12 months' therapy, but other systemic involvement was unchanged [54]. Others have noticed no alteration in skin score or improvement in visceral involvement [55]. IFN-α2a has also failed to improve visceral involvement [56]. Antithymocyte globulin is ineffective [57].

Symptomatic treatment for cardiac, renal and gastrointestinal symptoms may be required. Antihypertensive drugs, including minoxidil, reduce the blood pressure in malignant hypertension [58,59], and captopril, an oral ACE inhibitor, is a considerable advance in its treatment [60,61], as in most cases there is elevation of plasma renin

activity. It controls blood pressure in most, if not all patients and relieves encephalopathy. It can improve renal function and, if given early, prevents renal failure and death. Improvement in renal function over 2 years has been reported [62], but is not uniform [63]. There is little evidence for a more general improvement in the disease resulting from these agents [64]. Benefit must be weighed against side effects. Haemodialysis and renal transplantation have helped patients with renal failure, with surprising improvement in the renal function and cutaneous manifestations [65]. Recovery of renal function can occur after months of dialysis. In one case, renal biopsy 14 months after transplant showed no evidence of the original disease [66]. Cimetidine or ranitidine are worth trying for the symptoms of oesophageal reflux. Gastrostomy may be required for short-term feeding difficulties if dysphagia is severe [67]. Stricture of the oesophagus may benefit from surgical intervention [68]. Although the diffusion defect in the lungs cannot be altered, patients benefit from breathing exercises, and chest infections must be treated energetically with antibiotics. Pulmonary hypertension is a serious complication that may be treated with bosentan [69].

Many other preparations, including relaxin, Salazopyrin, 3-hydroxy-2-phenylcinchoninic acid (HPC), antihistamines, dihydrotachysterol and nicotinic acid, potassium *p*-aminobenzoate [70,71], intravenous disodium edetate, topical dimethyl sulfoxide [72], the combination of phenformin and ethylestrenol [73], and antiplatelet therapy [74] have not proved of benefit. Hyperbaric oxygen may occasionally produce some improvement [75]. Calcitriol 1.75 μg/day may be helpful [76]. Dietary essential fatty acids such as γ-linolenic acid do not improve the vascular or other features [77].

Migraine sometimes occurs with systemic sclerosis [78], and methysergide or drugs containing ergot should not be given to such patients.

Mixed connective tissue disease [1]

Overlap syndromes occur in the connective tissue diseases, and have recently been reviewed [1]. A number of attempts at defining diagnostic criteria, along the lines of those used for SLE, have been made with varying degrees of success [2]. Some associations are more frequent than others. For example, systemic sclerosis combined with dermatomyositis is more frequent than systemic sclerosis combined with SLE [3]. Some of these patients may have so-called 'mixed connective tissue disease', an entity associated with a specific antibody to U_1-RNP, an ENA first described by Sharp and colleagues in 1972 [4]. These patients, predominantly female, show features of SLE, systemic sclerosis, dermatomyositis and polymyositis. Raynaud's phenomenon, arthritis and arthralgia, sausage-shaped fingers and swelling of the dorsa of the hands, abnormal oesophageal motility, impaired pulmonary diffusing capacity and myositis are frequent. More than half have the abnormal nail fold capillaries seen in systemic sclerosis. Angiography shows obstruction of small blood vessels in almost 90% of cases [5]. Occasionally, vascular disturbances may be severe, with peripheral gangrene (Fig. 56.73) [6]. The incidence of clinical renal disease is only approximately 5% [7], but renal histology is abnormal in 20% [8]. Aseptic meningitis, trigeminal neuropathy, transverse myelitis and psychosis are prominent neurological features. Neuropsychiatric manifestations were noted in 15% of one series [9]. Rarely reported features include orogenital ulceration [10], pneumatosis intestinalis [11], protein-losing enteropathy [12] and autonomic neuropathy [13]. Enlarged nodes of Kikuchi's disease were the presenting feature in one case [14].

The response to treatment with corticosteroids is good [15], and this includes both skin and pulmonary involvement that may be severe [16]. The characteristic antibody may be suppressed by treatment, and disappears in patients in remission [17].

Fig. 56.73 Gangrene of the hands in mixed connective tissue disease.

Mixed connective tissue disease may be more severe in children, in whom cardiac and renal disease and arthritis are common, and thrombocytopenia may be marked [18], although the overall prognosis may be quite good [19]. Thrombocytopenia is also occasionally found in adult cases [20], and may occur with thrombotic thrombocytopenic purpura [21]. Statistically there is an increased risk of mixed connective tissue disease after silicone breast implants [22], but others have not found any association between breast implants and connective tissue disease [23]. Livedoid vasculitis [24], ankylosing spondylitis [25] and anti-neutrophil cytoplasmic antibody (ANCA)-related glomerulonephritis [26] are reported to occur with mixed connective tissue disease .

Immunology. All patients have the speckled type of antinuclear antibody together with a high titre of antibody to ENA, which is sensitive to digestion with ribonuclease (RNase), unlike the ENA antibodies often found in patients with SLE. Different molecular forms of U_1-RNP may be associated with different clinical variants [27]. Ro and La antibodies are also frequently found, usually in association with sicca symptoms [28,29]. Precipitating antibodies designated PM-1 [30] and Ku [31] occur in polymyositis/systemic sclerosis overlap, and SL-Ki in patients with SLE, scleroderma and the sicca syndrome [32]. Immune complexes occur in 90% of patients, and T cells are decreased. Complement levels are normal. Sometimes, anti-DNA antibody occurs in low titre, but this usually disappears with steroid therapy. There may be local, rather than generalized antibody production (e.g. in the pericardium in cases of pericarditis [33]). Antiendothelial antibodies occur in approximately 50% of cases, and are associated with abnormal pulmonary, neurological and cardiac function. They are also related significantly to spontaneous abortion in female patients [34]. HLA-DR4 is found more commonly in patients with arthritis than in normal controls, and is associated with a young age of onset of the condition [35]. There are also reports of familial cases [36]. Differences in HLA antigens between patients with mixed connective tissue disease and SLE indicate that they are genetically separate disorders [37].

Immunohistology may be helpful in distinguishing this condition from uncomplicated systemic sclerosis [38]. Immunoglobulin, particularly IgM or IgG, is present at the basement membrane of uninvolved skin [39], and this is in contrast with systemic sclerosis in which there is no basement-membrane immunofluorescence of lesional or non-lesional skin. However, the fluorescent band test cannot distinguish mixed connective tissue disease from SLE.

Direct immunofluorescence study of apparently normal skin reveals particulate ('speckled') epidermal nuclear staining, and this correlates with high titres of anti-RNP. Occasionally, epidermal nucleolar staining occurs. Clinically, patients with these features [40] show a high incidence of persistent, diffuse, non-scarring and focal alopecia, hyper- and hypopigmentation with follicular retention of pigment, swollen hands with sclerodactyly, and lesions of DLE.

Although the presence of anti-RNP is usually associated with a good prognosis, death occurs in approximately 4% from pulmonary hypertension, brought about by vascular changes similar to those seen in primary pulmonary hypertension [41], nephritis, myocarditis or widespread vasculitis. Other authors [42] noted that 25% developed into systemic sclerosis, 25% into SLE and a few patients with HLA-DR4 developed rheumatoid arthritis. In patients whose disease differentiated into systemic sclerosis, there was an association with HLA-DR5. These authors suggest that mixed connective tissue disease is frequently only an intermediate stage in a genetically determined progression. Those whose disease continues unchanged may be a distinct subset. Patients with a high titre of anti-RNP appear to have an increased risk of developing mixed connective tissue disease [43]. The relatively good prognosis has been confirmed recently [44].

With time, more variants of the overlap syndromes are being described, both with and without U_1-RNP antibody. Hence, some authors now regard mixed connective tissue disease as one among many 'undifferentiated connective tissue diseases' or 'overlap syndromes'. Doubts about the concept of mixed connective tissue disease have been expressed, particularly in children [45]; nevertheless, it is important to recognize this group of patients because of the good prognosis and the response to steroid therapy. There may be an increased risk of malignancy, with cancer developing in 10% of cases [46].

Cold, flexed fingers (Fig. 56.74)

Several female patients have been seen with cold, flexed fingers, but no evidence of systemic abnormality, despite extensive investigations including pulmonary function

Fig. 56.74 Cold flexed fingers: note the inability to extend the fingers fully.

tests. The presenting feature of inability to extend the fingers fully starts in the second to fourth decades. There may be difficulty in flexion of the fingers and in making a fist. All have thin, cold fingers, but there is no evidence of acrosclerosis, and Raynaud's phenomenon is not invariable. The condition remains unchanged for years and is not influenced by vasodilators or systemic corticosteroids.

Some patients may be early cases of systemic sclerosis. One patient has developed rheumatoid arthritis, with deformities of the hands.

The condition was first described in the first edition of this textbook in 1968 [1]. It appears to be similar to what has been termed 'bowed fingers' [2]. Some patients with bowed fingers had features of systemic sclerosis or mixed connective tissue disease.

Lichen sclerosus [1,2]

SYN. LICHEN SCLEROSUS ET ATROPHICUS; GUTTATE MORPHOEA; GUTTATE SCLERODERMA; WHITE-SPOT DISEASE

Definition. An uncommon disease of unknown aetiology in which characteristic, easily recognized, small, white, sclerotic areas occur at any site on the skin. This frequently involves the perineal skin in the female, and the penis and foreskin in the male. It may occur in genital and non-genital skin separately or together. Hallopeau [3] first described the condition in 1887, and Darier [4] reported the histological changes in 1892. They considered the disorder to be a type of lichen planus; others thought that the condition was related to circumscribed scleroderma. Most people now regard lichen sclerosus as a separate entity, because of the distinct clinical signs and pathological changes, but this point remains unclear. The term 'white-spot disease' is sometimes applied to the skin lesions on the trunk and limbs, although some authors refer to these lesions as 'guttate scleroderma'. It may be closely related to morphoea, as the two conditions can occur together and, rarely, morphoea can produce similar genital lesions [5]. White-spot disease has been reported with systemic sclerosis [6].

Incidence. The condition is an uncommon one. Females predominate; one series [7] consisted of 38 females and five males. In Wallace's [8] series of 359 patients, females outnumbered males by 10 : 1. Wallace and Whimster [1] found that in the vulva, lichen sclerosus was as common as leukoplakia and slightly more frequent than primary atrophy. With modern terminology, these figures are difficult to interpret. Approximately 20% of their patients with lichen sclerosus of the vulva had lesions on the trunk. Certainly, involvement of the vulva, perineum and perianal skin in females is more common than balanitis xerotica obliterans, which is the corresponding lesion in the adult male. The condition occurs particularly around and after the menopause, but also occurs in girls between the ages of approximately 1 and 13 years. The disease is not uncommon in boys with phimosis [9], and the incidence is probably underestimated. The mean age of onset in one series of cases [7] was 50 for females and 43 for males. The condition has been seen in mother and daughter, mother and son, brother and sister, and sisters and brothers, but not in father and son. It has occurred in monozygotic female twins [10] and in non-identical female twins [11]. It is uncommon in Bantu and in black people.

Aetiology. The aetiology is unknown, lesions usually appearing spontaneously without any precipitating factor. The predominance of females, the frequent onset around the menopause and the spontaneous improvement in girls after puberty suggest a hormonal factor, but no convincing causative factors have been identified. The increased prevalence of organ-specific antibodies and of associated autoimmune diseases in both female patients and relatives suggest an autoimmune cause, but there is no difference in the natural history of those with or without antibodies [12]. The incidence of other autoimmune diseases in patients is highest when the onset is between the ages of 41 and 60 years, but is not related to the site or duration of lesions. Once the diagnosis of lichen sclerosus has been established, patients do not seem to be at continued excessive risk of developing autoimmune diseases [13]. Approximately 50% of female patients will have a personal or family history of autoimmune disease [14]. Male patients also have an increased prevalence of autoimmune disorders and autoantibodies [15]. An increase in HLA-B40 in females has been reported [16] but not confirmed [17]. More recently, HLA-A29 and -B44 were found to occur more frequently, both separately and together [18], and the class II antigens DQ7, 8 or 9 were found to be present in 78% of patients [14]. In this last study, no HLA class I associations were found, although HLA-A2 was only found in patients with localized anogenital disease. In men, HLA-DR11, -DR12 and -DQ7 were found to be positively associated with the development of the disease, and the association with autoimmune disease is less marked [19].

A history of preceding vaginitis and, in the male, the limitation of genital involvement to the uncircumcised or very recently circumcised, who often give a history of chronic balanitis, suggests that infection may play a provocative or localizing part. Borrelial DNA has been found in skin biopsies, although there is no confirmed role for the organism in this disease [20]. There may be

geographical differences in the occurrence of *Borrelia*, with evidence of infection found in Germany and Japan but not in the USA [21]. The subject has been reviewed [22]. Vulval lesions are not related to parity. Trauma can also act as a precipitating factor, and lichen sclerosus has been reported in a vaccination site [23], in the area of radiotherapy following mastectomy [24], after severe sunburn [25], in an old burn scar [26], as a result of welding sparks [27] and at the site of a strawberry naevus [28].

Pathology. The striking histological change in lichen sclerosus is a band of hyalinization of the dermal collagen below the epidermis. The hyalinized tissue appears structureless and oedematous, and contains sparse cells, but may show dilated capillaries. The epidermis shows variable thickening, hyperkeratosis and follicular plugging. Later, the epidermis becomes thinned. A band of lymphocytic infiltration may also be seen below the hyalinized area: in older lesions this may be more scanty and focal. The subepidermal elastic tissue tends to be depressed and separated from the epidermis by oedema. The infiltrate contains lymphocytes staining with CD3, CD4 and CD8, as well as the macrophage marker CD68 [1], and HLA-DR^+ activated T cells associated with Langerhans' cells, which are increased in number [2]. There may be an expansion of specific T-cell clones in the skin, suggesting a specific antigen stimulus [3]. Many of the lymphocytes are $CD57^+$ [4]. Staining with HLA-DR can also be demonstrated on the surface of keratinocytes and around blood vessels. A decreased CD44 expression on epidermal cells may be related to hyaluronate deposition [5]. Androgen receptors are reduced [6]. Fibrillin, collagens I and III and elastin are all abnormal [7], and the distributions of tenascin, fibronectin and fibrinogen are abnormal [8].

In vulval lesions, secondary infection and superficial erosion are common, and may mask the primary changes. In lesions with sclerotic change, the epidermis shows marked thickening, irregularity and hyperkeratosis. The dermal oedema tends to regress and sclerosis and dense chronic inflammation occupy the subepidermal zone. These changes are seen in over half of all biopsies of vulval lichen sclerosus, and in two-thirds when there is itching [9]. They may occur in small areas, only a few millimetres in diameter, and be easily missed.

The condition must be distinguished from lichenification, in which the dermal papillae are prolonged and oedematous, with corresponding lengthening of the rete pegs. There is usually dermal oedema and epidermal spongiosis and parakeratosis. In primary atrophy of the vulva, the epidermis is thinned, the lower border is flattened and keratinization is normal or reduced. There is also a reduction in the elastic tissue, particularly in the superficial zone, but the collagen is unaltered. Immediately beneath the epidermis there is a band of chronic inflammatory cells. In leukoplakia, there is some degree of hyperplasia of the epidermis, with considerable irregularity in the outline of the deeper border, together with some hyperkeratosis. An inflammatory infiltrate occurs near

the deeper border of the epidermis. The collagen of the superficial part of the dermis shows hyaline changes and the elastic tissue is lost.

Electron microscopy has revealed striking changes in dermal collagen fibres and increased amounts of elastin [10]. Immunoglobulins (IgG, IgM, IgA), complement and fibrin may be demonstrated in the damaged skin. Immunohistology in balanitis xerotica obliterans is normal.

Clinical features. Lesions may occur in the following areas.

Non-genital lesions. The lesions on the skin are symptomless and occur on the trunk, particularly on the upper part and around the umbilicus, around the neck, in the axillae, on the flexor surfaces of the wrists (Fig. 56.75), around the eye and, very rarely, on the scalp, palms and soles [1]; they may be confined to the latter. They have also been described confined to the skin around the areolae [2]. Lesions can occur at sites of pressure (e.g. underneath bra straps or belts). The lesions are small, ivory or porcelain-white, shiny, round macules or papules, a few millimetres in diameter. Occasionally, they are semi-translucent and resemble mother-of-pearl. They may be very extensive, involving most of the trunk. Lesions may follow Blaschko's lines [3]. They are slightly raised, or level with the surface of the skin, and typically their surface shows prominent dilated pilosebaceous or sweat duct orifices, which often contain yellow or brown horny plugs. If the plugging is marked, the surface may be rather warty. Lichenification may occur as a result of rubbing. Occasionally, bullae, which may be very extensive [4], telangiectases and purpura may occur. In the later stages, atrophy occurs, and the surface of the lesions becomes wrinkled, and may actually be depressed. Usually, lesions are aggregated into plaques, but the individual lesions can nearly always still be identified. Plaques may resemble those of morphoea, but histology will distinguish between the two conditions. The degree of pigmentation is variable in coloured skin. Bullous lesions may resolve with the formation of a large number of milia [5]. Scarring alopecia may occur. Involvement of the tendon sheath of the superior oblique muscle of the eye can give rise to diplopia [6]. Nail disease is reported [7].

Fig. 56.75 Lichen sclerosus of the front of the wrist.

Anogenital lesions in women (see Chapter 68) [8,9]. The condition most commonly starts between 45 and 60 years of age but is not uncommon in childhood. Lesions occur on the vulva and around the anus, and may extend to the skin of the inner side of the thighs. The ivory-coloured atrophic papules with follicular hyperkeratosis and plugging can often be identified on the vulva but, owing to friction and moisture, the lesions frequently break down to form a red raw surface, resembling macerated intertrigo (Fig. 56.76). Vesicles and bullae, sometimes haemorrhagic, may occur. In other sites, the tops of the papules become smooth and the area becomes flat and glistening. Small telangiectases and purpuric lesions sometimes occur, probably as a result of injury to the atrophic skin. Irritation may be marked, although sometimes—particularly in children—the condition is symptomless (Fig. 56.77). Patients often complain

Fig. 56.76 Lichen sclerosus of the vulva and adjacent skin. (Courtesy of Professor J.L. Burton, Bristol, UK.)

Fig. 56.77 Lichen sclerosus of the vulva in a young girl.

of soreness rather than pruritus, and dyspareunia may be considerable. Atrophy is a feature, and there may be gross shrinkage of the vulva, especially of the clitoris and labia minora. Labial fusion, clitoral burial and labial resorption can all occur. The vaginal introitus may become as small as 1 cm in diameter. Despite this, pregnancy and delivery are uninfluenced [10].

Mouth lesions. Occasionally, lesions are found in the mouth. They consist of bluish white plaques, usually on the inner surface of the cheek or on the palate. There may be superficial ulceration. Sometimes, a reticulate appearance occurs and is difficult to distinguish clinically from the lesions of lichen planus [11]. The tongue can be involved. The presence of lesions of lichen sclerosus elsewhere is helpful, as biopsies from the mouth are sometimes difficult to interpret.

Fig. 56.78 Squamous carcinoma in an area of lichen sclerosus of the vulva.

Malignancy in lichen sclerosus. Premalignant and frankly malignant changes can occur in patients with lichen sclerosus, with as many as 50% of patients ultimately showing changes. These changes can occur in childhood [12]. Squamous cell carcinoma of the vulva occurred in 12 of 290 patients (4.4%) [13], although the true incidence may be greater than this. It usually arises in a sclerotic area, especially on the anterior part of the vulva (Fig. 56.78).

In a review of 83 cases of squamous cell carcinoma of the vulva [14], two patients with lichen sclerosus were found. Paget's disease may rarely occur in cases of lichen sclerosus of the vulva.

Lichen sclerosus in the male (balanitis xerotica obliterans) (Fig. 56.79) (see Chapter 68). Acquired phimosis or recurrent balanitis are the presenting features [15], together with itching and soreness, and erection may be painful. The prepuce becomes sclerotic and cannot be retracted. Ulceration of the foreskin can occur. The glans and undersurface of the prepuce are shining and bluish white,

Fig. 56.79 Lichen sclerosus of the penis.

and there can be considerable telangiectasia. There may be back pressure affecting the urinary tract, demonstrated by urography, as a result of meatal closure. This may require surgical correction [16]. The shaft of the penis is only occasionally involved. The condition is most common between the ages of 15 and 50 years. It can be overlooked in boys unless the prepuce is examined histologically in cases of circumcision for acquired phimosis. It was found in 22% of sections from boys aged 5–11 years, and less than 3% in boys under 5 years [17]. In one series, the condition only occurred in patients not circumcised early in life [18]. The scrotum and perianal area are not involved. Carcinoma may develop, and the condition may be associated with morphoea and vitiligo.

Very rarely, classical macular and papular lesions of lichen sclerosus occur on the glans and shaft of the penis and on the scrotum. The skin remains quite soft compared with the usual sclerotic skin of balanitis xerotica obliterans. Occasionally, classical lesions occur on the trunk.

Lichen sclerosus et atrophicus in female children [19]. The disorder is much less common in children than in adults. Published series show from 2% [20] to 15% [21] of cases begin before the age of 13 years. The earliest reported age of onset was at 6 months [10]. In Wallace's series [13], 28 of 50 started between the ages of 3 and 6 years. In this group, HLA associations are seen more frequently, although these may vary [22].

General health remains normal, and often the condition is symptomless. A vaginal discharge may precede the vulval lesions in approximately 20%, and pruritus vulvae occurs in approximately half of cases. Other presentations include pain on defaecation and dysuria, resulting in constipation, nocturia and nocturnal enuresis as well as rectorrhagia [22]. Lesions have followed trauma (e.g. in operation scars and in scratch marks). The individual lesions are identical to those seen in the adult [17]. The vulva and anal region may be encircled in a figure-of-eight pattern, and shrinking of the labia and stenosis of the introitus may be marked. Follicular plugging and delling are usually absent from areas of the vulva with few or no hair follicles. Vesicles and excoriations occur. The condition may be misdiagnosed as sexual abuse [23], causing much anxiety [24], but there are suggestions that sexual abuse may precipitate the condition as a Koebner phenomenon [25]. Abnormal hirsutism may be seen on the inner side of the labia majora, disappearing with resolution of the lichen sclerosus [13]. In approximately 5% of cases, the lesions are solely outside the anogenital region, and in just over 10% lesions are found both in the anogenital region and elsewhere.

The prognosis in childhood has been studied by Wallace [13]. Extragenital lesions usually clear before the menarche. In approximately two-thirds, anogenital lichen sclerosus involutes before or around the menarche. In the remaining one-third, the condition persists, sometimes with considerable atrophy. Premalignant changes and squamous cell carcinoma may develop. There appears to be an increased incidence of recurrent urinary infections and congenital abnormalities of the genitourinary tract [17].

Laboratory investigations. Approximately three-quarters of female patients have one or more organ-specific autoantibodies [1,2], usually to thyroid microsomes, thyroglobulin, gastric parietal cells or intrinsic factor. The prevalence in males is approximately half that in females, and the antibodies are mainly to smooth muscle and gastric parietal cells.

Differential diagnosis. Lichen sclerosus of the trunk must be distinguished from plaques of morphoea, but this is rarely difficult in the presence of characteristic papules with follicular plugging. Lichen planus is distinguished by its raised itchy violaceous papules. The atrophic form of lichen planus may simulate lichen sclerosus quite closely [3]. Lesions of lichen sclerosus may sometimes occur in association with patches of morphoea and, in some patients, typical plaque morphoea may resolve to leave the white sclerotic features of lichen sclerosus. In patients with vulval lesions, a search should be made for lesions elsewhere on the trunk, but even if none is present, the margins of the affected area of the vulva or the perianal area usually show a few typical papules, sometimes forming a well-defined edge. The differential diagnosis of the genital lesions is discussed in Chapter 68. Vulval cicatricial pemphigoid may mimic lichen sclerosus [4]. The annular atrophic plaque type of DLE on the face may resemble lesions of lichen sclerosus [5].

Associations. Morphoea was found in 13 and vitiligo in 10 of 380 cases [6], and these frequencies are greater than would be expected by chance. Vitiligo and alopecia areata are more common than expected in males [7], and pernicious anaemia is more common in females [1]. Rarely, it may be associated with SLE or limited cutaneous systemic sclerosis [8]. It may coexist with lichen planus [3] and primary biliary cirrhosis.

Prognosis. Lichen sclerosus is a chronic condition, but signs and symptoms may wax and wane. It is usually permanent but, occasionally, spontaneous resolution occurs. This is particularly likely in girls around the menarche [6,9–11]. Resolution of cases appearing after puberty is uncommon, and is probably restricted to extragenital lesions arising before the age of 30 years.

Treatment. There is no confirmed effective treatment for extragenital lesions. Calcipotriol may be helpful [12], and low-dose UVA-1 [13] has been reported to be of benefit. Mycophenolate mofetil was dramatically effective in one severe case seen by the authors.

For genital lesions, there is increasing evidence that the use of potent topical steroid preparations gives both symptomatic relief and prevents scarring, and may induce complete resolution of the problem, both histologically and immunohistologically [14]. Oestrogen [15] or testosterone [16] -containing creams have given symptomatic benefit, but there has not been a trial comparing their use with topical steroids, and no report suggests histological resolution with their use. Adrenocorticotrophic hormone (ACTH) injections helped a severe case with haemorrhagic bullae [17]. Potassium *p*-aminobenzoate, 12 g/day in divided doses, is claimed to have helped symptoms and haemorrhagic bullae, and softened the skin in some cases [18]. Topical ciclosporin is ineffective. Etretinate may have helped both adult [19] and juvenile cases [20]. Sulfasalazine has helped a solitary case [21]. Tangential excision produced a good result in one patient with bullous lesions [22]. Creams containing local anaesthetic preparations should not be prescribed because of the risk of sensitization. Superficial radiation or painting with thorium X are no longer used, and are potentially dangerous.

Vulvectomy is contraindicated for uncomplicated vulval lichen sclerosus, as recurrence occurs in approximately 80% of patients. Dysplastic change should at first be treated conservatively and observed regularly. Applications of liquid nitrogen may be useful, but treatment with a nitrous oxide cryoprobe has been found to be more satisfactory [23]. The carbon dioxide laser is also effective for genital lesions in both males and females [24]. Photodynamic therapy has been used to treat vulval disease [25]. Radical surgery is obviously required if a carcinoma develops. Surgery may also be required for severe narrowing of the introitus.

Topical corticosteroids, sometimes for short periods under a condom, or intralesional injections of triamcinolone may soften the sclerotic lesions of balanitis xerotica obliterans and reduce the phimosis. Circumcision may be helpful or even curative if the condition involves only the foreskin [26]. Meatal instillation of corticosteroid may help meatal narrowing. Attention to local hygiene and treatment of balanitis may be required.

Patients with genital lesions should be seen at intervals of 6–12 months to facilitate the early detection of carcinoma. Repeated biopsies may be required.

Scleroedema

SYN. SCLEROEDEMA ADULTORUM; SCLEROEDEMA OF BUSCHKE

Although the name of Buschke [1] is usually associated with this condition, it was originally described by Piffard in 1876. The older term, 'scleroedema adultorum' is incorrect, as the condition can occur in childhood [2]: 29% of cases start before the age of 10 years, and a further 22% between the ages of 10 and 20 years [3].

Definition. A rare disorder of unknown cause in which areas of induration appear in the skin, frequently after an infection but also in diabetes, and spontaneously clear in months or years. There is an excess of acid mucopolysaccharides in the dermis.

Aetiology. The aetiology is unknown. Suggestions that have been considered include obstruction to lymphatic channels by inflammation, streptococcal hypersensitivity and disorders of the peripheral nervous system or pituitary function. Sera from patients with paraproteinaemia stimulate collagen production in dermal fibroblast cultures [4]. Some persistent cases are associated with moderate to severe diabetes mellitus [5–8], and neither the skin nor the diabetes respond to antidiabetic treatment with insulin, chlorpropamide or phenformin. This persistent type, with no preceding infection and a strong association with diabetes, has been called scleroedema diutinum [9]. Scleroedema has been reported with malignant insulinoma [10], paraproteinaemia and multiple myeloma [11], Waldenstrom's macroglobulinaemia [12], rheumatoid arthritis and Sjögren's syndrome [13], primary hyperparathyroidism [14] and anaphylactoid purpura [15].

Histology. The epidermis is normal. The dermis may be three times its normal thickness. There is swelling and splitting of the dermal collagen bundles by an increase in ground substance. Clear unstained spaces, or fenestrations, occur between the bundles in severe cases. This process extends into the subcutaneous tissues, the fat of which is replaced by coarse collagen fibres. The ground substance stains metachromatically with cresyl violet or toluidine blue. Metachromasia in scleroedema is caused by the presence of hyaluronic acid [16], and is poorly seen in formalin-fixed sections as the hyaluronic acid is removed by the fixative, and in tissues treated by hyaluronidase. There is an excess of acid mucopolysaccharides, but neutral polysaccharides are normal. Mast cells may be increased [17]. Electron microscopy [18] shows an excess of interfibrillary material, and this is associated with clumping of the collagen fibrils. The voluntary muscle and heart may be affected. Deposition of IgG, IgM and C3 at the dermal–epidermal junction has been reported.

Clinical features. The condition is uncommon [19]. Occasional familial cases have been reported [3,20–22]. Females are more frequently affected than males in patients without diabetes, but scleroedema associated with diabetes occurs predominantly in males [21].

Although the condition may apparently start spontaneously, there is a history of an infectious episode, from a few days to 6 weeks prior to onset, in 65–90% [4] of cases. It is usually influenza, tonsillitis, pharyngitis, measles, mumps, scarlet fever, impetigo or cellulitis; prior

streptococcal infections appear to be particularly common. Sometimes, there is a history of trauma. Prodromal symptoms of slight fever, malaise, muscle and joint pains occasionally occur between the infectious episode and the onset of induration. The latter is usually symmetrical and often starts on the back and sides of the neck or on the face. This loses its expression, and the patient notices difficulty in wrinkling the forehead and in smiling. There may be difficulty in opening the mouth. The tongue and pharynx may be involved, with difficulty in swallowing. Later, the shoulders, arms, hands and upper trunk become involved, but less frequently the abdomen and legs may be affected. The condition can be limited to the thighs [23]. The induration is non-pitting and hard, and there is no sharp demarcation between normal and abnormal skin. Wrinkling occurs when the skin is compressed between the thumb and index finger, indicating that the epidermis is spared. Brownish pigmentation can be widespread in the indurated areas [24]. The onset is more insidious in diabetics, and the skin induration may be preceded by erythema or pustules [8]. Sometimes, there is stiffness and restriction of movement of joints. Pleural and pericardial effusions sometimes occur, and the skeletal and cardiac muscles can be affected. Occasionally, there are ocular manifestations. The parotid glands may be involved [25].

Laboratory investigations. The ESR may be moderately elevated, and the serum proteins usually show mild non-specific abnormalities. IgG [26,27] and IgA paraproteinaemia [28] have been reported. The paraproteins of scleroedema are most commonly IgGκ [29]. Hyperlipoproteinaemia has been reported [30]. The antistreptolysin-O titre may be raised, especially in children.

Prognosis. The condition may completely disappear in the course of some months, but many cases last approximately 2 years and a few may persist for many years. One case [17] still had changes 38 years after the onset. A fatal case occurred following the development of IgA myeloma [30].

Differential diagnosis. The condition is usually easy to diagnose in view of the rapidity of the onset, especially if there has been a history of preceding infection. Localized and generalized morphoea are usually of much slower onset, and the ivory sclerotic areas, with a well-defined and, frequently, lilac-coloured border, are characteristic. Systemic sclerosis is usually preceded by Raynaud's phenomenon. Dermatomyositis may present more difficulty, as cutaneous oedema is a feature of both conditions. However, the presence of heliotrope cyanosis, particularly around the eyes, dilatation of nail fold capillaries and muscle weakness should distinguish the condition. Pseudoscleroderma (induration of the legs as a result of chronic oedema) and localized myxoedema should rarely cause confusion. Trichinosis may have to be considered. In the newborn, sclerema and subcutaneous fat necrosis differ in their mode of onset and course.

Treatment. No effective remedy is known, although multiple therapies have been tried, including systemic and intralesional corticosteroids. In a case associated with multiple myeloma, the skin softened with intravenous pulses of cyclophosphamide and oral prednisolone [31]. Improvement with ciclosporin [32] and electron beam therapy [33] have been reported. PUVA using psoralen cream [34], extracorporeal photophoresis [35] and low-dose methotrexate are more recent suggestions [36].

Dermatomyositis [1]

Definition. A disorder mainly of skin, muscle and blood vessels in which characteristic erythematous and oedematous changes in the skin are associated with muscle weakness and inflammation. Calcinosis is frequent, especially in childhood, and is usually associated with a more favourable prognosis for life, but functional disability may be severe. In adults, the disease is commonly associated with an underlying carcinoma or lymphoma.

Incidence. Dermatomyositis is rarer than SLE, polyarteritis nodosa or systemic sclerosis. It occurs at least twice as frequently in females as in males. The incidence in children under 16 years was recently estimated as 1.9 per million, with the median age at onset of 6.8 years, and occurring much more frequently in girls (ratio 5 : 1) [2]. The onset in childhood cases is usually before the age of 10 years, and in adult cases is predominantly between the ages of 40 and 60 years. The mean age of onset is later in men than in women [3]. It may occur in infancy [4,5]. It appears to be approximately 10 times more common in the Bantu than in the white population of the Transvaal [6].

Aetiology. The cause is not known, but there is increasing evidence of early blood vessel damage, probably humorally mediated [7]. There may be significant titres of antiendothelial cell antibodies, particularly in those patients with pulmonary involvement [8]. The disorder is not consistently caused by infection, vaccination, immunization or drugs, nor is it associated with trauma, but occasional cases seem to follow such events [9]. Preceding heavy muscular exertion and stress have been suggested as triggering factors [7]. Polymyositis and dermatomyositis can occur with penicillamine therapy, and may be fatal as a result of cardiac involvement [10]. A possible relationship to tamoxifen therapy for carcinoma of the breast has been reported [11]. One patient developed dermatomyositis after taking oral progesterone for dysmenorrhoea. A very high frequency of IgM immunofluorescent antibodies to *Toxoplasma gondii* in patients with polymyositis/dermatomyositis suggests a possible association with recent infection with *Toxoplasma* [12], and treatment of such infection may produce remission of dermatomyositis [13]. In a patient who developed dermatomyositis in association with staphylococcal osteomyelitis, the former resolved after the infection had been treated, and onset of the disease has been reported after staphylococcal arthritis [14]. There is also a degree of homology between streptococcal type 5 protein and skeletal myosin, and flares of disease were associated with a rise in antistreptococcal antibodies, suggesting another role for infection in disease pathogenesis [15]. There are also suggestions that parvovirus B19 may have a causative role, at least in adult disease [16], and coxsackie B virus infection has been linked to childhood disease [17]. Tubular inclusions, possibly related to viral infection, have been reported [18].

Dermatomyositis affects all races and there is no obvious geographical variation. It very rarely occurs in relatives, but has been found in identical twins [19] and in first cousins: only three other familial cases are known [20]. A genetic factor is suggested by the increased incidence of HLA-B8 in childhood dermatomyositis in white people but not in black people [21], and -DR3 [22] and -B14 in adult patients [23]. Other HLA haplotypes may be associated with pulmonary disease [24]. It has been reported in a patient with absence of the second component of complement (C2) inherited as an autosomal recessive trait [25]. There are rare familial cases [26] and antinuclear antibodies occur in a significant percentage of first-degree relatives of patients with dermatomyositis and polymyositis [27].

Immunological abnormalities. It seems likely that immunological mechanisms are concerned in the development of dermatomyositis. There is some evidence of an increased incidence of hyperglobulinaemia in relatives [20], and the relation of the disease to malignancy in adults suggests that there may be an abnormal immunological response to the neoplasm. A patient with carcinoma of the breast showed skin sensitivity to an extract of her own breast tumour when it was injected intradermally [28]. Tests using an extract of normal skin, subcutaneous tissue and muscle were negative. In another female patient, with metastatic adenocarcinoma of the lung and dermatomyositis, positive intradermal reactions were found to injections of aqueous extracts of the tumour [29]. The immediate skin reaction and passive transfer tests established the humoral nature of the antibodies involved. Granular deposits of IgG, IgM and C3, alone or in combination, have been described in the walls of skeletal muscle

blood vessels, especially in childhood dermatomyositis [30]. Globulin has been demonstrated in plasma cells around hair follicles and sebaceous glands in a case of dermatomyositis associated with carcinoma of the breast [31]. In some patients, myopathy seems to have been mediated by an IgGκ paraprotein with antimuscle specificity [32]. It is not clear whether paraneoplastic dermatomyositis is the same entity as the condition occurring without an associated cancer.

Several precipitating autoantibodies have been demonstrated [33], including PM-1, Jo-1, PL-12 and, in Japanese patients, KU. Jo-1 and PL-12 antibodies are directed against tRNA synthetase enzymes and are associated with interstitial pulmonary fibrosis, and the antibody may be detected before the appearance of the lung disease [34]. It has been suggested that Jo-1 production may be linked to HLA-DR3 [22]. Patients with Jo-1 antibodies tend to have an onset of symptoms between February and July; this is not the case for the other serological subgroups of the disease [35]. Humoral antimuscle antibodies have not been demonstrated. The serum of patients may contain complement-fixing antibodies to their own tumour [36].

Circulating immune complexes have been demonstrated in 70% of patients [37]. There is evidence that polymyositis may be caused by lymphocyte-mediated hypersensitivity [38]. Large numbers of T lymphocytes can be demonstrated in the infiltrates in the muscle [39], and there is marked decrease of suppressor/cytotoxic cells in the blood [40]. Lymphocytes from patients with dermatomyositis and polymyositis have shown an increased response to muscle antigen in lymphocyte-stimulation tests, and the index of response showed some correlation with clinical activity. Lymphocytes from patients with dermatomyositis were cytotoxic to muscle cultures, and this cytotoxic action could be prevented by antilymphocyte serum [41]. Soluble CD30 levels are increased, indicating activation of T lymphocytes [42], and soluble TNF receptors are found [43]. An increased frequency of the more inflammatory polymorphisms of the TNF-α gene is found [44]. Soluble IL-2 receptor is elevated in juvenile disease [45].

Relationship to malignancy. Several possible mechanisms to account for the relationship with malignancy can be envisaged, but these are mainly speculative at present. Tumours are known to differ antigenically from the tissues from which they are derived. New antigens are produced, probably as the result of somatic mutation, and are regarded by the body as 'foreign' and lead to an immune response. If such tumour antigens share common antigenic determinants with skin and muscle, the immune response will be directed against these tissues. On the other hand, dermatomyositis might result from the damaging action of cellular autoantibodies synthesized by forbidden mutant clones of immunologically competent cells such as lymphocytes. If such was the mechanism, neoplasia could act as a precipitating factor by competing with a defence mechanism against the development of such forbidden clones. Removal of the tumour would then allow the defence mechanism to suppress the activity of the forbidden clones and a clinical remission of the dermatomyositis would result. There is no evidence to suggest that dermatomyositis results from a direct toxic effect of a chemical substance released by tumour cells.

The primary tumour most commonly occurs in the lung, breast, female genital tract [46], stomach, rectum, kidney or testis. In the Chinese, nasopharyngeal carcinoma accounted for 75% of malignant disease [47]. The association with a range of tumours has been reviewed [48]. Dermatomyositis precedes the neoplasm in 40%, both conditions may occur together (26%) or the neoplasm may occur first (34%) [49]. It is difficult to assess the incidence of carcinoma in association with dermatomyositis. Figures vary from 15 to 34% [50]. Using strict criteria, 26% of adult patients with dermatomyositis were found to have a malignancy [51]. Patients with dermatomyositis are more likely to have a malignancy than those with polymyositis, and usually do not fare so well. The incidence of neoplasia seems to be higher in males than in females with dermatomyositis [52], although this has not been noted by others [53]. The overall incidence in one series was 29% [54], but this rose to 40% in patients over 40 years and to 66% in males over 40 years. Neoplasia is not associated with childhood cases. Usually, dermatomyositis worsens in parallel with the progress of the neoplasm, but it may improve when the latter is treated. Neoplasia may be missed because of failure to reinvestigate relapse of previously stable dermatomyositis [53].

Pathology [1]. Dermatomyositis mainly involves the skin and muscles, although occasionally other organs are affected. The histological appearance of the skin depends on the stage of the disease. In acute dermatomyositis, the changes resemble those of subacute LE, although the dermal oedema may be more extensive and involve all layers of the dermis. There is usually some lymphocytic infiltrate, either perivascular or in clumps. The majority of the cells are $CD4^+$ T cells and HLA-DR-expressing macrophages. B lymphocytes are absent [2]. The infiltrate may also include histiocytes, plasma cells and, occasionally, eosinophils. Mucin deposits commonly occur in the dermis, and mucin in an otherwise non-specific skin biopsy, although not diagnostic, is suggestive of dermatomyositis [1]. Hyperkeratosis, acanthosis and mild papillomatosis are features seen in Gottron's papules [3]. In the later stages, the collagen of the dermis may show thickening, homogenization and sclerosis, with thickening of the walls of cutaneous blood vessels. The epidermis becomes atrophic, with flattening of the rete ridges, and the basal layer may show an increase in pigment. At this stage, the appearance can be similar to that of scleroderma [4,5]. On direct immunofluorescence, IgM, IgG and C3 may be found at the dermal–epidermal junction in 50% of cases. Those with IgM may also have cytoid bodies [6]. The subcutaneous fat may show mucoid degeneration and lymphocytic infiltration, or sclerosis and calcification, sometimes with membranocystic changes [7].

The most frequently involved muscles are those of the limb girdles, the proximal parts of the limbs, the pharynx and the tongue. The muscle involvement [8] is not uniform. It is important to remember this, because histological examination of biopsy material may be negative. It

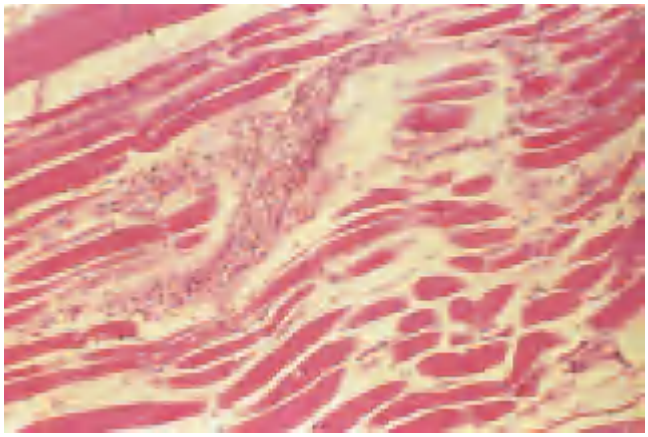

Fig. 56.80 Dermatomyositis: variable degeneration of the muscle bundles with oedema and inflammatory cells.

is better to try to obtain a specimen from a muscle that is clinically weak. The affected muscles may be pale, soft and flabby, or firm and fibrotic, depending on the stage of the disease. In patients with fibrosis, there may be calcification in the muscles and soft tissues. Histologically, in the early stages, the muscle fibres show loss of transverse striation, hyalinization of the sarcoplasm and an increase in sarcolemmal nuclei (Fig. 56.80). Later, the fibres fragment and show granular and vacuolar degeneration, and basophilic staining with histiocytic phagocytosis. There is variable cellular infiltration, mainly of lymphocytes, but also occasional plasma cells and macrophages. The blood vessels in the muscles may show eosinophilic intimal thickening, resembling the changes seen in malignant hypertension. Later still, the affected muscle fibres become atrophied and sclerosed, and resemble the changes seen in the muscles of systemic sclerosis. No significant morphological differences have been found in the muscles in any of the diagnostic subgroups of polymyositis and dermatomyositis, and no consistent relationship between pathological changes in serial biopsies and clinical improvement in individual patients [9].

Intimal proliferation and thrombosis of arteries and arterioles of the skin, fat and alimentary tract [10] are sometimes seen, and the latter accounts for the gastrointestinal ulceration and haemorrhage that occasionally occur [11]. Changes resembling those seen in systemic sclerosis occur in the lungs or in the kidneys. The heart muscle may show changes similar to, but milder than those in the voluntary muscles. Vasculitis of the cerebral and meningeal vessels has been reported, and in one case resulted in subarachnoid haemorrhage [12].

Clinical features. The clinical picture is variable. Some patients with typical features of muscle involvement show little or no evidence of skin involvement, and the condition is then known as polymyositis [1,2]. Sometimes, the rash occurs alone [3,4], a condition that has been called amyopathic dermatomyositis, and this appears to imply a good prognosis [5]. Severe calcinosis may occur even in this variety [6]. In one series, the rash preceded muscle weakness in 56% of patients [7]. Usually, the patient first notices aching and weakness of the muscles, which may be painful and tender, and later show some atrophy. Typical histories include difficulty in going up stairs or rising from a chair, or difficulty in raising the arms high enough to comb the hair. Occasionally, patients may present with, or have nasal speech and regurgitation. Usually, there is a feeling of malaise, and fever may occur. Raynaud's phenomenon occurs in approximately 10% of adults, but is very rare in children. Obliteration of digital arteries may be revealed by arteriography [8]. Recurrent bursitis of shoulders and hips may precede myositis, and joint effusions occur [9,10].

The rash in well-developed cases is diagnostic. A purplish red heliotrope erythema occurs on the face, especially involving the eyelids, the upper cheeks, forehead and temples (Fig. 56.81). Oedema of the eyelids and periorbital tissues is not uncommon [11]. The distribution may resemble that of seborrhoeic dermatitis [12]. Oedema of the hands and arms and sometimes of much of the body may also be found, and this is usually associated with erythema of the backs of the forearms, the upper back and, sometimes, elsewhere. Small erythematous or violaceous, flat papules (Gottron's papules [13]) and small plaques occur over the knuckles, on the dorsa of the finger joints and around the nail folds (Fig. 56.82). They also occur on the dorsa of the toes, on the front of the knees and on the backs of the elbows. Frequently, the rash of dermatomyositis on the dorsa of the hands occurs as linear streaking over the extensor tendon sheaths (Fig. 56.83). These may be hyperpigmented as the only cutaneous

Fig. 56.85 Dermatomyositis: dilated nail fold capillaries and hypertrophic ragged cuticle.

sign in Afro-Caribbeans (Fig. 56.84) [14]. As well as diffuse redness and shininess of the nail folds, the capillary loops of the nail folds may be dilated, irregular and tortuous, and easily visible with or without a lens, or by capillaroscopy. The capillary changes are more marked in patients with Raynaud's phenomenon, arthritis and pulmonary involvement, but are not related to active myositis or malignancy (Fig. 56.85) [15]. Thickening, roughness, hyperkeratosis and irregularity of the cuticles, with minimal or no redness or inflammation [16], is frequent. Ragged cuticles are also found in other connective tissue diseases

Fig. 56.86 Panniculitis with calcinosis in the thigh in dermatomyositis.

such as systemic sclerosis and LE. When healing occurs, reticulate telangiectatic erythema may be seen, with areas of atrophy and scarring, and sometimes pigmentation and depigmentation. At this stage, the appearances may resemble radiodermatitis.

Some cases show less specific changes, spreading erythema of the face and neck or of the limbs, and fleeting or more persistent oedema of the face and limbs. A wide variety of lesions has occasionally been reported: dermographism, bullous lesions [17], urticarial lesions [18], photosensitivity [19], erythema nodosum, erythema multiforme, follicular keratosis, hypertrichosis [20], hyperhidrosis, psoriasiform eruptions and pitting of the fingernails. Gingival telangiectasia appears to be common in childhood disease [21]. Linear, violaceous, itchy and oedematous streaks, mainly on the trunk and lasting a few weeks, have been likened to the pattern of zebra skin and called flagellate erythema [22]. Rarely, exfoliative dermatitis may occur. Hyperpigmentation occurs in the later stages. Erythema of the scalp, with diffuse alopecia, may develop. Livedo reticularis may occasionally be seen, and sometimes the skin breaks down to form ulcers up to 3 cm in diameter, containing pale green sloughs. In other patients, red firm tender areas of panniculitis develop (Fig. 56.86), and these may ulcerate or break down to form sinuses [23,24]. In the Chinese, hyperkeratotic follicular erythematous papules occur on the face, back of the neck, trunk, dorsa of the hands and feet, and palms and soles. On the dorsa of the hands and feet, the lesions occur in a linear fashion [25]. Patients with antisynthetase antibodies may have 'mechanics hands'—hyperkeratosis, fissuring and linear hyperpigmentation of radial and palmar surfaces of the fingers [26]. Histology shows hyperkeratosis, acanthosis, a mononuclear dermal infiltrate and liquefaction necrosis of the basal layer [27].

In addition to the weakness of the limb muscles, which is mainly proximal, there may be difficulty with speech and swallowing (because of involvement of the muscles of the tongue, the pharynx and the upper third or distal part [28] of the oesophagus), diverticular out-pouching of the oesophagus [29], impaired muscular activity of the small intestine, pneumatosis intestinalis [30], sometimes with pneumoperitoneum [31], wide-mouthed diverticula of the colon, weakness of the ocular muscles and respiratory difficulty from involvement of the intercostal muscles and diaphragm. The cause of death is usually respiratory infection or heart failure. Interstitial pneumonitis [32], with non-productive cough, dyspnoea and hypoxaemia and radiological infiltrates or pulmonary fibrosis, may be the presenting manifestations or may occur in the course of the disease [33]. Pulmonary hypertension, with cor pulmonale [34] and fibrosing alveolitis [35], has been reported. Interstitial lung disease may be more frequent than suspected [33]. Myocarditis, myocardial fibrosis, disorders of conduction and cardiac failure occur in approximately one-third of cases [36]. Renal lesions are uncommon [37]. Retinitis produces fluffy exudates around the papilla and along the veins; permanent visual loss occurs rarely [38]. A case of myoglobinuric acute renal failure has been reported [39]. Calcification [40] occurs in the muscles of more than half of childhood cases, and approximately 15% of adults. The muscles mainly involved are those of the shoulder and pelvic girdles, and to a lesser extent those of the trunk and the limbs, especially around the elbows and hands. In adults, the distribution is less markedly around the pelvic and shoulder girdles than in childhood. Calcinosis increases over the course of months or years and, if extensive, can cause severe functional disability. Calcification also occurs in the subcutaneous tissues. Extrusion of calcium through the skin is associated with ulceration and cellulitis. Calcinosis is a good sign for survival, but functional recovery is less likely. Sometimes, patients present with widespread calcification and apparently have not had a preceding myositic illness. In these cases, it is presumed—but not proved—that calcinosis is the result of old dermatomyositis. Sometimes, calcinosis developing in childhood decreases in adolescence; rarely, hypercalcaemia may occur [41]. A mild inflammatory arthritis may occur; erosive arthritis is rare. Patients with arthritis frequently have pulmonary involvement [42]. Trigeminal neuropathy has been reported [43].

Dermatomyositis in childhood. This has been well described [1,2]. It is possible that microchimerism may be an aetiological factor [3]. The condition resembles that seen in adults, but malignancy is rarely associated with it and it is usually much more severe than in adults. The prognosis is variable. Calcification occurs more frequently than in adults and contractures develop in under 5%. Widespread vasculitis affecting small arteries, capillaries and veins of the skin, muscle, subcutaneous tissue and gastrointestinal tract is a prominent feature of the so-called Banker type [4,5]. It may take many years for the disease to burn out. Occasionally, a child recovers without any residual disability. Late recurrences are rare. Psychological difficulties occur more frequently than might be expected [6]. A rare feature is hypertrichosis (Fig. 56.87) [7,8]. Juvenile dermatomyositis can be associated with partial lipodystrophy [9].

Fig. 56.87 Hypertrichosis in an area of erythema on the knee in childhood dermatomyositis.

Sclerodermatomyositis in childhood. This is an overlap syndrome in which cutaneous changes of systemic sclerosis and dermatomyositis are associated with myositis and the homogeneous nucleolar pattern of antinuclear antibody (anti-PM/Scl antibody). Serum muscle enzymes are normal or only slightly raised. The features of dermatomyositis are usually transient and respond to non-steroidal anti-inflammatory drugs or corticosteroids, and aggressive treatment is not usually required. The systemic sclerosis features such as Raynaud's phenomenon, calcinosis and arthritis tend to grumble on over years, but visceral involvement is not marked. One case with 'mechanic's hands'—hyperkeratosis and fissuring on the tips and sides of the fingers resembling a labourer's dirty hands—has been reported [1].

Dermatomyositis in pregnancy [1,2]. Pregnancy exacerbates the disease in approximately 50% and is associated with remission in 20%. Dermatomyositis can start in pregnancy. The overall fetal loss is over 50%, and half of pregnancies end prematurely. Fertility is decreased [3]. Pregnancy should be planned at a time of remission and the patient monitored at least every month. If possible, treatment should be confined to oral steroids.

Association with other disorders. The association with carcinoma in adults has already been mentioned. Dermatomyositis has been reported in association with thymoma [1] and hyperthyroidism [2], and complicating penicillamine therapy [3]. A dermatomyositis-like eruption has been reported in association with hydroxyurea therapy, where ulceration of the legs may occur [4]. Calcinosis universalis, involving the central portion of the trunk, probably results from old dermatomyositis. Presentation with aplastic anaemia [5] and haemolytic anaemia [6], and in association with agammaglobulinaemia [7], cystinuria [8], Hashimoto's disease and ovarian carcinoma [9], generalized amyloidosis [10], multiple myeloma [11], lichen myxoedematosus [12], dermatitis herpetiformis [13], as well as coeliac disease [14], bullous pemphigoid [15], porphyria cutanea tarda [16], fibrosing alveolitis [17], cutaneous vasculitis [18], Sjögren's syndrome [19] and Hughes' syndrome [20] have been described. Linear morphoea of the back of the thigh in a child of 7 years with dermatomyositis and calcinosis has been seen. Polymyositis has been reported with periorbital fasciitis [21]. Multiple asymmetrical lesions of lipoatrophy have been reported in a patient with juvenile dermatomyositis [22], and partial lipodystrophy has also occurred with phaeochromocytoma and urticarial vasculitis [23].

Differential diagnosis. The diagnosis depends upon the association of a typical rash with muscle weakness, and is confirmed by muscle biopsy, electromyography and certain laboratory investigations. The serum creatine phosphokinase (CPK), glutamic oxalacetic transaminase (SGOT) or aldolase are frequently, but not invariably raised [1,2], and in certain cases may reflect the activity of the disease and be helpful in regulating the dosage of steroids [3,4]. However, some patients continue to show considerable activity in the presence of normal serum enzymes, so serial estimations of the 24-h urinary creatine are helpful, if available [5]. Skin and muscle biopsy are helpful, but histological changes may be absent or minimal. Radiology of the muscles in the later stages may show calcinosis, a feature that may differentiate the condition from SLE [6]. In dermatomyositis, the calcium deposits are widely scattered throughout the muscles and soft tissues, whereas in systemic sclerosis the calcium deposits are found mainly in the hands and around the elbows and knees. Moreover, in the latter, the tips of the terminal phalanges often show some bone resorption. MRI scanning [7] and ultrasound give useful information for longitudinal studies and are non-invasive [8]. In patients with little or no rash, muscular dystrophies may be closely simulated [9]; dermatomyositis is of more rapid onset and remissions are frequent.

Electromyography [10] is helpful in distinguishing myopathy from neuropathy. The ESR is moderately elevated in some, but not all patients in the active phase, and there may be some elevation of the serum globulin. It has been claimed that an elevated ESR and cutaneous necrosis are potential markers of malignancy [11]. Antinuclear factor, raised DNA binding and anti-RNP may occur, especially in overlap syndromes [12]. Antibodies to aminoacyl-tRNA synthetase are antibodies to soluble nuclear antigens and are associated with myositis [13]. Anti-Jo-1 antibody, an autoantibody directed at the cellular enzyme histidyl-tRNA synthetase, is found in 25% of patients with myositis, especially in those with cryptogenic fibrosing alveolitis, Raynaud's phenomenon, sicca syndrome and mild arthritis [14]. Anti-Ku antibody is associated with dermatomyositis–systemic sclerosis overlap syndromes, which have a good prognosis [15], and anti-KJ with polymyositis and interstitial lung disease [16]. KL6 may also be a marker for interstitial lung disease [17]. Antibodies to cytoplasmic antigens such as anti-SRP (signal recognition particle) occur, and antibodies to the nuclear antigen Mi-2 are strongly associated with dermatomyositis [18]. Occasionally, rheumatoid factor is found. The Wassermann reaction is negative. Anticardiolipin antibodies were found in three out of 14 patients with juvenile dermatomyositis, two of whom had vascular complications [19]. In all adult cases, a determined effort to exclude internal malignancy should be carried out [20], but most of the neoplasms can be diagnosed by physical examination (including the breasts, pelvis and rectum), blood count, radiography of the chest, examination of the stools for occult blood and, in men, acid phosphatase estimation.

Dermatomyositis can be confused with systemic sclerosis, and the two conditions can occur together. The muscle changes may be identical in the two disorders, but visceral changes are much more common in systemic sclerosis. Antinuclear factor can commonly be demonstrated in the serum in systemic sclerosis, but is frequently absent in dermatomyositis. From the clinical point of view, differentiation between the two diseases may be difficult, particularly in those cases showing sclerosis in the healing phase. Occasionally, patients with systemic sclerosis show heliotrope cyanosis of the eyelids, and dilatation of the nail fold capillaries. Sometimes, patients with dermatomyositis resemble patients with SLE but, in the latter, antinuclear factors and anti-DNA antibodies can usually be demonstrated. Myositis is a feature of so-called mixed connective tissue disease (see p. 56.116). Neuropathy is distinguished by the electromyographic changes and the presence of a raised CPK and urinary creatine excretion. The atrophic changes of the skin in the later stages may resemble morphoea, but the history should lead to the correct diagnosis. Polymyositis [21,22] is more common than dermatomyositis. It is usually found in adults in the third to the fifth decades. Females are three times more likely to develop the disease than males. Occasionally, scleroedema may cause difficulty. It is important to exclude metabolic disorders in those patients with only muscle disease [23].

Prognosis [1–4]. The course is variable. The prognosis is said to be better in dermatomyositis than in polymyositis; however, some have found the reverse to be true [5]. Patients without muscle involvement have a better prognosis and may not require steroids [6]. Doubts have been cast about the dosage of steroids required. No alteration in survival was shown when low-dose therapy was compared with high-dose therapy [7]. Combined therapy with azathioprine produces better results than steroids alone [8]. Approximately 50% of patients seem to be responsive to therapy; the remainder appear to be relatively resistant. The overall mortality is approximately one-quarter [9], and two-thirds of deaths result from carcinoma [1]. Adverse factors include acute pulmonary infiltrations, dysphagia, cutaneous necrosis and increasing age. Fulminating cases may deteriorate rapidly despite therapy, and some 20% die within the first year. After an acute phase lasting some months, most cases settle slowly and burn out in time, usually over several years. Sometimes, patients complain of vague aching in the limbs when there does not appear to be any residual activity. One patient had three separate episodes over 33 years [10]. Some are left with minimal cutaneous change and no residual weakness. Others, particularly children, have gross disability, with contractures of the limbs and calcinosis. Of the children followed up for 5–16 years, 75% survived [11]. Removal of an underlying carcinoma in adults can lead to regression of the dermatomyositis [12].

Calcinosis is a good prognostic feature. Out of 75 adults without calcification, 26 died, usually in approximately 2 years, whereas of 12 adults with calcinosis none died [13]. Seven out of 14 children without, and only one of 17 with calcinosis died in a mean time of approximately 16 months. Calcification can decrease without treatment.

Death usually occurs from respiratory infection, cardiac failure, malnutrition, weakness or debility because of difficulty in swallowing, carcinoma, or from the side effects of steroid therapy.

Treatment [1]. Rest is essential in the acute phase. In adults it is important to exclude an underlying carcinoma. Treatment with corticosteroids is required in almost all cases, the dosage depending upon the degree of activity. Initial dosage of as much as 60–120 mg/day prednisolone may be required. This dosage should be gradually reduced as the patient clinically improves and the biochemical markers improve. However, a maintenance dosage of between 5 and 15 mg/day may be required for many months, or even years, and it is important to balance the maximum therapeutic effect against the presence of side effects. If the clinical signs and serum CPK level are not improving sufficiently quickly, bolus infusions of methylprednisolone (1 g on three successive days) may be tried. Alternatively, an antimetabolite should be added. Oral azathioprine (1.5–3 mg/kg/day in divided doses) as a steroid-sparing agent, or oral methotrexate in a small

weekly dosage (7.5–15 mg) may be used. This may only suppress disease activity [2], and treatment may have to be stopped because of side effects [3]. Intravenous methotrexate (0.5–0.8 mg/kg at weekly intervals, after a test dose) has been advocated [4]. Patients not responding to prednisolone and immunosuppressives may be helped by the addition of ciclosporin 5 mg/kg/day [5]. Ciclosporin is also effective in childhood in a dosage of 2.5–7.5 mg/kg [6]. It has also been used alone in childhood as an initial treatment [7]. A number of studies have indicated a successful role for intravenous immunoglobulin in a regimen of 1 mg/kg for 2 days each month over 4–6 months [8,9]. Lower dosage may also be successful, and it may be combined with ciclosporin [10]. Cyclophosphamide 100 mg/day [11], or as pulsed intravenous therapy, is used for pulmonary interstitial fibrosis.

Children with minimal myopathy may remit with indometacin without steroids [12], and antimalarials may help the rash of dermatomyositis, which may persist when muscle activity settles [13]. Topical steroid or a topical calcineurin inhibitor may be of value [14]. Levamisole (100 mg/week) [15] or plasma exchange [16,17] may help patients with severe disease not responding to steroids or immunosuppressives. Improvement may occur within 48 h of plasmapheresis [18]. Extracorporeal photochemotherapy may be useful in combination with other therapies [19]. Methandienone (30 mg/day) [20], dapsone [21] and pentoxifylline [22] have all produced apparent improvement in patients unresponsive to corticosteroids. Whole-body radiation produced dramatic improvement in a patient with polymyositis [23]. Antiplatelet agents—aspirin (650 mg/day), dipyridamole (400 mg/day) and sulfinpyrazone (400 mg/day)—helped one patient with *in vivo* platelet thrombi formation causing digital and vascular ischaemia [24].

Therapy, with either prednisolone alone or in combination with an antimetabolite, may be required for some years, and the dosage is reduced very gradually until the disease is burnt out. Any recrudescence is treated with an increase in dosage. Early treatment with low-dose steroids in children is associated with fewer relapses and lower morbidity [25]. Occasionally, weakness may arise from corticosteroid myopathy, and may be difficult to distinguish from an exacerbation of the disease. Serum enzymes are normal, but the 24-h urinary creatine excretion is raised [26]. Recovery on reduction of dosage takes up to 4 months. Weakness in dermatomyositis may occur because of hypokalaemia, the result of corticosteroid therapy. Regular electrolyte estimations are required and potassium supplements should be given.

Gastrointestinal haemorrhage may occur as a result of the disease or corticosteroid therapy. Constipation can be a feature, and octreotide may increase gastrointestinal motility. Osteoporosis is a considerable risk because of immobility and corticosteroid therapy, and prophylactic treatment should be given to both female and male patients. Backache may be caused by corticosteroid osteoporosis, although it is also a common symptom of the disease itself.

Treatment of calcinosis is usually ineffective, although spontaneous improvement can occur after the disease burns out. Warfarin (1 mg/day) [27] or probenecid 2 g/day [28] may be worth trying. The results of the administration of chelating agents have been disappointing [29]. Aluminium oxide, by producing insoluble aluminium phosphate, decreases the intestinal absorption of phosphate and has been successfully used in calcinosis in a child. Aludrox 15 mL four times daily (2.4 g/day aluminium oxide) was given by mouth [30]. Diltiazem has also been used succesfully [31].

Physiotherapy plays a considerable part in preventing the development of contractures, and careful splinting may also be required. Artificial ventilation may be required in reversible transitory ventilatory failure [32], as may intravenous feeding in patients with severe oesophageal involvement. If there is definite serological evidence of recent infection with *Toxoplasma gondii*, treatment with pyrimethamine and/or sulfadiazine may be indicated [33].

Dermatological manifestations of rheumatoid disease

Dermatologists may be concerned with the diagnosis and management of several skin lesions that may occur in association with rheumatoid arthritis, although most patients will probably be under the care of a rheumatologist. Others present primarily as dermatological problems, and the presence of rheumatoid arthritis is detected on general examination of the patient. The occurrence of rheumatoid nodules and vasculitis in rheumatoid disease is well recognized, but more recently other abnormalities, such as transparent skin and linear subcutaneous bands, have been described in detail [1]. Localized areas of atrophy and liver palms also occur.

Sometimes, there may be difficulty in deciding between rheumatoid disease and SLE. In the skin of the former, fluorescence of the dermal–epidermal junction is not found [2], even in cases with a high titre of antinuclear factor [3].

Pseudosclerodermatous changes, particularly of the hands, occur in rheumatoid arthritis, and arthralgia, tenderness and swelling of the joints are presenting features of some patients with systemic sclerosis. Systemic sclerosis and rheumatoid arthritis may also coexist [4].

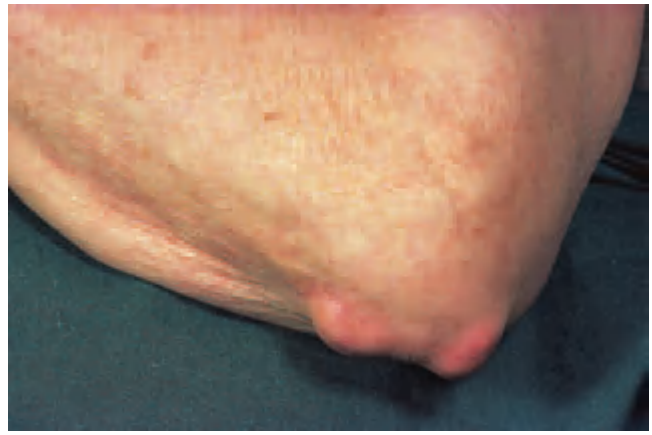

Fig. 56.88 Rheumatoid nodules on the elbow.

Fig. 56.89 Ulcerated rheumatoid nodule on the ear.

Rheumatoid nodules (Fig. 56.88)

Palpable subcutaneous nodules occur in approximately 20% of patients with rheumatoid arthritis. The most common site is on the ulnar border of the forearm. Less commonly, they occur on the dorsa of the hands, on the knees, on the ears, over the scapulae and occasionally in other areas, especially those subject to pressure, such as the sacrum, buttocks or heels. They vary in size up to several centimetres in diameter, are firm in consistency and tend to ulcerate with trauma (Fig. 56.89). This is particularly important on the sacrum, where ulceration may be missed [5]. Secondary infection with staphylococci can result

in staphylococcal septicaemia and septic arthritis. Subcutaneous nodules can erode the underlying bone [6]. Sometimes, there are numerous violaceous papules with centripetal scaling. A variant of rheumatoid disease, termed 'rheumatoid nodulosis' [7], has been described in which nodules occurred with palindromic rheumatism and little evidence of synovitis. Nodules are multiple and small, and recur mainly on the hands and feet. Rheumatoid nodulosis may, after many years, turn into rheumatoid disease with joint involvement.

Nodules are almost invariably associated with more severe forms of the disease, and rheumatoid factor and antinuclear factors are frequently found in the serum. Occasionally, nodules may occur in mild rheumatoid arthritis and in anarthritic rheumatoid disease [8]. Sometimes, they may precede rheumatoid arthritis by some years [9]. Rheumatoid nodules may rarely occur in the sclera (scleromalacia). The sclera becomes atrophic and may perforate (scleromalacia perforans), leading to complete blindness.

Histologically, rheumatoid nodules consist of fibrous tissue in which foci of fibrinoid necrosis are scattered, surrounded by a palisade of cells, mainly fibroblasts and histiocytes. A peripheral zone of lymphocytes and plasma cells occurs. Within the necrotic area are thin reticulum fibres, similar to those seen in young granulation tissue, amorphous material and some nuclear debris. Vasculitis can occur in rheumatoid nodules and papules. The histology has features in common with those of granuloma annulare (see Chapter 57).

The subcutaneous nodules of rheumatic fever [10] can be distinguished histologically from those of rheumatoid arthritis. There is much fibrinoid material, considerable oedema of the collagen, but relatively little infiltration with fibroblasts, histiocytes or lymphocytes. There is little attempt at zoning and fibrosis is minimal or absent. Large mononuclear cells, like those seen in Aschoff's nodes in the myocardium, may be found. Nodules from patients with Still's disease (juvenile rheumatoid arthritis) [10] resemble those seen in rheumatic fever.

Linear subcutaneous bands [11]

Elongated subcutaneous bands, 3–5 mm wide and 10 cm or more in length, have been described in patients with rheumatoid arthritis with nodules.

Histologically, the bands show changes similar to the nodules. The bands, which are firm and non-tender, are adherent to the skin. They have so far been observed in the axilla, and extending from the axilla to the iliac crest.

Vascular lesions in rheumatoid arthritis [1–5]

The presence of vascular lesions in rheumatoid arthritis has been increasingly recognized in recent years. Raynaud's phenomenon is uncommon; it occurred in only 2.7% of one series [6].

The most characteristic lesions of arteritis in rheumatoid patients are small infarcts around the nails, sometimes at the apex of small cutaneous nodules. These are best seen with a magnifying glass and a bright light. The lesions are usually transitory and may last only 2 or 3 days. Because they are usually painless, patients rarely complain about or even notice the lesions. Usually, a small brown spot persists a little longer, and sometimes scarring may occur. Occasionally, infarcts of the nail fold may result in grooving of the nail. Such lesions occurred in 34% of males and 18% of females in 157 consecutive cases of rheumatoid arthritis [3]. This sex incidence is similar to that found in other forms of arteritis in rheumatoid arthritis. Of these patients, 50% were on long-term corticosteroids, whereas of those without arteritic changes only 38% were on steroids. It is difficult to be certain whether patients are more likely to develop arteritis on steroids, although there is some evidence that this may be so [7]. Certainly, arteritic lesions seem to occur when steroids are stopped suddenly or the dosage is changed, or when the patient is under physical stress. In addition to arteritic lesions in the skin, a sensory or motor neuropathy may occur at these times. The lesions may also be confused with those caused by occupational trauma. Tailor's cutters are particularly liable to show small black marks on the nail folds, which are the result of trauma from needles [3], and similar-looking lesions have been reported in a woodworker whose nail folds had been hit by a hammer [3]. The occurrence of digital necroses is closely correlated with the presence of rheumatoid factor and rheumatoid nodules [2]. Anticardiolipin antibodies can sometimes be demonstrated in patients with vasculitis, and are statistically significantly related to rheumatoid nodules but not

Fig. 56.90 Felty's syndrome: pyoderma gangrenosum of the perianal area.

to thrombotic events [8]. In 13 out of 24 patients antinuclear factor could be demonstrated, sometimes transiently, but these were not regarded as cases of SLE. In addition to the infarcts around the nail folds, the pulps of the fingers may show small painful purpuric nodules (Bywaters' lesions). Histologically, these show leukocytoclastic vasculitis [9]. Palmar erythema is common.

In addition, the skin may show purpuric and necrotic arteritic lesions, which can be painful. The haemorrhagic areas appear without preceding trauma, and vary in size from small petechiae to areas of bruising and necrosis several centimetres in diameter. Sometimes, these areas develop black crusting, which may break down and ulcerate. The ulcers are well defined, with a surrounding bluish red halo. Some of the ulcers are related to rheumatoid nodules. Healing occurs with scarring and may be slow. Arteritis occurs widely in rheumatoid disease, and involvement of the gastrointestinal tract [10] gives rise to abdominal pain, which may result from multiple ischaemic ulcers, gangrene of the bowel, intraperitoneal haemorrhage or splenic infarction.

Gangrene may result from changes in the digital vessels, and sometimes this may extend to involve a large part of the foot or hand, occasionally within a few days. Extensive pustular panniculitis, particularly on the legs, may occur as the result of breakdown of red painful nodular lesions. Treatment can be very difficult [11].

Leg ulcers are not uncommon in the rheumatoid population. Although vasculitis is an important cause, it was only considered to be a factor in 18% of rheumatoid patients in a recent series [12]. Venous insufficiency, complicated by immobility and postural factors, occurs in nearly half of cases, and trauma, pressure or arterial insufficiency are also major factors. Leg ulcers [13] may also be pyodermatous (Fig. 56.90). Arteritic ulcers are more common in males, particularly those with subcutaneous nodules and positive tests for rheumatoid factor. They are usually deep, punched out and slow healing. There is little discoloration of the legs and usually no sclerosis. Some of the ulcers may start as frankly purpuric or nodular lesions. Secondary infection is common, especially with *Staphylococcus aureus*. Response to treatment is slow and relapse frequent. Ten of 27 cases [13] were associated with other clinical evidence of arteritis. Although six patients with leg ulcers and rheumatoid arthritis were described as cases of SLE [14], mainly because of the demonstration of LE cells in four of them, there seems little doubt that they had rheumatoid arthritis. Leg ulcers are said to be more common in Felty's syndrome, in which arthritis is associated with splenomegaly and leukopenia.

Sometimes, bullae of the finger- and toetips may occur in the arteritic lesions of rheumatoid arthritis and occasionally spread to involve a large part of the body [3]. Livedo reticularis [15] also occurs in rheumatoid arthritis, as does delayed pressure-induced vasculitis.

Peripheral sensory or motor neuropathy [16–18] is often associated with clinical evidence of arteritis elsewhere, and is caused by occlusion of the vasa nervorum by the arteritic process. These patients also have a high incidence of rheumatoid factor and nodule formation.

A rash identical to that found in Still's disease (juvenile rheumatoid arthritis; see p. 56.142) occurs in adult rheumatoid arthritis, but is rare. It was found in only seven out of more than 500 patients [19].

Rheumatoid neutrophilic dermatosis. This may occur [20,21] in patients with severe arthritis as symmetrical erythematous nodules and 'urticaria-like' plaques on the dorsa of the hands and arms, extensor aspects of the joints, and the back of the neck and scalp and trunk. They are sometimes tender. Vertical symmetrical infiltrated linear cords on the median axillary line have been reported [22]. Ulceration and vesiculation may occur. Histologically, there is a dense diffuse infiltrate of neutrophils in the dermis, papillary microabscesses and leukocytoclasia, but no vasculitis. The lunulae may be red [23]. Pyoderma gangrenosum may occur in association with neutrophilic dermatosis [24]. Dapsone, either alone or combined with colchicine, may help rheumatoid vasculitis and neutrophilic dermatosis [25]. Another possible cause of nodulosis is the coexistence of erythema elevatum diutinum [26].

Many patients with rheumatoid arthritis who have been treated with steroids show the typical purple discoloration of corticosteroid therapy. This is mainly found on the posterior aspect of the forearms, although it may occur on the legs and elsewhere, and is caused by shearing of the blood vessels in the dermis as the result of degeneration of the dermal collagen.

Associations with other disorders. These have been comprehensively reviewed [27]. They include bullous pemphigoid, pemphigus vulgaris, pemphigus foliaceus, dermatitis herpetiformis, subcorneal pustular dermatosis [28], epidermolysis bullosa acquisita, yellow-nail syn-

drome, acquired cutis laxa [29] and angioendotheliomatosis [30].

Erosive pustular dermatosis of the scalp has been reported [31].

Fig. 56.91 Nodules on the dorsa of the interphalangeal joints in fibroblastic rheumatism. (Courtesy of Dr M.H.A. Rustin, The Royal Free Hospital, London, UK.)

Fibroblastic rheumatism

This entity was originally described by Chaouat *et al*. [1] in 1980, and since then further cases have been described, mainly in France [2]. It occurs at all ages and affects both sexes equally. Clinically, it starts suddenly with symmetrical polyarthritis and cutaneous nodules. These are between 5 and 20 cm in diameter, and can occur before the onset of arthritis. Raynaud's phenomenon, sclerodactyly with inability to join palms, joint effusions and stiffness are frequent. The nodules occur on both surfaces of the hands, usually over the joints, and on the elbows, knees, ears and neck (Fig. 56.91). They are smooth, firm and usually skin-coloured. They resolve in 6 months to a few years. Histology shows a marked proliferation of spindle cells and dermal fibrosis. The hyperplastic cells have the phenotypic features of muscle, suggesting myofibroblastic differentiation [3]. There is a reduction of collagen and non-collagen protein synthesis by the fibroblasts from involved skin, which contrasts markedly with the increase in collagen synthesis in scleroderma.

Systemic involvement does not usually occur—all laboratory tests are negative.

Spontaneous resolution of the nodules may be expected. Joint erosions may develop and changes tend to persist. It is impossible to say whether treatment with aspirin, corticosteroids, colchicine, penicillamine and other anti-inflammatory agents influences the outcome.

Still's disease

SYN. JUVENILE RHEUMATOID ARTHRITIS

The characteristic rash [1] is seen in approximately 25% of patients with Still's disease. It occurs in boys (36%) more frequently than in girls (22%), the incidence decreasing with age. It consists of small non-pruritic macules or papules up to 3 mm in diameter, with a slightly irregular margin. Larger lesions up to 5 cm show central pallor. The colour is bright salmon pink, often surrounded by a zone of pallor. The rash occurs most frequently on the limbs and trunk, but may occur on the face and neck, and lasts only a few hours, characteristically appearing at midday or in the evening with increased temperature of the patient or environment. It is more common in patients with fever, splenomegaly, lymphadenopathy and a raised ESR. It usually appears in the first 2 weeks of the disease but may precede other manifestations by up to 9 years. The rash may occur intermittently for many years and has no prognostic value [2].

Histologically, there is a scanty infiltrate, sometimes of neutrophils if the rash is marked, in the dermis. The rash fades as the disease settles; corticosteroids do not have a specific effect.

The rash can be distinguished from erythema marginatum by the smaller size of the lesions, their occurrence on the face and the fact that lesions are at their greatest size at the onset.

Subcutaneous nodules occur in Still's disease. The histology resembles that seen in the nodules of rheumatic fever rather than in those of rheumatoid arthritis [3]. Still's disease has been associated with Kikuchi's disease (see p. 56.62) [4,5].

Adult Still's disease [1]

In 1971, Bywaters [2] described 14 adults with arthritis and clinical features similar to those of juvenile rheumatoid arthritis. Features include a high spiking fever, sore throat, joint pain and arthritis, a transitory maculopapular rash, lymphadenopathy, hepatosplenomegaly and serositis. The white cell count is raised, and rheumatoid and antinuclear factors are usually absent. Both sexes are equally affected, and the onset is usually in the mid-twenties. The salmon pink maculopapular rash is transitory. It usually occurs in the evening, with fever in over 80% of patients, on the proximal limbs, trunk and face. Alopecia is another feature. Histologically, there is a perivascular dermal infiltrate of lymphocytes and histiocytes. Immunofluorescence is negative. The rash is an adverse prognostic indicator. Approximately one-third remit and another third become chronic; the remainder have an intermittent course. Aspirin and other non-steroidal anti-inflammatory drugs are the first line of treatment, but systemic steroids may be required. In the more chronic cases, intramuscular or oral gold may be helpful. Methotrexate has been of benefit in refractory cases [3].

Sjögren's syndrome [1,2]

SYN. GOUGEROT–HOUWER–SJÖGREN SYNDROME

In 1933, Sjögren [3] drew attention to the syndrome that now bears his name. The first case was described in 1888, although earlier authors had noted several of the manifestations. The most common features of the condition are dryness and atrophy of the conjunctiva and cornea (keratoconjunctivitis sicca), a dry mouth (xerostomia) and rheumatoid arthritis. Two of these three components, particularly the first two, are considered sufficient for diagnosis. The nasal mucosa, the throat and vagina may show similar dryness and atrophy, and there may be diminished gastric secretion. Swelling of the lacrimal and salivary glands may also occur. The diagnosis of keratoconjunctivitis sicca is confirmed by Schirmer's test, which measures tear secretion, staining the cornea and conjunctiva in the region of the palpebral fissure with rose bengal solution, and slit-lamp microscopy, which shows filiform keratitis. The syndrome has been divided into primary Sjögren's syndrome (sicca syndrome), which is not associated with any other connective tissue disease, and secondary Sjögren's syndrome, in which it is associated with rheumatoid arthritis, SLE or systemic sclerosis. The 'sicca' components alone occurred in 35% of one series [4]. Malignant lymphoma is associated with the primary form [5].

Aetiology. The onset occurs most frequently in the fourth, fifth and sixth decades, and 95% of the patients are women. A genetic predisposition is indicated by the finding of an increased incidence of HLA-B8 and -DR3 in patients with Sjögren's syndrome. Associations with the

complement allele C4AQO [6] and HLA-DRw52 [7] in Japanese patients have been reported. That genetic subsets occur is shown by the increased frequency of DR2 in primary Sjögren's syndrome associated with rheumatoid arthritis [8]. There is also an increase in DR4 in patients with primary Sjögren's syndrome and Raynaud's phenomenon [9]. Antibodies to Ro occur in excess in relatives of patients with Sjögren's syndrome, especially in association with DR2 and DR3 [10]. The presence of hypergammaglobulinaemia, antinuclear factors and precipitating antibodies in the serum [11], together with the female predominance and age distribution, and the occurrence of a Sjögren-type syndrome after allogeneic bone marrow transplantation [12], suggest an autoimmune aetiology. Further evidence is provided by the infiltration of the tissues by lymphocytes and plasma cells, and the experimental production of sialoadenitis in guinea pigs [13]. Over 90% show reactivity to parotid extract antigen in the leukocyte migration test [14]. Tubuloreticular structures possibly related to viral infection have been found in labial salivary glands [15]. Raised levels of IgG antibody to cytomegalovirus have been reported [16] and there have been recent suggestions of a link to hepatitis infection [17].

Pathology [1]. The changes in the salivary glands are strikingly similar to the thyroid changes in Hashimoto's disease. Infiltration with lymphocytes and plasma cells, and connective tissue proliferation, are followed by fibrosis. Histological examination of skin may show absence of sebaceous glands and a decrease in the number of sweat glands [2]. Cellular infiltration round the sweat glands has been reported [3,4]. Focal lymphocytic infiltration has been observed in the mucous membranes, and reduced secretory activity of the submucous glands of the respiratory and upper alimentary tracts and of the vagina accompanies progressive atrophy. Degenerative changes are also reported in apocrine glands and in the external root sheath of hair follicles [5].

The mucocutaneous lesions are largely the result of diminished exocrine gland activity, but the ocular changes may not be entirely attributable to reduced secretion of tears. The conjunctiva is at first oedematous but is later very thin. In the subepithelial tissue there is early destruction of elastic tissue, hyalinization of collagen and infiltration with plasma cells.

Clinical features [1–6]. The clinical picture is extremely variable. The consequences of reduced exocrine gland activity may be a minor manifestation of a serious systemic illness, or the presenting, and for many years the only features. In a prospective study of patients presenting with dry eyes, 43% were found to have keratoconjunctivitis sicca with xerostomia, and 23% had associated connective tissue disease, particularly rheumatoid arthritis [7]. Oral symptoms may precede ocular, or both may occur late in the disease. Some cases present with generalized or anogenital pruritus, or with diffuse alopecia. Reduction in the appreciation of taste and smell has been observed [8]. Infections, including pneumonia, oral candidosis and bacterial conjunctivitis, are frequent.

Skin manifestations. Dryness of the skin occurs in approximately 50% of patients, and scaling occurs in approximately

Fig. 56.92 Hyperglobulinaemic purpura in Sjögren's syndrome.

25% of these. The skin may be irritable, and secondary lichenification can develop. Annular erythematous lesions, considered to be a variant of SLE [9], have been reported, but other patients have had no histological evidence of LE [10,11]. Annular erythema in Japanese patients may differ from others. In Japan, annular erythema has been subdivided into three types clinically: Sweet's disease-like annular erythema with an elevated border; SCLE-like marginally scaled erythema; and papular erythema [12]. Annular erythema of Asian patients is the counterpart of SCLE in white people, and may occur in patients with LE, Sjögren's syndrome or both diseases [13]. Lesions are recurrent and often occur on the face and trunk; they clear without pigmentation. They are not photosensitive in origin. Ro antibody-positive patients tend to develop annular polycyclic lesions of SCLE as well as neuropsychiatric and pulmonary disease, and have a guarded prognosis [14]. Partial or complete loss of sweating may be noted. Vascular responsiveness may also be impaired [15], and nail fold capillary abnormalities are found [16]. The hair may be dry, sparse and brittle, and diffuse alopecia may involve the scalp, limbs, axillae and pubis. Erythema of the nose and cheeks has been reported [5].

Non-thrombocytopenic purpura may occur as recurrent crops of round pink lesions in dependent areas (Fig. 56.92). The lesions resolve in a few days, leaving brown pigmented stains, but crops occur over many years. Biopsy shows perivascular mononuclear infiltration. Hypergammaglobulinaemia is a feature of patients with purpura. Other vascular lesions occur, including an arteritis like that seen in rheumatoid arthritis, lesions indistinguishable from polyarteritis nodosa and nail fold infarcts, splinter haemorrhages and gangrene of the fingers [17]. Raynaud's phenomenon occurs in 25% of cases.

Mouth. The saliva is at first thick and mucoid, but later salivary volume decreases. The tongue is red, smooth and dry, and in severe cases there may be difficulty in swallowing dry food. Parotid duct narrowing and web formation may develop [18]. Dental caries is often severe and progressive. The lips are red, dry and scaly. There are frequently cracks at the corners of the mouth. Chronic oral candidiasis is frequent. Recurrent episodes of swelling of one or both parotid glands or, less often, the submaxillary and sublingual glands, may be accompanied by fever.

Other mucous membranes. Atrophic changes in the mucous membranes of the upper respiratory tract lead to nasal crusting and dryness, recurrent episodes of infection, hoarseness or aphonia. Pulmonary infiltration, atelectasis or fibrosis may occur. Atrophic rhinitis can occur, and the sense of smell may be reduced. Digestive symptoms are attributable to atrophy of the gastric mucous membrane with achlorhydria. Similar changes in the vulva and vagina give rise to pruritus and vaginitis, and dryness of the anal and rectal mucous membrane leads to dyschezia and pruritus.

Other manifestations. In patients without associated connective tissue disease, mild articular symptoms occur in 83%, with mild synovitis. They respond to non-steroidal anti-inflammatory drugs [19]. Cervical or generalized lymphadenopathy and enlargement of the liver and spleen, which is sometimes considerable, may be found. Features of Sjögren's syndrome can be demonstrated in patients with primary biliary cirrhosis [20]. Splenomegaly occurred in approximately 20% of one series [1]. Oesophageal dysfunction has been reported in one-third of patients [21]. The pancreas may be involved. Pulmonary abnormalities occur in 9–29% of cases, and appear to be similar in patients with primary or secondary Sjögren's syndrome [22]. They include pulmonary fibrosis, pulmonary hypertension [23], recurrent chest infections, granulomatous infiltration and fibrosing alveolitis. The most common functional disorders are a restrictive ventilatory defect and impaired gas transfer. Speckled antinuclear factor is frequent. Neurological abnormalities are generally mild [6], but peripheral and trigeminal neuropathy (probably resulting from vasculitis of the vasa nervorum), cerebral manifestations, both focal and diffuse, and spinal cord disease are associated with the presence of anti-Ro antibodies [24]. Migraine is more frequent than expected and is associated with Raynaud's phenomenon [25]. Myopathy and myasthenia [26] have been reported. Interstitial nephritis [27], renal tubular acidosis, impaired renal concentrating ability and generalized aminoaciduria [28] are the main renal lesions. Impaired renal function can occur without clinical manifestations [29]. A high prevalence of fetal loss has been

recorded, but there was no correlation with anticardiolipin or anti-Ro antibodies [30].

Sjögren's syndrome in childhood. Primary Sjögren's syndrome is rare in childhood. Recurrent annular erythema similar to that seen in adults has been reported on the face, trunk and limbs [1]. Episodes, with or without fever and parotid swelling, occur over years and last a few months. Anti-Ro antibodies are positive but there is no evidence of SLE. Histology of the lesions shows a dermal lymphocytic infiltration but no vasculitis, and immunohistology reveals no immunoglobulins or complement at the dermal–epidermal junction or around blood vessels. The condition responds to oral steroids.

Laboratory abnormalities. Hypergammaglobulinaemia and rheumatoid factor are frequently demonstrated in the serum, even in patients without arthritis. There may be increased serum viscosity [1,2]. Antinuclear antibodies are present in more than 50% of patients (homogeneous factor is more frequent than speckled, and nucleolar factor is only occasionally found). Anti-DNA antibody can occasionally be demonstrated, but anti-Sm and anti-RNP antibodies are never found in the sicca syndrome alone. Precipitating antibodies reacting with saline extracts of human tissues were demonstrated 30 years ago [3]. Similar, or identical, antibodies have been designated anti-Ro (also called SS-A) and anti-La (SS-B).

Antibodies to Ro/La were found in 53% of patients with Sjögren's syndrome [4]. Facial rashes, photosensitivity and serositis in patients with Sjögren's syndrome were associated with SLE. Initially, anti-La was thought to be highly specific for the sicca complex but this is not correct. Anti-Ro antibodies are particularly associated with vasculitis, purpura, lymphadenopathy, and haematological and serological abnormalities [5]. Precipitating antibodies to extracts of lacrimal and salivary glands have been reported in three cases [6]. Antibody to salivary duct epithelium can be demonstrated in approximately 50% but is also found in uncomplicated rheumatoid arthritis [7]. Thyroglobulin antibodies are present in 25% of cases [8]. Leukopenia and eosinophilia are not infrequent. Immune complexes occur in 60%, but are not related to disease activity [9]. Recurrent annular erythema is associated with anti-La antibodies in Sjögren's syndrome [10,11] but not all anti-La-positive patients have a rash, and no disease-specific epitope has been demonstrated [12]. The epitope of anti-Ro antibody is similar in the annular erythema of Sjögren's syndrome and SCLE [13].

Associations [1]. Sjögren's syndrome occurs in association with systemic sclerosis [2,3], DLE [4,5], SLE [6,7], polyarteritis nodosa [8] and polymyositis and dermatomyositis [9]. Of 122 patients with Sjögren's syndrome, 26% had rheumatoid arthritis, 22% had systemic sclerosis, 22% had sicca syndrome and 20% had primary biliary cirrhosis [10]. Sjögren's syndrome occurred in 69% of patients with systemic sclerosis in this series but in only 20% of another [11]. Three patients had anti-DNA antibodies in the absence of any evidence of SLE [1]. Sjögren's syndrome has also been associated with SCLE and Sweet's syndrome [12]. A range of lymphoproliferative disorders occurs, including B-cell [13] and T-cell [14] lymphomas. Drug allergy, especially to penicillin [15], is more common than expected. The 'sicca complex' [16] is common in patients with active chronic hepatitis, primary biliary cirrhosis and cryptogenic cirrhosis [17]. Sjögren's syndrome may be associated with complete or partial lipodystrophy [18], and has been reported with granulomatous panniculitis [19]. Features indistinguishable from Sjögren's syndrome have been found in a case of Behçet's disease [20]. It has occurred with coeliac disease and autoimmune thyroiditis [21], hypoparathyroidism [22], myasthenia gravis [23], idiopathic haemochromatosis [24], autoimmune haemolytic anaemia [25], dermatitis herpetiformis [26], Darier's disease [27], multicentric histiocytosis [28], ulcerative colitis, sarcoidosis [29] and Waldenstrom's hypergammaglobulinaemic purpura [30].

Diagnosis. So variable is the clinical picture that the diagnosis is easily overlooked, except in the more obvious cases presenting with ocular or oral symptoms.

It should also be suspected in the presence of anogenital pruritus in association with ocular and oral changes or with rheumatoid disease, and should be confirmed by specialist ophthalmological examination. Biopsy of labial salivary glands [1] or nasal mucosa [2] is useful, and the value of lip biopsy has been stressed, but a negative biopsy does not exclude the diagnosis [3]. The demonstration of antisalivary duct antibody may be helpful. Contrast sialography is useful [4], and sequential salivary scintigraphy [5] gives objective and sensitive estimation of salivary gland function. Every case requires detailed investigation to determine the extent and nature of the associated abnormalities. The demonstration of anti-Ro (SS-A) and anti-La (SS-B) antibodies may be helpful in diagnosis. Anti-La may antedate clinical evidence of Sjögren's syndrome by months or even years [6].

Treatment. Symptomatic treatment for the dryness of the eyes is best accomplished by lubricating agents, such as 0.5% methylcellulose eye drops instilled into the eyes four or five times daily. Bromhexine (Bisolvon R) 16 mg three times daily has been found to increase the lacrimal secretion [4], but has no effect on salivary flow [7]. However, it does change the salivary composition towards normal [8]. Artificial saliva can be prescribed, and steam inhalations or an air humidifier may help dryness of the respiratory tract. Patients with Sjögren's syndrome associated with SLE seem to improve more than those with primary Sjögren's syndrome. Systemic corticosteroids are effective in reducing parotid swelling, but rarely increase parotid or lacrimal secretion. The immunological abnormalities in the serum are not markedly altered by corticosteroids, although patients remain in good health. Chloroquine or hydroxychloroquine sulphate by mouth have been found useful by some authors [9] but not by others [10]. Ciclosporin improved subjective xerostomia and seemed to retard the histopathological lesion [11], but its use is probably not justified. Nifedipine may help pulmonary Raynaud's phenomenon [12]. A patient with associated polymyositis improved with monthly intravenous pulse cyclophosphamide therapy [13]. The annular erythema in Japanese patients may be controlled by prednisolone 10–20 mg/day or by dapsone.

Rheumatic fever

Erythema marginatum is the characteristic rash of rheumatic fever, and occurs in 25% of cases [1]. It appears as evanescent asymptomatic pinkish superficial semicircles and rings, which disappear without scaling or pigmentation in a few days. Histologically, there is a perivascular infiltration of neutrophils in the papillary dermis, and biopsy may help in the early diagnosis of rheumatic fever when the rash precedes arthritis and carditis [2]. Erythema multiforme, petechiae and urticaria may sometimes be seen in rheumatic fever. Livedo reticularis has been reported [3]. The overall clinical picture must be distinguished from post-streptococcal reactive arthritis [4].

Subcutaneous nodules occur particularly on the occiput, wrist and the backs of the forearms, and are smaller and more transient than those seen in rheumatoid arthritis, from which they can be distinguished histologically [5–7]. Generalized eruptive histiocytomas have also occurred [8].

The cutaneous porphyrias

[R.P.E. Sarkany, pp. 57.1–57.23]

Introduction

The porphyrias are a group of disorders caused by defects in the biosynthesis of haem. Their relevance to the skin arises from the phototoxic properties of the porphyrins, which accumulate in most porphyrias and cause photosensitivity.

The majority of the porphyrias are inherited. Many of them affect other organs as well as the skin. The recognition and management of both the genetic and internal consequences of porphyrias presenting in the skin are a key challenge for the dermatologist.

Clinical management in these disorders is made easier when the clinician understands their theoretical basis. Thus, this section is divided into two halves. The first provides a theoretical basis for understanding the porphyrias, the general principles of clinical management and a clinician's guide to laboratory testing. The second half covers each individual disease in detail.

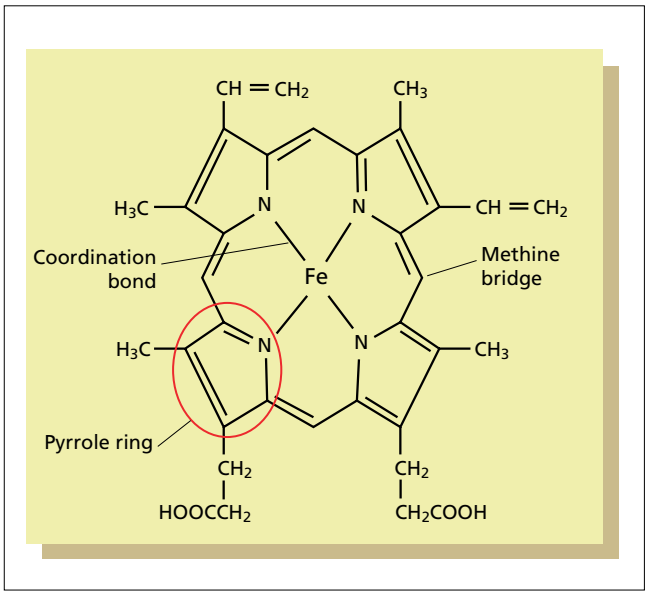

Fig. 57.1 The haem molecule and its key structural features. The alternation of single and double bonds around the tetrapyrrole ring indicates the aromaticity of the molecule, central to its chemical characteristics. The four coordination bonds between iron and nitrogen atoms are shown. The two remaining bonds between the iron and either molecular oxygen or amino acid residues lie perpendicular to the page.

General considerations: theoretical basis, clinical features and laboratory testing in porphyria

A theoretical basis for understanding the porphyrias

The phototoxicity of porphyrins

The phototoxic properties of porphyrins are responsible for the cutaneous features of the porphyrias. Porphyrins are intermediates in the biosynthesis of haem, and consideration of the chemical features of the haem and porphyrin molecules is necessary to understand the cause of porphyrin phototoxicity.

The chemistry of porphyrins and haem [1]. A pyrrole is a ring composed of four carbon atoms and one nitrogen atom. Four pyrroles linked into a ring create a tetrapyrrole, a remarkable and biologically critical molecular structure found in chlorophyll, haem and vitamin B_{12}. A porphyrin is a special type of tetrapyrrole in which four pyrrole rings are linked by methine bridges into a large ring structure.

Haem is the molecule created by the insertion of ferrous iron into the centre of the porphyrin molecule, protoporphyrin IX (Fig. 57.1). Essentially, incorporation of iron into the porphyrin molecule enables it to become biologically useful. Iron's capacity to bind to molecular oxygen, and to transfer electrons (by moving between the 2+ and 3+ oxidation states) makes it potentially useful in biological systems, but free iron precipitates in the presence of water. For iron to be useful, it has to be kept soluble by protecting its binding sites against water. In addition, subtle modification of the electronic structure of the iron atom can optimize its ability to transfer electrons and reversibly bind molecular oxygen. Binding of iron to the porphyrin molecule solubilizes iron and also optimizes its electronic structure. The porphyrin's central cavity is the right size to fit an iron atom, and its four central nitrogen atoms occupy four of the iron's coordination binding sites leaving only two free. A key feature of the porphyrin structure is that (see Fig. 57.1) each double bond is adjacent to a single bond, so it is 'aromatic' with 18 of its electrons being delocalized and free to move around the molecule. This electron current results in the central nitrogen atoms tending to donate electrons to the iron atom, as well as other subtler electronic interactions involving transient changes in the porphyrin's electronic state [2]. Haem can bind to a variety of proteins, and the nature of this interaction reflects the protein's function. In proteins with electron transport functions, such as respiratory cytochromes, amino acids bind to both remaining coordination binding sites on the iron so that haem can transfer electrons through alterations in the iron's oxidation state. In proteins with oxygen-binding functions, such as haemoglobin, an amino acid binds to one of the iron's remaining coordination binding sites, leaving the sixth site free to bind to oxygen. In summary, the aromatic porphyrin structure is well suited to complexing with iron to form haem, rendering the iron useful for electron transfer (respiratory cytochromes), reversible oxygen binding (haemoglobin and myoglobin), and oxidation and reduction reactions (cytochrome P450, catalase), with fine tuning of the iron's functionality being determined by the apoprotein which binds to the haem.

Photochemistry of the porphyrins [3,4]. The complex electronic structure of the large aromatic porphyrin molecule results in its 18 delocalized electrons having unusual excitation characteristics. These electrons are excited by relatively long wavelength light. The main absorption peak is at 408 nm ('Soret band') [3], and this long wavelength of exciting light predisposes to phototoxic behaviour by the porphyrin; these photons have insufficient energy to chemically alter the porphyrin structure, so that alternative fates for the energy, particularly fluorescence and phosphorescence, become more likely [4]. Thus, following excitation by light around the 408 nm peak, electrons either return to the non-excited ground state by releasing the energy as the characteristic red fluorescence, or the porphyrin's excited singlet state transforms (by intersystem crossing) to the longer-lived excited triplet state.

Transfer of energy from this excited triplet state to neighbouring molecules leads to the phototoxicity responsible for the clinical features of the cutaneous porphyrias. Thus cutaneous disease in the porphyrias can be thought of as a by-product of the unusual porphyrin structure which enables haem-proteins to fulfil their biological functions.

Enzyme deficiencies and the porphyrias

The porphyrias all result from a partial deficiency of one of the enzymes required for the biosynthesis of haem. Such a partial deficiency causes the accumulation of the enzyme's substrate. The toxicity profile of the accumulated molecule determines the clinical features of the resulting porphyria. Thus, a basic understanding of the biosynthetic pathway enables the clinician to interpret laboratory results and to predict the clinical features of each porphyria on the basis of each porphyrin's properties.

The biosynthesis of haem [1,2] (Fig. 57.2). Haem is synthesized from simple biochemicals (glycine and succinyl CoA) via an eight-step pathway, each step being catalysed by an enzyme. Synthesis of the pyrrole ring (porphobilinogen (PBG)) is followed by assembly of the tetrapyrrole structure (hydroxymethylbilane). One of the pyrrole rings (the 'D' ring) is 'flipped' around to create the III isomer (the alternative I isomer forms in the absence of the cosynthase enzyme). Next, the carboxylic acid side-chains of uroporphyrinogen III are progressively decarboxylated via coproporphyrinogen III to protoporphyrinogen, which is then oxidized to protoporphyrin IX. It is likely that the progressive decarboxylation to remove six of the eight electron-withdrawing carboxylate groups increases the flux of electrons onto the molecule's central nitrogens to facilitate coordination with iron. Finally, ferrous iron is chelated into the protoporphyrin's central cavity to form haem. Around 80% of haem is synthesized in erythroid cell precursors in the bone marrow (for haemoglobin production). The decarboxylation of uroporphyrinogen to coproporphyrinogen, and thence to protoporphyrinogen, decreases water solubility, so that uroporphyrinogen is only excreted via the kidneys whereas hydrophobic protoporphyrinogen and protoporphyrin are exclusively excreted into the bile. Coproporphyrinogen is excreted by both routes. Physiological concentrations of porphyrins stay low because of the high efficiency of haem synthesis.

Clinical features of the porphyrias: general considerations

Porphyrias present with either skin disease or acute attacks or both.

The classification of the porphyrias [1,2]

In any porphyria, a partial enzyme deficiency causes the accumulation of porphyrins. The enzyme deficiency associated with each disorder is shown in Fig. 57.3. The porphyrias have previously been classified, according to the predominant site of porphyrin accumulation, into the erythropoietic group (congenital erythropoietic porphyria and erythropoietic protoporphyria) and the hepatic group (all the others). This division is not of value clinically. For the clinician, the key division is between porphyrias that cause acute attacks and those that cause skin disease. In this chapter the following classification is used for the six common porphyrias:

1 Cutaneous disease only:
Porphyria cutanea tarda (PCT)
Congenital erythropoietic porphyria (CEP)
Erythropoietic protoporphyria (EPP).
2 Cutaneous disease and acute attacks:
Hereditary coproporphyria (HC)
Variegate porphyria (VP).
3 Acute attacks only:
Acute intermittent porphyria (AIP)

Porphyria and the skin

The cutaneous porphyrias share many features. Consideration of these underlying similarities is necessary for a logical approach to clinical management of patients.

All the cutaneous porphyrias, except EPP, present with fragility and blistering in light-exposed skin, and can appear so similar that they can only be reliably differentiated by biochemical analysis. The term 'bullous porphyrias' is often used for this group of diseases. Also, the

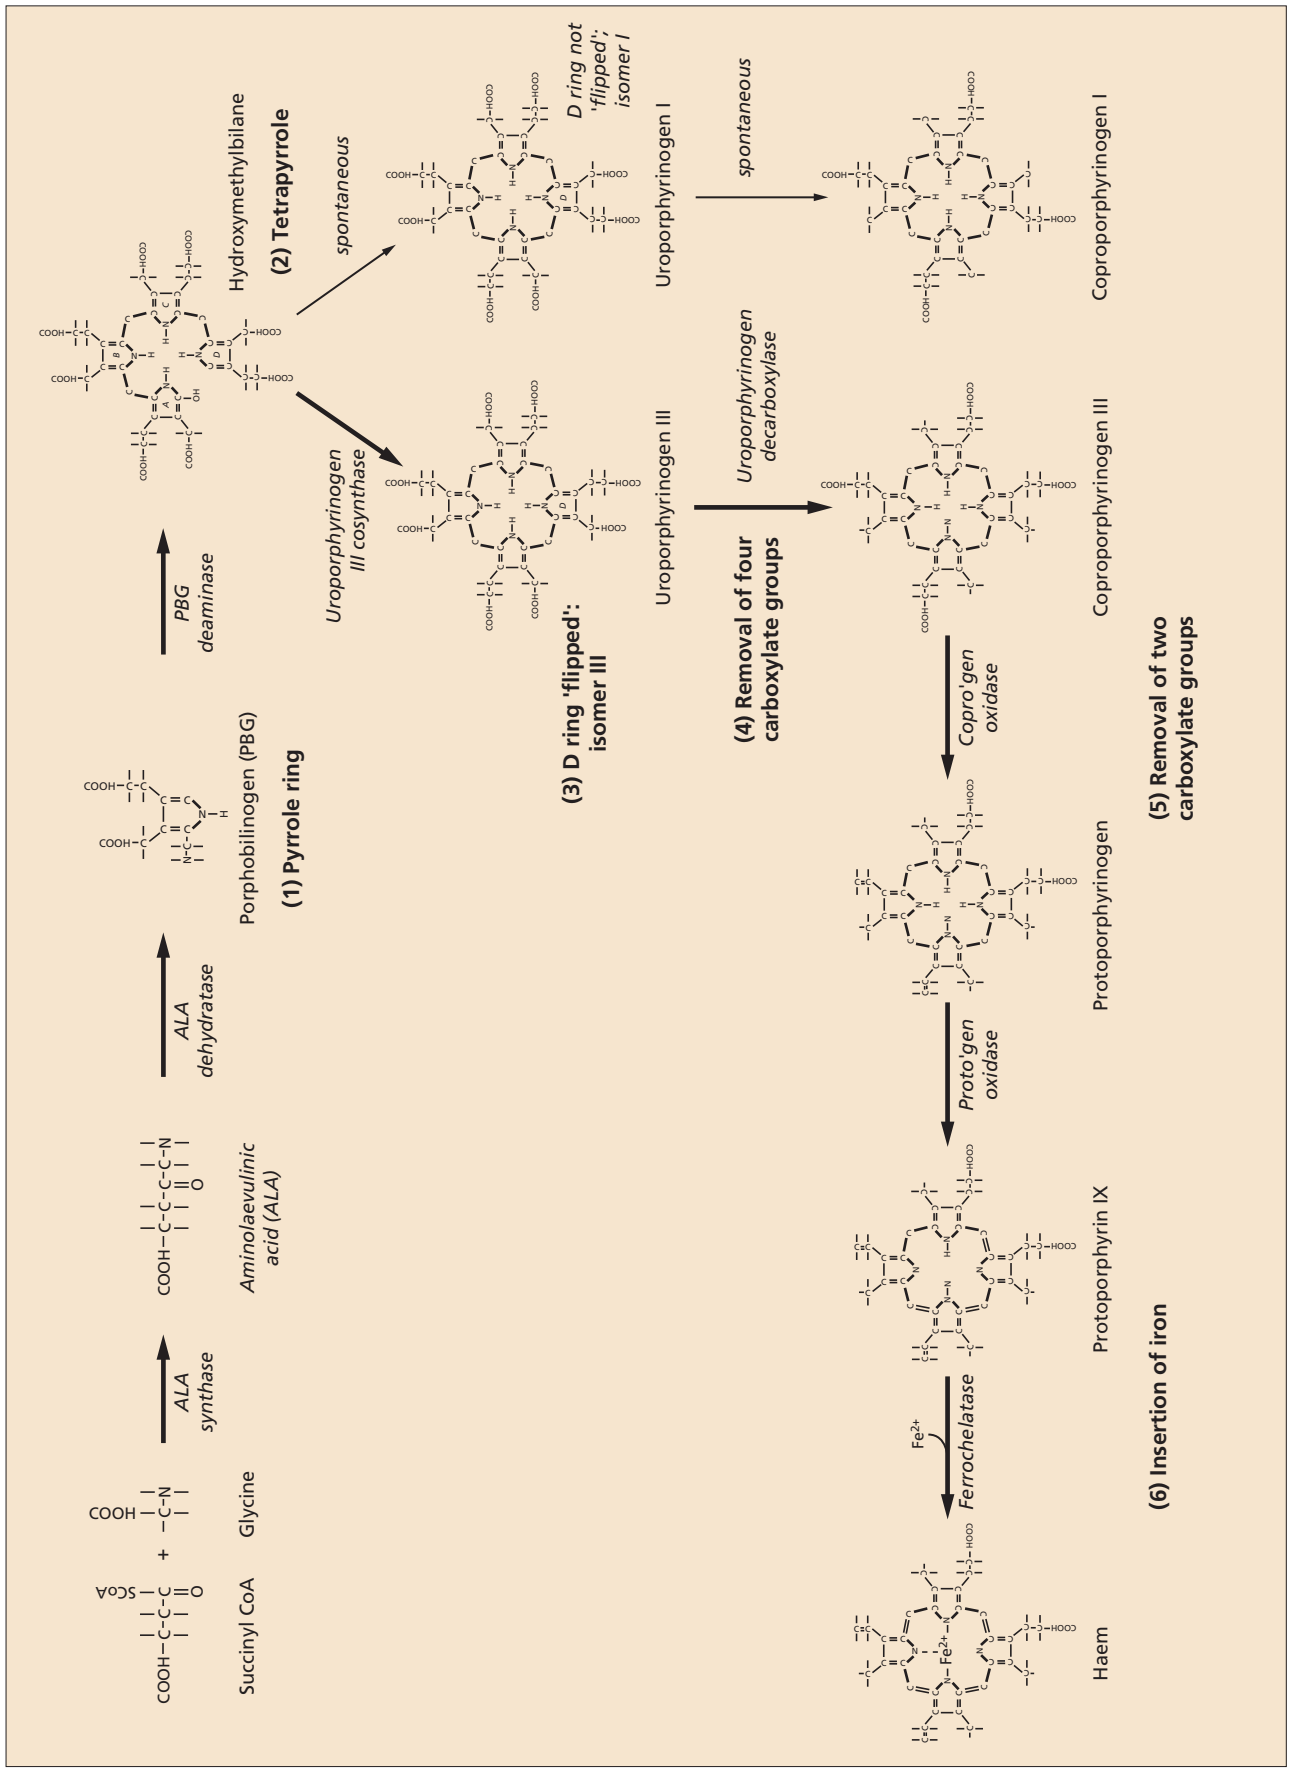

Fig. 57.2 The pathway of haem biosynthesis showing the six key structural changes.

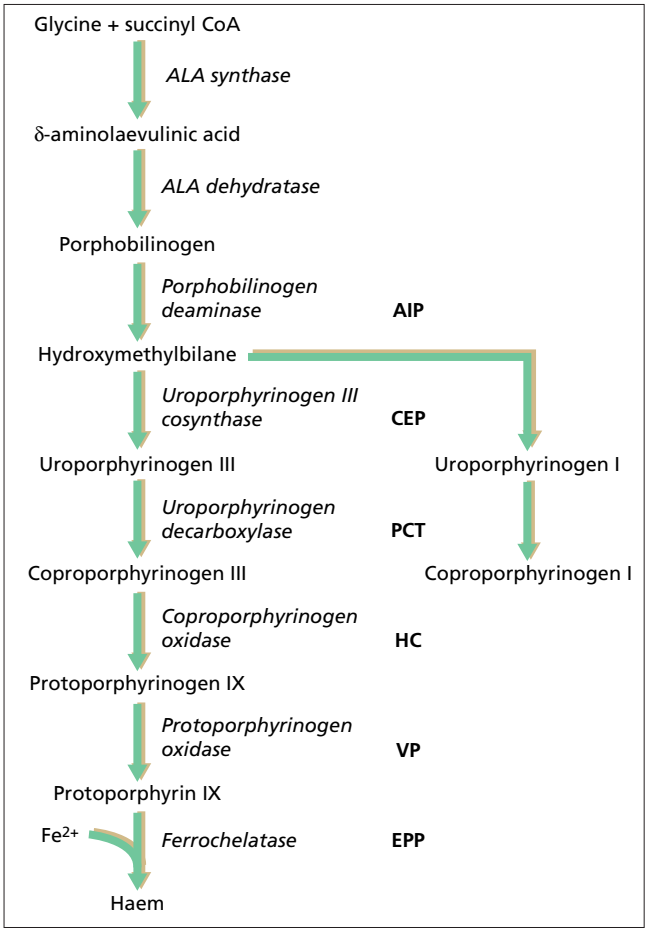

Fig. 57.3 The pathway of haem biosynthesis showing the enzyme deficiency associated with each porphyria. (The abbreviations of disease names are defined in the text relating to classification of the porphyrias.)

mechanism underlying the skin disease in all cutaneous porphyrias is a local porphyrin phototoxicity reaction, and this common pathogenetic mechanism results in similar histopathological appearances. Finally, Soret wavelength light (408 nm) causes the skin disease in all these disorders, so the same strategy for photoprotection applies to them all, as detailed below.

The pathogenesis of skin disease in porphyria (Fig. 57.4) [1,2]. Photons of violet light, with a wavelength peak at 408 nm, transform the porphyrin molecule into an excited singlet state. This may revert to the unexcited ground state by emission of the characteristic red porphyrin fluorescence, but intersystem crossing can convert it to the excited triplet state, long-lived enough to interact with other molecules, particularly molecular oxygen, converting it to excited singlet oxygen in the process. The singlet oxygen damages tissue directly, and also indirectly by stimulating complement activation [3], mast cell degranulation [4] and matrix metalloproteinase activity [5]. The site of this phototoxic reaction in the skin determines the clinical characteristics of the porphyria. In EPP, lipophilic protoporphyrin tends to localize to membranes including endothelial cell membranes, and to remain within erythrocytes, and the phototoxic reaction involves upper dermal blood vessels causing pain. In PCT, the water-soluble uroporphyrin diffuses easily into surrounding tissues and the phototoxic reaction occurs in the upper dermis, causing lysis of cells in the superficial dermis with the formation of membrane-limited vacuoles which merge to produce a blister under the basal lamina, producing the characteristic clinical presentation [6]. In VP, copro- and protoporphyrin accumulate (Fig. 57.3), but patients suffer from PCT-like upper dermal blisters rather than EPP-like acute pain. This is likely to be because, although hydrophobic porphyrins predominate in plasma in VP, hydrophilic porphyrins, particularly uroporphyrin, predominate in the skin, probably due to secondary local photoinactivation of uroporphyrinogen decarboxylase (UROD) in the skin by coproporphyrin [2]. In addition, the protoporphyrin in VP is conjugated to a peptide which may reduce its phototoxicity.

There is no simple correlation between the plasma porphyrin concentration and the severity of cutaneous disease in porphyria because of the large number of local variables which can alter the extent of the phototoxic reaction in the skin, and an increased plasma porphyrin concentration is not always associated with cutaneous disease [7].

Histopathology of the skin in porphyria [8,9]. In all the cutaneous porphyrias, homogeneous material is seen within vessel walls of the upper dermal and papillary vascular plexus. It is periodic acid–Schiff (PAS)-positive and diastase resistant, and contains a protein polysaccharide complex, lipids and tryptophan. Immunofluorescence reveals immunoglobulins (mainly IgG) in a similar vascular distribution, and IgG at the dermal–epidermal basement membrane zone, in involved skin. Electron microscopy shows reduplication of the vascular basal lamina and the presence of masses of fine fibrillar material, mainly around these blood vessels and often also at the dermal–epidermal junction. In EPP the vessel wall changes are more pronounced, whereas the basement membrane zone changes predominate in affected skin in PCT and VP. In the bullous porphyrias, bullae are subepidermal with the split occurring in the lamina lucida [10] (Fig. 57.5) leaving the dermal papilla protruding into the blister cavity, an appearance called 'festooning' [9]. The findings in bullous porphyrias are indistinguishable from those of pseudoporphyria. In EPP in the acute phase there is visible endothelial damage in superficial dermal vessels [11]. Electron microscopy shows the 'amorphous' material seen in vessel walls on light microscopy in light-exposed skin to be a replicated, layered and fragmented

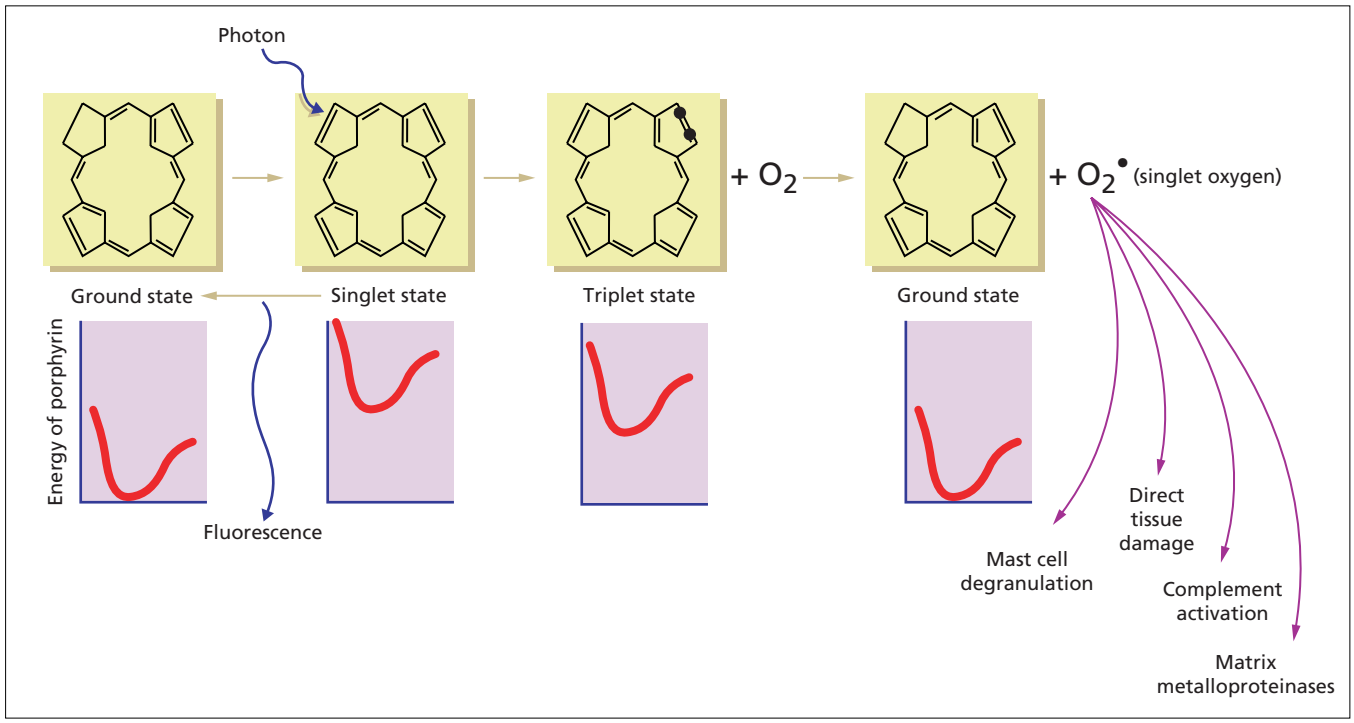

Fig. 57.4 The pathogenesis of skin disease in porphyria.

basement membrane, with fine fibrillar material permeating the capillary connective tissue sheath and extending beyond the vessel walls, caused by the repeated episodes of damage [12,13].

General considerations in the management of skin disease in porphyria. Apart from PCT, and to some extent CEP, where effective specific treatments exist, the management of the skin in the other cutaneous porphyrias is based on preventing violet (Soret wavelength) light penetrating the epidermis. The connection between sun exposure and symptoms is obvious in EPP, but is not obvious to patients with the bullous porphyrias where fragility and blistering are not related to individual episodes of sun exposure. It can therefore be difficult to convince these patients of the importance of photoprotection. Basic measures include sun avoidance behaviour, sun-protective clothing and hats. Most sunscreens, including UV-absorbent chemical 'total sunblocks', do not protect against the visible violet Soret wavelength [14]; any sunscreen providing significant visible light protection will be opaque rather than transparent. Sunscreens containing reflectant particles, particularly large particle size titanium dioxide (pigmentary grade), zinc oxide and iron oxide, can effectively protect against violet light [15], and cosmetically acceptable sunscreens with reasonable protection up to 430 nm are available commercially, e.g. Dundee sunscreen, Tayside Pharmaceuticals, Dundee, UK [14,15]. Dihydroxyacetone paint induces formation of a light-absorbing brown pigment in the stratum corneum, and has been used in some patients with EPP [16]. Some reasonably clear window films can absorb some violet light, and are useful on car or home windows, particularly in EPP and CEP [17]. This author generally uses two films which are clear and provide reasonable, though not complete, protection against Soret wavelength light (Dermagard film, Bonwyke, Hants, UK; CLS200XSR film, Madico, USA). Clearly, films applied to car windows must comply with local legislation, which varies considerably in different parts of the world.

Acute attacks of porphyria [1,2]

AIP, HC and VP can all cause acute attacks, and HC and VP may also cause cutaneous disease. (A rare autosomal recessive acute porphyria, aminolaevulinic acid (ALA) dehydratase porphyria, which does not cause skin disease has also been reported and will not be discussed further.)

Definition. An acute and potentially fatal illness, frequently triggered by drugs and hormones which are metabolized by cytochrome P450. It is characterized by an acute neurotoxic reaction in many tissues.

Prevalence. The commonest acute porphyria is AIP, followed by VP. HC is rare. The prevalence of clinically overt acute porphyria in Europe is 1–2/100 000 inhabitants, but over 90% of individuals possessing AIP or VP gene defects are asymptomatic, so the enzyme deficiencies are common; PBG deaminase deficiency, which causes AIP, is present in 0.2% of all blood donors [3].

Aetiology [4]. Impaired activity of PBG deaminase is associated with acute attacks. The deficiency can be primary (as in AIP) or secondary, the latter being due to inhibition of the enzyme by accumulated coproporphyrinogen and protoporphyrinogen (as in HC and VP) [5]. In the liver, haem is mostly incorporated into cytochrome P450 proteins, whose production is induced by many of the drugs and hormones metabolized by the P450 system. When a drug or hormone induces cytochrome P450, and hence acutely increases the hepatic requirement for haem, the inability of the pathway to respond adequately because of the PBG deaminase deficiency is exposed. This acute hepatic haem deficiency in turn causes secondary accumulation of ALA and increased ALA synthase activity due to loss of end-product negative feedback. The symptoms of the acute attack result from neuronal dysfunction, the pathogenesis of which is not fully understood though postulated mechanisms include disturbed metabolism of neurotransmitters (due to reduced activity of haem-containing hepatic trytophan dioxygenase), direct neurotoxicity of accumulated ALA (which structurally resembles the neurotransmitter γ-aminobutyric acid (GABA)) and acute haem deficiency within neurones.

Factors that may precipitate an acute attack [1]. The most common precipitants are drugs and the menstrual cycle, with recurrent attacks often occurring in the late luteal phase. Alcohol, cannabis, fasting, stress and infection may also trigger attacks. It is not possible to predict whether a specific drug will provoke an attack in an individual. Drugs should be prescribed only after reference to a drug list (Table 57.1), but such recommendations are not absolute and do not substitute for clinical judgement. The risk of a drug provoking an attack is obviously highest where

Table 57.1 Drugs considered to be safe in patients with acute porphyria. This list was compiled in 2002. It is regularly updated and the most up-to-date version is available on the Internet [http://www.uwcm.ac.uk/study/medicine/medical_biochem/porphyria/porphyria3.htm (2002)]. § Safety under review.

that drug has previously caused an attack in that patient, and in any patients who have previously had symptoms suggestive of an acute attack.

Clinical presentation [1,2]. Acute attacks are five times more common in females, and most frequently occur between the ages of 10 and 40 years. They are rare before puberty. The severity of acute attacks varies from mild abdominal pain, sometimes accompanied by vomiting and constipation, through to very severe attacks with bulbar palsy and respiratory paralysis. Severe, constant abdominal pain occurs in almost all acute attacks. It can be in any quadrant or even in the back, buttocks and thighs, and may require large amounts of opiate analgesia. There may be guarding but no true peritonism. Vomiting and constipation (due to partial ileus) occur in at least half of attacks. The pulse rate and blood pressure are often moderately raised, dehydration is common and hyponatraemia (probably caused by inappropriate secretion of vasopressin) may be severe enough to cause convulsions. The pain, tachycardia, hypertension and partial ileus are all caused by an acute autonomic neuropathy. Sensory or sympathetic involvement with severe dysaesthesia or causalgia are rarer. A motor neuropathy occurs in 5–10% of cases, usually heralded by aching pains in the limbs and sometimes by disappearance of the abdominal pain. It may cause a severe acute Guillain–Barré-type syndrome. The motor neuropathy usually occurs when porphyrinogenic drugs have been adminstered inadvertently during the developing acute attack. Respiratory paralysis is the commonest cause of death. Confusion, abnormal behaviour, agitation and hallucinations occur in up to 50% of attacks. Porphyria is not related to any chronic psychiatric disease, except generalized anxiety.

Biochemical diagnosis of an acute attack [7,8]. The diagnostic finding is of increased urinary PBG excretion. Although qualitative screening tests may be useful in an emergency, their low sensitivity makes it essential to also carry out a quantitative assay. Commercially available kits can provide a rapid and reasonably sensitive semi-quantitative assay, after which a specific quantitative assay should be carried out (reliable quantitative assay kits are commercially available). A normal urinary PBG concentration excludes an acute porphyric attack (except in ALA dehydratase porphyria). An increased PBG concentration does not necessarily mean that an acute attack is occurring since urinary PBG falls between attacks but does not always return to normal, particularly in AIP. The higher the PBG concentration, the more likely an acute attack, but, in the presence of an increased urinary PBG, an acute attack can only be diagnosed on clinical grounds. Urinary ALA is also increased during an acute attack but to a lesser extent than PBG and is not as useful diagnostically (the only exception being ALA dehydratase porphyria in which only ALA is increased and urinary PBG is normal).

Long-term management of patients with acute porphyria [1,2]. The dermatologist may diagnose VP (or less commonly HC) on the basis of cutaneous disease before any acute attack has occurred. Once an acute porphyria has been diagnosed, the patient should be given a list of drugs with information about their safety in acute porphyria. Many lists exist both of 'safe' drugs and 'unsafe' drugs. It is obviously vital for clinicians and patients to be clear about whether they are dealing with a list of 'safe' or of 'unsafe' drugs, and there are advantages to using a 'safe' list. A widely recognized list of safe drugs is shown in Table 57.1 [6]. A standard list of unsafe drugs is also widely available [9]. It is important to recognize that a list of safe drugs is a guide, and that no drug can be guaranteed to be safe in an individual patient. Conversely, drugs which do not appear on a 'safe' list should not be withheld in patients who need them to treat a serious or life-threatening illness; in that situation expert advice should be sought from a specialist centre.

The patient should also be advised to abstain from alcohol, cannabis and from prolonged calorie-restricted diets, and to wear an emergency identification bracelet (e.g. MedicAlert) so that medical staff are aware of the diagnosis if the patient is ever found in an unconscious or confused state. Screening of relatives is essential to identify those with clinically latent disease, who are also at risk of acute attacks. The choice of test and interpretation of results can be complex and details are covered in the 'laboratory testing' section and under each individual disorder in this chapter. Such testing is ideally carried out in a specialist centre. Relatives diagnosed with an acute porphyria need the same advice as the index case. Conversely, patients with PCT, EPP and CEP can be reassured that acute attacks are not part of their disease.

Treatment of the acute attack [1,2]. The key to managing an acute attack is early diagnosis. Once the diagnosis has been made, avoidance of acute attack-inducing drugs is essential to prevent exacerbation. Supportive treatment includes analgesia, sedatives and antiemetics (with drugs known to be safe in acute porphyria) and careful management of fluid balance with rehydration and correction of hyponatraemia. The specific treatments are intravenous haematin or haem arginate (Normosang, Orphan Pharmaceuticals), which have now replaced carbohydrate as the treatment of choice. These drugs suppress hepatic ALA synthase activity and so reduce ALA and PBG accumulation. Haem arginate is more effective when given earlier during an attack, increasing the importance of early diagnosis. Advice from a specialist centre should be sought when treating an acute attack.

A clinician's guide to laboratory testing in porphyria [1–3]

Although clinical features may raise the possibility of a porphyria, the cutaneous presentations of several porphyrias are very similar. Precise diagnosis is essential in porphyria because of the great differences in clinical management between porphyrias which can be clinically indistinguishable. An accurate diagnosis can only be made on the basis of porphyrin analyses carried out in an experienced laboratory. The clinician's role is to suspect the diagnosis of cutaneous porphyria, and then to use laboratory testing to confirm whether this is the diagnosis, and if so to precisely identify the porphyria. For any porphyria characterized by acute attacks, testing for latent porphyria in relatives will then be necessary.

What samples to send. In an adult with suspected bullous porphyria, it is generally sufficient to analyse urine and either plasma (where fluorimetry is available) or faeces (where it is not). However, urine, plasma and faeces need to be analysed in children, because of the increased complexity of the differential diagnosis. Faecal analysis is also necessary in instances when urine and plasma results do not differentiate HC from CEP, and in renal failure, where urine may be unavailable and plasma analysis unhelpful because renal failure increases plasma porphyrins. In suspected EPP, red cells and either plasma or faeces should be analysed.

Handling of samples. Laboratory testing of body fluids measures porphyrins, since porphyrinogens are spontaneously oxidized to their respective porphyrins outside the body. PBG has a tendency to polymerize to other molecules but porphyrins are reasonably stable when protected from light and oxidants. Thus, all specimens should be kept at room temperature or at 4°C in the dark and ideally should be analysed within 48 h of collection.

For urine and faecal analysis, fresh random specimens (10–20 mL urine or 5–10 g dry weight faeces) are preferable to 24 h collections. Random specimens yield equally useful results, and 24 h collections delay samples reaching the laboratory. Very dilute urine (creatinine < 4 mmol/L) is unsuitable.

Laboratory analysis of porphyrins. Old-fashioned qualitative screening methods for detecting porphyrins in specimens (often involving a Wood's light) are insensitive, and negative results from such tests are not of value. In urine, faeces and red cells or whole blood, quantitative screening using spectrophotometric or fluorimetric techniques is necessary and yields results as a total porphyrin concentration. Whole blood or red cell porphyrin testing measures both the total and free protoporphyrin concentrations. Plasma is analysed by fluorimetric scanning, a diagnostically powerful and simple qualitative technique. In urine and faeces, the finding of an increased porphyrin concentration will lead on to high-performance liquid chromatography (HPLC) which can be used to rapidly identify the accumulated porphyrins (Fig. 57.6). For PBG measurement in urine, qualitative tests are insensitive,

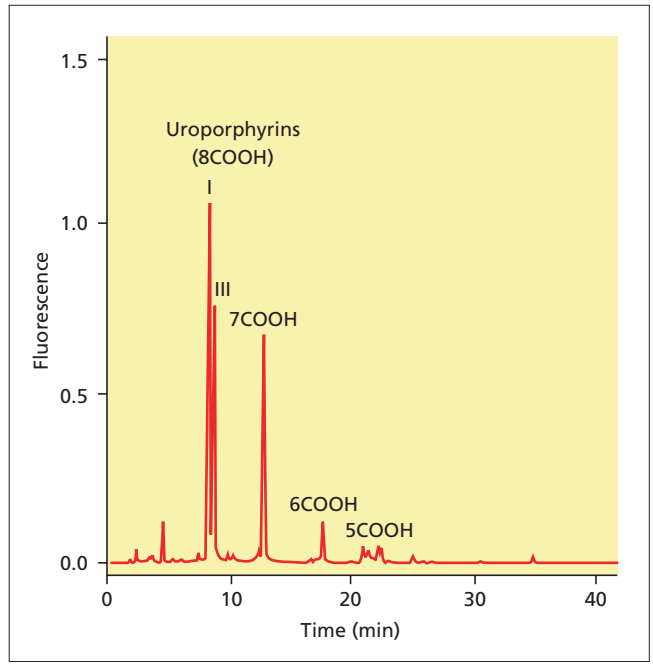

Fig. 57.6 High-performance liquid chromatography (HPLC) analysis: the more carboxylate groups it possesses, the faster a porphyrin molecule passes through the column. After passing through the column, porphyrins are detected by fluorimetry. This HPLC trace of urine shows the porphyrin profile typical of porphyria cutanea tarda (PCT). (Courtesy of Dr A. Deacon, King's College Hospital, London, UK.)

Table 57.2 The major biochemical findings in the cutaneous porphyrias. (Adapted from Deacon and Elder [4].)

	Urine	Faeces	Red cell	Plasma fluorimetry
Congenital erythropoietic porphyria	Uroporphyrin I; coproporphyrin I	Coproporphyrin I	Zinc- and free protoporphyrin; uroporphyrin I; coproporphyrin I	Peak at 615–620 nm
Porphyria cutanea tarda	Uroporphyrin III; heptacarboxy-porphyrin	Isocoproporphyrin; heptacarboxy-porphyrin	Normal	Peak at 615–620 nm
Hereditary coproporphyria	Coproporphyrin III	Coproporphyrin III	Normal	Peak at 615–620 nm
Variegate porphyria	Coproporphyrin III	Protoporphyrin; coproporphyrin III; X-porphyrin	Normal	Peak at 624–627 nm
Erythropoietic protoporphyria	Normal	Protoporphyrin (not diagnostically helpful)	Free protoporphyrin	Peak at 626–634 nm

and quantitative measurement, usually using a kit, is required, with semi-quantitative test kits being useful in emergencies where a result is needed quickly.

Interpretation of results [4] (Table 57.2). In cutaneous porphyrias, the accumulated porphyrin can usually be detected in plasma as an emission peak on spectrofluorimetry. Uro- and coproporphyrin are excreted into the urine and copro- and protoporphyrin into the faeces. Protoporphyrin accumulates in red cells in EPP.

(i) Plasma spectrofluorimetry. In plasma spectrofluorimetry, the sample is excited by 410 nm light, and fluorescent emissions detected. An emission peak at 615–620 nm indicates the presence of uro- or coproporphyrin and suggests a diagnosis of PCT, HC, CEP or HEP (urine analysis will differentiate PCT and HEP from the other two conditions). A peak at 624–626 nm indicates the presence of a porphyrin-peptide conjugate diagnostic of VP. This 624–626 nm peak is a sensitive indicator of VP and may even persist during periods of clinical remission when faecal excretion becomes normal. It is also positive in most cases of latent VP (in relatives) [5,6]. A peak around 633 nm (it can lie between 626 and 634 nm) is caused by protoporphyrin and suggests EPP, and EPP is an unlikely diagnosis in the absence of this peak. Plasma porphyrin concentrations, particularly uroporphyrin, increase in renal failure and can be as high as those found in patients with PCT.

(ii) Whole blood/red cell. An increased free protoporphyrin concentration is the diagnostic finding in EPP. The total protoporphyrin concentration includes both free and zinc-protoporphyrin. Zinc-protoporphyrin is also increased in iron deficiency, lead poisoning and certain anaemias. In a child with plasma, urine and faecal results typical of PCT, red cell UROD activity needs to be measured to exclude hepatoerythropoietic porphyria (HEP).

(iii) Urinary and faecal analysis. An increased total porphyrin concentration suggests a diagnosis of cutaneous porphyria. The total urinary porphyrin concentration is used to monitor disease activity in PCT. HPLC analysis is used to identify the porphyrins once an increased concentration has been found.
(a) In urine. An increase in uroporphyrin (and other highly carboxylated porphyrins especially heptacarboxyporphyrin) is typical of PCT though this does not exclude VP. Plasma spectrofluorimetry differentiates these two conditions and faecal analysis is required where this is unavailable. When PCT goes into remission and the total urinary porphyrin concentration returns to normal, it may still be possible to diagnose PCT from the characteristic urinary HPLC pattern. Coproporphyrinuria, in the presence of normal faecal porphyrin levels, does not indicate porphyria and can be caused by certain drugs, lead toxicity and hepatobiliary disease.
(b) In urine and faeces. Increased coproporphyrin suggests VP, but does not exclude HC. Isomer III to isomer I ratios are increased in every porphyria except CEP (where they are decreased). In CEP, excess type I isomers of uro- and coproporphyrin are present in urine and type I coproporphyrin in faeces.
(c) In faeces. In the presence of a plasma spectrofluorimetry peak at 615–20 nm, if urine HPLC does not show the PCT pattern, faecal analysis is required to differentiate HC (increased coproporphyrin III concentration) from CEP (increased coproporphyrin I concentration). Increased faecal isocoproporphyrin is characteristic of PCT. In renal failure, faecal analysis is vital, since urine may be unavailable and plasma porphyrins are increased in renal failure (PCT is the porphyria most commonly associated with renal failure). Increased faecal protoporphyrin is suggestive but not diagnostic of EPP, since it can also derive from bacterial degradation of haem in the gut and may indicate gastrointestinal haemorrhage when porphyrin concentrations are normal elsewhere.

Biochemical diagnosis of an acute attack of porphyria [3,4]. This is discussed above (Acute attacks of porphyria, p. 57.7). A definitive diagnosis of VP or HC can usually be

made on the basis of detailed porphyrin analysis. A definitive diagnosis of AIP requires enzyme or genetic tests.

Screening of relatives. In VP and HC, porphyrin levels are normal before puberty. Over the age of 15 years, a plasma fluorimetry scan is a reasonably sensitive biochemical test for latent VP in asymptomatic relatives of patients, picking up most cases. A positive scan is diagnostic of latent VP but a negative result is uninformative [5,6]. Faecal analysis, to measure the ratio of coproporphyrin isomers, will pick up some cases of latent HC after puberty [7]. In VP and HC, a negative porphyrin screening test in a relative needs to be followed by DNA analysis before latent disease can be excluded. The lack of any common mutations in porphyria (apart from South African VP) means that the causative mutation usually has to be identified for each family.

The individual porphyrias

Porphyrias which cause cutaneous disease but do not cause acute attacks

Congenital erythropoietic porphyria (Günther's disease)

Definition. A severe and rare childhood porphyria causing lifelong mutilating photosensitivity and haematological disease.

Aetiology. Congenital erythropoietic porphyria (CEP) is caused by an autosomal recessive inherited deficiency of the uroporphyrinogen III cosynthase enzyme. Since this enzyme is required to form the biologically useful type III porphyrin isomers, its absence results in non-enzymatic reactions producing large amounts of type I isomer porphyrins which cannot participate in haem formation, and which massively accumulate in erythroid cells and then gradually leak into the plasma. The incidence in the UK is 2 per 3 million live births and less than 100 cases have ever been reported worldwide.

Fig. 57.7 Congenital erythropoietic porphyria (CEP): scarring of skin with resorption of terminal phalanges. (Courtesy of Dr A. du Vivier, King's College Hospital, London, UK.)

Clinical features [1–3]. CEP has a wide spectrum of presentation, from hydrops fetalis through to severe disease starting in infancy and also mild forms presenting later in life. The first sign of CEP is often the child's mother noting brown discoloration of amniotic fluid at the onset of labour, or observing pink or brown porphyrin staining of nappies (which fluoresce red-orange under Wood's light).

(i) The skin in CEP [1,3]. Severe photosensitivity begins in infancy, often in the neonatal period, with blisters developing in light-exposed skin on minimal light exposure. Phototherapy for neonatal jaundice may trigger lesions. Most children are so sensitive to the light that they have problems throughout the year. Exposed (and sometimes non-exposed) skin is fragile. The repeated bouts of inflammation with vesicles and bullae, often complicated by secondary infection, cause mutilating scarring particularly of the face and hands (Fig. 57.7). This photomutilation is associated with erosion of the terminal phalanges, onycholysis and destructive changes affecting the pinnae and nose. A diffuse pseudoscleroderma-tous thickening of exposed skin often gradually develops, with microstomia and sclerodactyly-like changes [3]. Hypertrichosis is found in most patients, particularly on the upper arms, temples and malar region. Patchy hypo- and hyperpigmentation occur even in minimally exposed areas.

A milder late onset form, presenting at any age from the third decade onward, has been described; this presents in a manner similar to PCT or VP, but may also cause thrombocytopenia secondary to hypersplenism [4]. Although clinically much less severe, enzyme activities in late onset CEP are often as low as in the childhood form [1].

(ii) Involvement of eyes and internal organs [3]*:*
(a) Eyes. Keratoconjunctivitis, blepharitis, cataracts, corneal ulcers, scars, cicatricial ectropion and scarring alopecia of eyelashes and eyebrows may all occur. Scleromalacia, pterygium formation, optic atrophy and retinal haemorrhage are less common.
(b) Bones and teeth. When teeth emerge, they are almost always stained brown (and fluoresce under Wood's light). Decreased bone density, osteopenia and osteolytic lesions secondary to erosion by hyperplastic bone marrow are seen on X-ray and are associated with vertebral compression and collapse, and with pathological fractures. In the hands there is resorption of terminal phalanges with acroosteolysis and cortical bone rarefaction. Occasionally, strict avoidance of the sun may impair vitamin D metabolism.
(c) Haematology [1,3]. The high concentrations of porphyrins in red cells cause haemolytic anaemia, severe enough to induce marrow hyperplasia often with visible expansion of the maxillary bones in the face. Hypersplenism is common. The haemolysis can be fully compensated or may cause a severe anaemia, and is occasionally so severe that some patients become transfusion dependent. The severity of the anaemia often fluctuates strikingly over time. Very severe haemolytic anaemia may even cause hydrops fetalis. Bone marrow examination reveals normoblastic hyperplasia, and under violet illumination most normoblasts have persistent red fluorescence localized to their nuclei, with haem-containing inclusion bodies being seen in the nuclei of these fluorescent cells.

Differential diagnosis. The photosensitivity differentiates CEP from other scarring blistering disorders of childhood, including epidermolysis bullosa dystrophica. The cutaneous changes may resemble HEP (the homozygous form of familial PCT) or homozygous VP. The cutaneous disease in late onset CEP is clinically indistinguishable from PCT or VP.

Biochemical findings [1]. The uroporphyrinogen III cosynthase enzyme deficiency results in the massive accumulation in all tissues of type I isomers of porphyrins, mainly uroporphyrin, along with coproporphyrin and smaller amounts of 7-, 6- and 5-carboxylic acid porphyrins. Red cells and urine contain large amounts of uro- and coproporphyrin (mainly type I) and faeces contains increased concentrations of coproporphyrin (mainly type I). A plasma spectrofluorimetry peak is seen at 615–620 nm. The absence of isocoproporphyrins and the normal level of 5-carboxylic porphyrin excretion in faeces distinguish CEP from HEP.

Prognosis. In the past most patients died by the age of 40 years but improvements in supportive care (particularly use of antibiotics) have improved the prognosis, though the haematological complications may be fatal. Long-term hypertransfusion causes significant problems with iron overload as patients reach adulthood, even when iron chelation has been used. Bone marrow transplantation now holds out the promise of cure for these patients (see below).

Treatment [5]. The photosensitivity is so severe that photoprotection is crucial. Sun avoidance and use of sun protective clothing and hats are essential. Opaque sunscreens containing pigmentary grade titanium dioxide or zinc oxide, possibly with added iron oxide, may be of limited value [6,7], and amber window films on home or car windows can reduce exposure to Soret wavelength light (TA81SXR, Madico, USA) [8], though more opaque films may be necessary (which are obviously not allowed on car windows). Prompt treatment of secondary infection is important.

β-Carotene may help cutaneous disease in some patients [1].

Many therapies reduce the porphyrin concentrations by suppressing erythropoiesis. Hypertransfusion with regular blood transfusions to maintain a polycythaemia inhibits endogenous haemoglobin production and decreases porphyrin formation, and may reduce haemolysis and cutaneous symptoms in moderately affected patients. However, splenomegaly may increase transfusion requirements and the value of hypertransfusion often decreases at puberty [5]. Hypertransfusion is frequently complicated by iron overload, even when desferrioxamine has been used, and blood-borne infections can be a complication. Hydroxyurea has been used with hypertransfusion and may be useful in transfusion-dependent CEP [9]. Intravenous haematin has been tried in late onset disease [10]. Haemolysis worsens the porphyria by causing anaemia and usually necessitates blood transfusion. Splenectomy may reduce haemolysis though the improvement may be temporary [5]. Lights during surgical procedures may cause phototoxic reactions and, at the least, clear filters should be used over the operation lights during any unavoidable surgery.

Since 1991, allogeneic bone marrow transplantation (bone marrow or umbilical cord blood stem cells) from a human leukocyte antigen (HLA)-compatible sibling has emerged as the treatment of choice in severe CEP. It provides a long-term cure [11] though the difficulties of finding a tissue-matched donor, and the dangers of marrow

transplantation, mean that it should be reserved for the most severely affected patients. Gene therapy has been successfully used '*in vitro*', but no '*in vivo*' studies have been carried out yet [12].

Genetic counselling. Since CEP is autosomal recessive, parents will be unaware of the risk until an affected child has been born, and the risk of disease is in further offspring rather than subsequent generations. For parents of an affected child, the chance of each future offspring suffering from the disease is 25%. The diagnosis may be made before birth by measuring the uroporphyrin I concentration in amniotic fluid, which is increased as early as 16 weeks *in utero* [13]. If the mutations in the index case have been identified, or the fetus is homozygous for the common C73R mutation, prenatal diagnosis from chorionic villous biopsy is possible [13].

Porphyria cutanea tarda [1,2]

Definition. Porphyria cutanea tarda (PCT) is the commonest of all the porphyrias. It is characterized by fragility and blistering of exposed skin. It is usually acquired and is often associated with liver disease. It does not cause acute attacks.

Aetiology and classification. PCT results from deficiency of UROD [3]. This causes accumulation of uroporphyrin and other highly carboxylated porphyrins. Seventy-five per cent of patients have the *type I* (*sporadic*) form in which the enzyme deficiency is acquired and restricted to hepatocytes, due to inhibition of a normal UROD enzyme [3]. Twenty-five per cent have *type II* (*familial*) disease where the enzyme deficiency is hereditary, present in all tissues and associated with a UROD gene mutation. The penetrance of this autosomal dominant inherited form is so low that a family history is present in under 7% of cases, and since at least a 75% reduction in enzyme activity is required for clinical expression, some enzyme inhibition in the liver also occurs in familial PCT. Thus, UROD mutations are increasingly thought of as a risk factor for the development of PCT, rather than as representing a completely separate familial form of the disease. *Type III* disease is rare and characterized by an hereditary enzyme deficiency localized to the liver. *Toxic porphyria*, in which halogenated aromatic hydrocarbons inhibit the enzyme, is rare and mainly affects workers making herbicides [4]. A major epidemic of toxic porphyria in the 1950s in Turkey was caused by hexachlorobenzene added as a fungicide to seed wheat [5].

In PCT, the UROD enzyme is inactivated by an inhibitor which binds to its catalytic site. The inhibitor is generated in the liver by reactive oxygen species in the presence of iron (Fig. 57.8) [6]. The accumulated uroporphyrin diffuses from the plasma into surrounding tissues, causing a phototoxic reaction in the upper dermis in sun-exposed skin. This leads to lysis of cells in the superficial dermis with the formation of membrane-limited vacuoles which merge to produce a blister cavity under the basal lamina [7].

Histopathology [8]. The bullae in PCT are subepidermal with a sparse inflammatory infiltrate and 'festooning' of dermal papillae into the bullae. There is deposition of PAS-positive diastase-resistant fibrillar glycoprotein material in and around upper dermal blood vessel walls, and reduplication of the basement membrane. Immunofluorescence reveals IgG, a little IgM, fibrinogen and complement at the epidermodermal junction. Morphoea-like lesions in PCT are histologically indistinguishable from other forms of morphoea.

Clinical features (Fig. 57.9) [9]. Sporadic PCT usually presents in middle age whilst the familial form can occur at a younger age. Almost all patients notice increased fragility on light-exposed skin, particularly the backs of the hands and forearms, with minor trauma shearing the skin away to leave sharply marginated erosions. Most patients suffer from bullae, which can be over 1 cm in diameter and may be painful. They crust and resolve over a few weeks, leaving atrophic scars, milia and often mottled hyper- or

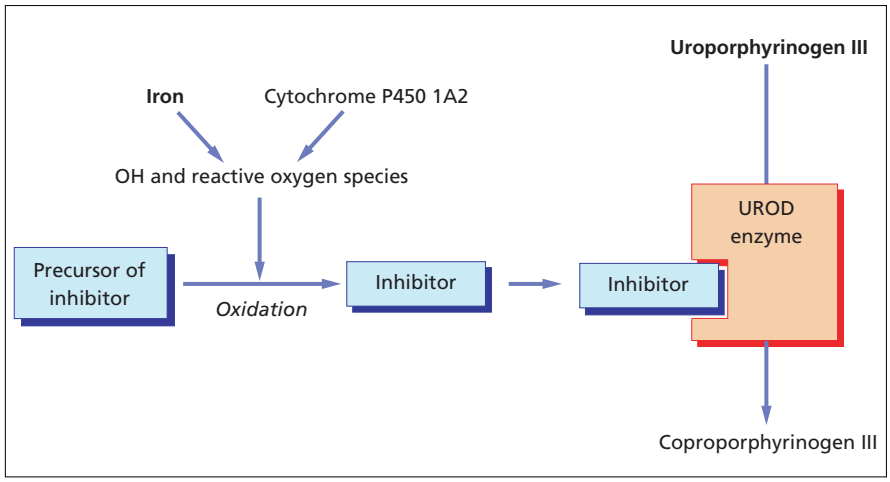

Fig. 57.8 Porphyria cutanea tarda (PCT) is caused by production of an inhibitor of uroporphyrinogen decarboxylase (UROD) in the liver, in the presence of iron. (Adapted from Elder [2].)

Fig. 57.9 Porphyria cutanea tarda (PCT): erosions, blisters, pigmentary changes and scarring.

hypopigmentation. Patients rarely associate development of new lesions with sun exposure, but symptoms are generally worse in the summer. Other common features are: patches of scarring alopecia following resolution of bullae on the scalp; hypertrichosis, usually on the upper face and forehead, sometimes on the ears or arms [10] and occasionally affecting the whole body; hyperpigmentation in a melasma-like pattern on the cheeks and around the eyes, or in a diffuse pattern on light-exposed skin, or occasionally in a reticulate distribution [9,10]. Photo-induced onycholysis [11] and accelerated solar elastosis [10] may also occur. Morphoea-like plaques may develop, particularly on the head and upper trunk. They are histologically indistinguishable from true scleroderma and mainly occur in longstanding untreated disease. It has been postulated that they arise as a result of the induction of collagen synthesis by uroporphyrin I [12]. These plaques may calcify, and may require excision and grafting if they ulcerate [9]. On the scalp, the morphoea-like change may cause a slowly expanding scarring alopecia starting in the frontoparietal and occipital areas [9,10,13], and even sclerodactyly or the facial changes of systemic sclerosis have been reported.

Hepatoerythropoietic porphyria [10,14]. The homozygous form of familial PCT, hepatoerythropoietic porphyria (HEP), is associated with over 90% reduction in UROD activity. It usually causes a severe disease clinically similar to CEP, with photosensitivity during infancy causing immediate pain on sun exposure, blisters on sun-exposed skin, and mutilating scarring of face and fingers. Prominent hypertrichosis, fluorescent teeth, eye involvement and shortened distal phalanges also occur. Haemolysis is milder than in CEP, and life expectancy is normal. HEP can occasionally present with a milder disease similar to PCT. Since the mutated alleles in HEP have to be associated with some residual enzyme activity to be compatible with life, the UROD gene mutations in HEP patients are different to those found in type II PCT [15].

Differential diagnosis. PCT can be clinically indistiguishable from VP, drug-induced pseudoporphyria, renal pseudoporphyria, HC, late onset Günther's disease or mild HEP. Biochemical analysis is necessary to diagnose PCT and it is particularly important to exclude VP and HC among the differential diagnoses, since they can cause acute attacks.

Biochemical findings [2]. In PCT, the urinary porphyrin concentration is increased, consisting mainly of uroporphyrin, some heptacarboxylic acid porphyrin, and sometimes also hexa- and pentacarboxylic acid porphyrins. A plasma spectrofluorimetry peak is seen at 615–620 nm. Isocoproporphyrin accumulates in the faeces. Urine analysis alone is insufficient to diagnose PCT, since a few patients with VP have the PCT urine pattern ('dual porphyria') [16]. In patients with renal failure, faecal analysis is essential, since plasma porphyrins are increased by

haemodialysis and urine collection may not be possible. The biochemical marker of disease activity and response to treatment is quantitative urinary porphyrin excretion measured in a random urine sample.

In HEP, the findings are as in PCT, but with the additional finding of a raised red cell zinc-protoporphyrin, and lower red cell UROD activity than occurs in type II PCT.

The investigation of the patient with PCT. PCT is essentially a liver disorder with secondary effects in the skin. It is crucial to investigate patients thoroughly both regarding other systemic diseases predisposing to the development of PCT, and in order to assess the severity of any liver disease.

(a) Risk factors for the development of PCT [17]. The major risk factors for developing PCT are subclinical genetic haemochromatosis, hepatitis C infection, alcohol and oestrogens. They all predispose to the inhibition of the UROD enzyme in the liver. Since some inhibition of the hepatic enzyme is also required for clinical expression of familial PCT, the same risk factors apply to sporadic and familial PCT. Since most of the risk factors have significant implications both for treatment and for the patient's general health, it is essential to investigate for risk factors in all patients diagnosed with PCT.

(i) Haemochromatosis. As expected in a disorder where hepatic iron plays a key role, almost all patients have increased stainable iron in the liver, and total body iron stores are increased in at least 60% of patients [2,17,18]. In the USA and Northern Europe, around 20% of PCT patients have true hereditary haemochromatosis [17,19] with homozygosity for the Cys282Tyr haemochromatosis mutation. Homozygosity for this mutation increases the risk of developing PCT 60-fold [17]. The clinical relevance of heterozygosity for the mutation is unclear. In Southern Europe, haemochromatosis is a less important risk factor. The iron overload found in PCT patients who do not have haemochromatosis is milder, and its cause obscure.

(ii) Hepatitis C infection. In Southern Europe, 70–90% of all PCT patients are infected with the hepatitis C virus [20,21], compared with around 60% of patients in the USA [17] and 7–12% in Northern Europe [22,23].

(iii) Alcohol. Between 30% and 90% of PCT patients consume over 40 g of alcohol daily, and 2% of all alcoholics with cirrhosis develop PCT [6].

(iv) Oestrogens. Ingested oestrogens, in the oral contraceptive pill or in hormone replacement therapy, are the sole risk factor in over a quarter of female patients [17]. Stopping the hormone may be sufficient to induce remission if the duration of therapy has been short [24]. If it is not possible to stop the hormone therapy, transdermal drug delivery is a safer alternative than the oral route [25].

There are other less common risk factors for developing PCT: haemodialysis predisposes to PCT [10], though PCT is less common in renal failure than pseudoporphyria —faecal porphyrin analysis differentiates these disorders. Human immune deficiency virus (HIV) infection predisposes to PCT [26], an association which may be due to coinfection with the hepatitis C virus [27]. Non-insulin dependent diabetes mellitus, systemic lupus erythematosus, dermatomyositis, hepatitis A and B infection, haematological malignancy, sideroblastic anaemia and thalassaemia have all been reported to be associated with PCT [2,9,28].

Most patients possess more than one risk factor for developing PCT, with hepatitis C infection and alcohol being strongly linked in men.

(b) Liver disease in PCT [18]. Since PCT is primarily a liver disorder with secondary effects in the skin, liver disease is a major concern. In almost all cases, liver biopsy reveals increased stainable iron, fatty change and intracellular porphyrin crystals. Fifty per cent of patients have more severe changes (lobular necrosis or inflamed fibrotic portal tracts), and cirrhosis occurs in 15% [18]. As one would expect, the most severe liver disease tends to occur in patients who have alcoholism, hepatitis C infection and iron overload [17]. The accumulated porphyrins are carcinogenic to the liver, and so PCT confers an additional risk for developing hepatocellular carcinoma on top of the risk conferred by the hepatitis C infection present in many patients [29]. In Southern Europe around 15% of PCT patients develop hepatocellular carcinoma during the decade after presentation, the main risk factors being a symptomatic period longer than 10 years prior to treatment, severe changes on hepatic histology at presentation, male sex and age over 50 years at presentation [30,31]. The incidence of hepatic malignancy is probably not as high in countries with lower hepatitis C infection rates. The converse situation, where a primary hepatic tumour secretes porphyrins to cause a PCT-like skin disease, is rare [32]. Hepatic function must be assessed at presentation in all PCT patients, and patients at high risk of hepatic malignancy require regular ultrasounds and serum α-fetoprotein measurement to detect carcinoma at a treatable stage [30]. PCT should be managed as a liver disorder, and the threshold for referral to a hepatologist should be low.

Treatment

Photoprotection. Visible light sunscreens containing pigmentary grade titanium dioxide or zinc oxide, sometimes with added iron oxide [33,34], and filter films for car and home windows, play an important role in controlling symptoms during the period of several months before specific therapies take effect.

Elimination of risk factors. Stopping oestrogen therapy [24], if it has not been used for more than 2 years, can induce

remission. However, elimination of the underlying cause by abstaining from alcohol, or by treating hepatitis C with interferon-α [35], usually does not induce remission. All patients should be advised to abstain from alcohol or oestrogen therapy to prevent exacerbation of the disease.

Specific treatments. Definitive treatment with venesection or low-dose antimalarials is required in almost all cases. Venesection depletes iron stores and eliminates hepatic iron overload, thus restoring normal enzyme activity. Around 500 mL of blood is removed every week or every 2 weeks, aiming to decrease transferrin saturation to 15%, haemoglobin to 11–12 g/dL and plasma ferritin to below 25 µg/L [36,37]. Blistering usually resolves within 2–3 months, skin fragility within 6–9 months [38], and porphyrin concentrations generally normalize within 13 months or so [9], at which point treatment should be stopped. Hypertrichosis [9] and sclerodermoid lesions [13] respond more slowly during the years after treatment has stopped. Excision and grafting may be needed for ulcerated sclerodermoid lesions [9]. Desferrioxamine leads to earlier remission than venesection [39] because it rapidly chelates hepatic iron, but it is expensive and requires use of a subcutaneous pump at night. Erythropoietin mobilizes hepatic iron into haemoglobin and is the treatment of choice for PCT in renal failure where patients are too anaemic for venesection and cannot excrete chloroquine [40]. Low-dose antimalarials are a very effective treatment for PCT. They work by complexing with uroporphyrin and promoting its excretion into the bile [41]. Daily doses of chloroquine cause a potentially dangerous acute hepatitis but chloroquine at the low dose of 125 mg [42,43] or 250 mg [44,45] taken twice a week is safe and effective. It leads to clinical remission within 6 months or so and biochemical remission after 6–15 months, at which point treatment is stopped [42–45]. Retinopathy does not seem to occur with such low doses of chloroquine [44]. Hydroxychloroquine (200 mg twice weekly) can be used but duration of remission is shorter than with chloroquine [46,47].

Low-dose chloroquine is the treatment of choice except in the following situations, in which venesection is preferable: (i) patients who do not respond to chloroquine; (ii) patients with a pathologically high serum ferritin concentration or homozygous for the Cys282Tyr mutation (if genetic analysis is available), who require iron depletion to protect internal organs; and (iii) patients with significant hepatitis C liver disease, who require iron depletion since hepatic siderosis increases their virally induced liver damage [48] and reduces the effectiveness of interferon [49]. However, chloroquine is not contraindicated in these situations, and may be needed when venesection is not possible, particularly in patients with hepatitis C liver disease where venous access is impaired by previous intravenous drug abuse. In renal failure, erythropoietin is the treatment of choice [40].

Remission with low-dose chloroquine generally lasts 17–24 months [43,44]. With venesection, relapse generally occurs around 2.5 years after the end of treatment [9,42]. Long-term follow-up is necessary for all patients to monitor for relapse (by measuring urinary porphyrin excretion), and for the management of coexisting liver disease.

Genetic counselling [50]. Familial and sporadic PCT can be differentiated by measuring red cell UROD activity. Since additional inhibition of the hepatic enzyme is required for clinical expression of disease in familial PCT, UROD mutations can be considered as a risk factor for developing the disease rather than as a different form of PCT. In view of the identical management of sporadic and familial PCT, the lack of evidence that identifying latent PCT in relatives alters outcomes, and the very low penetrance of familial PCT, it is difficult to justify family screening in familial PCT. It is therefore of little value to measure red cell UROD activity unless one is trying to differentiate HEP from PCT.

Erythropoietic protoporphyria

Definition. EPP is an hereditary porphyria characterized by painful lifelong photosensitivity and occasionally liver disease.

Incidence and aetiology. The prevalence of EPP is around 1/100 000. EPP results from deficient activity of ferrochelatase, the final enzyme of haem biosynthesis. This causes the accumulation of protoporphyrin predominantly in cells of the erythroid series, which causes a phototoxic reaction as the porphyrin-laden cells pass through small upper dermal blood vessels and are exposed to the Soret wavelength in sunlight. The photoactivated porphyrin from red cells and plasma causes an acute injury to the endothelium mediated by singlet oxygen [1]. Many ferrochelatase gene mutations have been identified in EPP patients and none are particularly common [2]. A few adult onset cases have been reported which are associated with haematological malignancy and may be associated with chromosomal deletions involving the ferrochelatase gene [3].

Histopathology [4,5]. In the acute phase there is visible endothelial damage in superficial dermal vessels [6]. In the chronic phase, in exposed areas of skin, the repeated episodes of damage to small vessels in the upper dermis cause deposition of PAS-positive diastase-resistant hyaline material in the walls of blood vessels of the upper dermal and papillary vascular plexuses. Immunofluorescence shows immunoglobulins (mainly IgG) in a similar distribution. On electron microscopy the hyaline material can be seen to be a greatly replicated, layered and fragmented basement membrane, with fine fibrillar material permeating the capillary connective tissue sheath and extending beyond the vessel walls [4,7].

Clinical features [8,9]. Unlike the other cutaneous porphyrias, EPP causes immediate pain on exposure to bright sunlight. It presents most commonly between the ages of 3 and 5 years, and also quite often in babies who usually present with crying in their prams in sunny weather, or crying for no obvious reason at night in the summer. Onset later in childhood does occur but onset in adulthood is rare. In spring and summer, after anything from a

Fig. 57.10 Oedema during an acute painful attack in a child with erythropoietic protoporphyria (EPP).

Fig. 57.11 Typical scars on the cheeks in erythropoietic protoporphyria (EPP).

few minutes to an hour or two of sun exposure, patients describe discomfort, tingling or itching in exposed skin, particularly the dorsae of the hands and the face. If exposure continues, severe burning pain follows which can last anything between an hour and several days. Children often find partial relief with cold water and wet cloths, and this feature may be diagnostically useful. Usually the only physical sign during an attack is oedema which may be subtle (Fig. 57.10). Erythema is less common. The lack of physical signs often leads to delay in diagnosis, with some patients initially being labelled as malingerers. Many patients experience a 'priming phenomenon' in which sunlight tolerance is reduced on the day after significant sun exposure [10]. In severe attacks, purpuric lesions and crusted erosions or vesicles may occur; these take a week or two to resolve after the attack settles down, and the pain may be severe enough to require hospital admission. Rare cases of EPP with prominent purpura and histological changes resembling a leucocytoclastic vasculitis [11], acute photo-onycholysis [12] or erythematous plaques [13] have been described. Physical signs may develop during childhood, with slight thickening of skin over the metacarpophalangeal and interphalangeal joints, superficial vermicular waxy scarring on the nose, shallow linear, punctate or small circular scars on cheeks and forehead and radial scars around the lips (Fig. 57.11). The skin over the nose, cheeks and forehead can become roughened and 'pebbly' in texture. However, most patients have no physical signs at all [8]. Children with EPP suffer from social isolation due to difficulty joining friends to play outside, and sensitivity to psychosocial issues is important for clinicians. Although EPP is lifelong, childhood and adolescence are frequently the most difficult times because it is easier for adults to organize their lives to reduce sun exposure. Symptoms usually improve and porphyrin levels fall during pregnancy [14]. Patients may develop a mild hypochromic microcytic or normocytic anaemia which can be associated with decreased serum iron levels and increased serum iron binding capacity [8]. With the exception of patients with EPP liver failure, operating theatre lights do not necessarily cause severe photosensitivity after surgery, though photosensitive reactions can occur [15]. It would seem reasonable to advise patients to avoid sun exposure for 48 h prior to elective surgery (to avoid priming), and to use clear filter films (e.g. Dermagard film, Bonwyke, Hants, UK; CLS200XSR film, Madico, USA) if available, over operating theatre lights, particularly for long procedures. Anaesthetists can be reassured that acute attacks do not occur in EPP. In contrast, operating theatre lights can cause a devastating and potentially fatal phototoxic reaction in patients undergoing liver transplantation for protoporphyric liver failure.

Biochemical investigation [16]. The diagnostic finding is of an increased red cell free protoporphyrin concentration. Protoporphyrin is seen as a peak at 633 nm on plasma fluorimetric scanning. Sixty per cent of EPP patients have an increased faecal protoporphyrin concentration though this is not very useful diagnostically because

of its lack of specificity. Urinary porphyrins are normal except in biliary impairment, when coproporphyrinuria develops.

Treatment [9]. No therapy has ever been proven to be effective in EPP mainly because of the lack of an objective test for disease activity in EPP, and high placebo rates make useful clinical trials difficult. This author's experience is that results with the specific therapies are generally fairly disappointing, and that attention to sunlight protection is the key to management.

Photoprotection. Basic measures include sun avoidance behaviour, sun-protective clothing and hats. Most sunscreens do not protect against the Soret wavelength including the UV-absorbent chemical sunscreens often misleadingly called 'total sunblocks' [17,18]. Some sunscreens containing reflectant particles can effectively protect against violet light, particularly large particle size titanium dioxide (pigmentary grade) or zinc oxide sometimes with added iron oxide [18]. Reasonably cosmetically acceptable sunscreens which protect against light up to 430 nm wavelength are available commercially (Dundee sunscreen, Tayside Pharmaceuticals, Dundee, UK) [17,18]. Dihydroxyacetone paint, which induces formation of a violet light absorbing brown pigment in the stratum corneum, has also been used in some patients with EPP [19]. Some relatively transparent window films, which absorb violet light, can be useful for car or home windows, particularly in severely affected patients. This author recommends two films to patients which are slightly yellowish grey but clear and provide partial protection against Soret wavelength light (Dermagard film, Bonwyke, Hants, UK; CLS200XSR film, Madico, USA). Regulations concerning films applied to car windows vary widely between countries.

The acute reaction. For the acute reaction, complete sun avoidance (even through windows) leads to earlier resolution, and fans and cold water provide some pain relief. Antihistamines and most analgesics are of little value. For severe attacks, hospital admission may be necessary, for light avoidance and analgesia (usually opiate).

Specific therapies. Oral β-carotene is the most widely used treatment, usually at a dose around 180 mg daily in adults (90 mg daily in children) taken throughout the spring and summer. It is postulated to scavenge free radicals involved in the acute phototoxic reaction. Although many patients report that it reduces symptoms, others do not, and proof of efficacy from controlled trials is lacking. Patients may need to take it for several months before any effect is observed. The most common adverse effect is reversible skin discoloration. A controlled trial of *N*-acetyl cysteine has shown no benefit [20]. Short courses of a few weeks of psoralen and long-wave UV radiation (PUVA) [21] and narrow-band UVB [22] used in the early spring may be valuable, particularly in milder cases, and probably increase photoprotection by inducing epidermal thickening and pigmentation. Unlike PUVA, narrow-band UVB does not overlap with the EPP action spectrum and so cannot trigger attacks of pain. Many other systemic treatments with antioxidant or free radical scavenging properties have been used in EPP in an uncontrolled way on small numbers of patients, with conflicting and generally unconvincing results.

Genetic counselling. Although rare cases of autosomal recessive inheritance have been reported [23], EPP is generally an autosomal dominant disorder with incomplete penetrance, the disease resulting from co-inheritance of a gene mutation on one ferrochelatase allele with a low expression variant on the other allele. This low expression variant is present in around 10% of the Caucasian population and is associated with reduced ferrochelatase mRNA levels resulting from the presence of the polymorphic variant IVS-48C [24]. Overall, the probability of each offspring of an EPP patient suffering from the disease is under 10% [25], but testing for the IVS-48C polymorphism in a patient's partner is now available and can indicate more precisely whether there is a significant probability of future offspring being affected. This is useful for patients who would not consider having children if there were a significant likelihood of them having the disease. For a disorder which is rarely life-threatening, termination of pregnancy and thus antenatal diagnosis are not relevant.

Liver disease in EPP [23]. Protoporphyrin is excreted exclusively into the bile. It precipitates to form gallstones in around 12% of patients [8]. It is also hepatotoxic, particularly to bile canaliculi, and severe liver damage occurs in around 1% of patients. EPP liver failure is most common in the teens and twenties. Usually a patient develops jaundice, worsening photosensitivity and often upper abdominal pain over a period of weeks or months. Investigation shows severe or total cholestasis, and a dramatically high red cell protoporphyrin concentration (due to its impaired excretion), which causes the worsening photosensitivity. Liver histology reveals deposition of protoporphyrin in vacuoles within bile canaliculi and hepatocytes, which may be accompanied by cirrhosis (Fig. 57.12). Although such acute episodes may resolve spontaneously, the porphyrin-induced cholestasis may become increasingly severe and itself further increase the protoporphyrin concentration in a vicious cycle, in which case the patient will die unless a liver transplant can be performed. Under operating theatre lights during the transplant surgery, the very high protoporphyrin concentration may cause a severe phototoxic reaction with

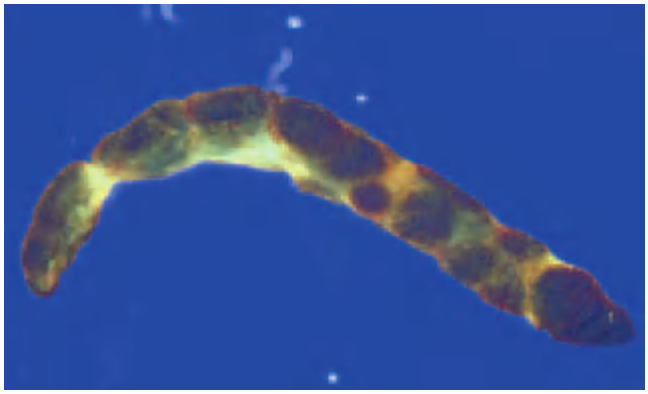

Fig. 57.12 Liver biopsy in protoporphyric liver disease, showing nodules of cirrhosis and black staining by deposits of protoporphyrin.

postoperative burns, massive haemolysis and a severe neuropathy, so clear filters protective against violet light need to be used over operating theatre lights [23]. If these immediate postoperative complications are avoided, the prognosis after liver transplantation is good. Protoporphyric liver disease may recur in the graft over several years, although severe recurrent liver disease has been reported in only one case [26].

It is vital to recognize impending protoporphyric liver failure early enough that arrangements can be made for a liver transplant if it should become necessary. Thus, all EPP patients should have liver function tests and red cell protoporphyrin concentration checked at least once a year. The appearance of coproporphyrin in the urine is a sensitive indicator of significant liver disease in EPP [27]. Worsening photosensitivity may be the only clinical indication of the development of severe liver disease. Although protoporphyric liver failure is rare, mild abnormalities of liver function tests are common in EPP [27]. Since the significance of these abnormalities is unclear, it is advisable to monitor closely in these patients, and to refer the patient to a hepatologist if the abnormality is persistent or deteriorating. In such patients, an ion exchange resin such as cholestyramine may protect the liver against further porphyrin toxicity. The major difficulty for the dermatologist is the lack of any means of identifying those EPP patients at risk of liver failure. Since several cases have been described in siblings, patients with a relative who has suffered protoporphyric liver failure should be treated as being at increased risk of developing it themselves. Recessive inheritance of EPP may increase the risk of severe hepatic disease, though it is not clear how significant an association this is [28].

Iron deficiency anaemia may trigger or exacerbate hepatic disease by increasing porphyrin accumulation [23], and subsequent iron replacement may make the situation temporarily worse by acutely stimulating haem biosynthesis.

Porphyrias which cause cutaneous disease and acute attacks

Hereditary coproporphyria

The skin is not affected in most patients suffering from this rare acute porphyria. Like VP, the disease presents from puberty onwards and only around 10–20% [1] of patients have cutaneous involvement with fragility and blistering in sun-exposed areas, that is indistinguishable from PCT or VP. The skin disease may be triggered or exacerbated by intercurrent liver disease [2]. HC is caused by an autosomal dominant inherited deficiency of coproporphyrinogen oxidase. The biochemical findings are of a 615–620 nm peak on plasma spectrofluorimetry, increased uro- and coproporphyrin concentrations in urine, and increased coproporphyrin in faeces. Predominance of the type III isomer in faeces is a sensitive indicator of HC [1]. Rare variants include a homozygous form characterized by short stature, acute attacks and skin changes with prominent hypertrichosis and pigmentation [3], and harderoporphyria which causes haemolysis in the neonate or bullae.

Variegate porphyria

Definition. A rare inherited disease usually characterized by photo-induced skin fragility and blistering, which may cause acute attacks.

Aetiology and incidence. VP is caused by an autosomal dominant inherited deficiency of protoporphyrinogen oxidase. In addition to causing photosensitization, accumulated coproporphyrinogen and protoporphyrinogen also inhibit PBG deaminase, the probable mechanism for acute attacks in VP [1]. In South Africa, VP is common (due to a founder effect) with a prevalence in whites and Afrikaner-descended non-whites of 1/200. Elsewhere the prevalence is around 1/100 000 [2]. At least 80% of South African carriers of a pathogenic VP mutation are completely asymptomatic [3].

Pathogenesis of skin lesions in VP. It is perhaps unexpected that the accumulated copro- and protoporphyrin should cause PCT-like upper dermal blistering rather than EPP-like acute pain. This is likely to be because, although hydrophobic porphyrins predominate in plasma, hydrophilic porphyrins, especially uroporphyrin, predominate in the skin. This local accumulation is thought to result from secondary local photo-inactivation of UROD in the skin by coproporphyrin [3]. In addition, the protoporphyrin in VP is conjugated to a peptide which may reduce its phototoxicity.

Clinical features [2–4]
Skin. Of those patients with symptomatic VP, around 70% of patients have cutaneous involvement, and only around 17% of these patients will ever suffer an acute attack [5]. VP only very rarely presents before puberty, and usually the skin disease begins in adolescence or young adulthood. Patients describe skin fragility, usually fairly mild, affecting sun-exposed skin particularly on the backs of the hands [2,3]. The skin disease is generally indistinguishable from PCT, with painful tense bullae occurring in sun-exposed skin, as well as scarring, pigmentary abnormalities, sometimes pseudosclerodermatous changes of the hands and fingers, and occasionally photo-onycholysis. However, a significant number of patients do not describe worsening in the summer, and the patients who do describe seasonal variation often have their worst problems in late summer and autumn. In addition, around half of patients with VP describe mild transient light-related eruptions in the early summer. The examination findings of scarring, patches of hypo- and hyperpigmentation at sites of blisters, milia and mild hypertrichosis particularly around the eyes, are indistinguishable from PCT. Intercurrent biliary obstruction exacerbates the cutaneous disease since the accumulated porphyrins are excreted into the bile. Acute photosensitivity can occur in patients with disturbed liver function. Hormonally induced hepatic dysfunction may explain the exacerbations of skin disease seen in females taking oral contraceptives and during pregnancy. VP sometimes goes into clinical and biochemical remission in old age.

Acute attacks [2,3,5]. As in other acute porphyrias, women are three times as frequently affected as men, and 70% of acute attacks occur between the ages of 20 and 40 years. Around 17% of patients with cutaneous VP ever suffer an acute attack: the number has declined recently due to improved use of prophylactic measures. The severity of acute attacks varies from mild abdominal pain, sometimes accompanied by vomiting and constipation, through to very severe attacks with bulbar palsy and respiratory paralysis. The presentation, diagnosis and management of acute attacks is covered in the section on acute attacks of porphyria, p. 57.7.

Homozygous VP [6]. In this disease, a mutation on both protoporphyrinogen oxidase alleles results in an enzyme activity less than 20% of normal, compared to the 50% in

other VP patients. In homozygous VP, fragility, bullae and often hypertrichosis develop in exposed (and sometimes non-exposed) skin in neonates or infants and the skin disease may be severe. Delayed development, epilepsy, sensory neuropathy, nystagmus, various hand deformities and growth retardation also commonly occur. Acute attacks do not occur in these patients. The biochemical findings are the same as in VP, except for the lower enzyme activity.

Differential diagnosis. VP cutaneous disease is easily distinguished from non-photosensitive blistering disorders. It can be clinically very similar to PCT, late-onset CEP, HC and pseudoporphyria. Biochemical analysis is required to diagnose VP.

Biochemical findings. A plasma spectrofluorimetry peak around 626 nm (caused by a porphyrin–protein complex) is diagnostic of VP in the absence of a raised free red cell protoporphyrin level, and is present in virtually all symptomatic cases of VP. It may persist during periods of clinical remission when faecal excretion becomes normal. The urine contains increased levels of coproporphyrin, and increased concentrations of copro- and protoporphyrin are found in faeces. In a few patients, the urine shows the typical PCT pattern of uroporphyrin accompanied by hepta- and sometimes hexa- and pentacarboxylic acid porphyrins, a situation known as 'dual porphyria' [7]. Thus, urinary analysis alone can result in the misdiagnosis of VP as PCT, with potentially disastrous consequences. During acute attacks, urinary PBG (and ALA) are raised. The urinary PBG usually falls to normal within weeks of the attack resolving, but may stay a little increased outside the context of an acute attack [8].

Treatment. The key to successful management of the skin disease is photoprotection with sun avoidance using clothes, hats and gloves. Opaque sunscreens, containing pigmentary grade titanium dioxide or zinc oxide sometimes with the addition of iron oxide, are protective against Soret wavelength light [9,10]. The skin disease is rarely severe enough to require filter films for car and home windows. Since the relationship between sun exposure and skin lesions is not obvious, the role of light in producing the skin lesions should be explained to the patient. β-Carotene and canthaxanthin have also been claimed to provide limited protection in some patients, and narrow band UVB phototherapy may also be of value [3]. If liver function tests indicate biliary obstruction, relief of this will reduce cutaneous symptoms. The risk of acute attacks is the key issue for safe management of patients and their families. Patients should be given a list of drugs to avoid, including those which can induce attacks (see Table 57.1), those known to induce cholestasis, and cannabis; they should also be advised to wear an emergency identification bracelet, to avoid low calorie diets, and to become teetotal.

Genetic counselling. It is important to identify relatives who have latent VP because of the risk of acute attacks. The plasma 624–626 nm peak is found in the majority of cases of latent VP but only from teenage onwards. A positive plasma fluorimetry result is diagnostic of latent VP but a negative result is uninformative [11,12]. The only completely reliable way to identify those carrying the VP gene defect if the plasma scan is negative is to identify the protoporphyrinogen oxidase gene mutation in the index case and then assess its presence or absence in relatives. This is labour intensive because, outside South Africa, most families have their own private mutation. Relatives found to have the gene defect are at a low risk (roughly 5–10%) of acute attacks and should take all the precautions taken by any patient diagnosed with an acute porphyria. The risk of a patient passing the mutated gene on to each offspring is 50%, and around 20% of those carrying the mutation will eventually develop symptoms of some sort.

Mucinoses [1–5]

[S.M. Breathnach, pp. 57.23–57.36]

Mucins are jelly-like acid glycosaminoglycans (formerly known as mucopolysaccharides) of the ground substances and probably play a part in the extravascular exchange of

metabolites. Mucin is normally produced in small quantities by fibroblasts. Acid glycosaminoglycans, such as hyaluronic acid and heparin, stain with toluidine blue, colloidal iron, or with alcian blue at pH 2.5, the coloration depending on the number and nature of the acid groups [6]. PAS stains heparin, but not hyaluronic acid. In general, acid glycosaminoglycans stain much brighter in frozen fixed tissue, or in 1% cetylpyridinium chloride solution [7], rather than in formalin-fixed biopsies [8].

Neutral glycosaminoglycans are glycoproteins in which the hexosamine sugar polymer is incorporated in a protein chain. Hale and alcian blue stains are negative but PAS stain is positive. The mucins in the skin and their histochemistry have been well reviewed [9]. Histopathological examination of many cutaneous mucinoses reveals that collagen fibres are fragmented [10].

Classification of the cutaneous mucinoses [1–5]

Mucinous infiltration of the skin is found in many widely differing disorders, some affecting the skin only, others related to systemic disease [1–5,11]. The association of HIV infection with lichen myxoedematosus seems to be more than coincidental [12]. They can be classified as shown in Table 57.3.

Table 57.3 Classification of the cutaneous mucinoses.

Primary

Diffuse (degenerative-inflammatory mucinoses):
Generalized myxoedema (Chapter 59)
Pretibial myxoedema (Chapter 59)
Lichen myxoedematosus (papular mucinosis, scleromyxoedema)
Reticular erythematous mucinosis (plaque-like mucinosis)
Scleroedema (Chapter 56)
Self-healing juvenile cutaneous mucinosis
Cutaneous mucinosis of infancy
Papular and nodular mucinosis associated with lupus erythematosus
Papular mucinosis of the toxic oil syndrome

Focal (neoplastic-hamartomatous mucinoses):
Cutaneous focal mucinosis
Mucous (myxoid) cyst
Acral persistent papular mucinosis
Mucinous naevus

Follicular forms:
Follicular mucinosis (alopecia mucinosa)
Urticaria-like follicular mucinosis

Secondary

Collagen vascular diseases (especially dermatomyositis, lupus erythematosus)
Malignant atrophic papulosis (Degos' syndrome) [13]
Hereditary progressive mucinous histiocytosis
Papular mucinosis in L-tryptophan-induced eosinophilia–myalgia syndrome
Mucinosis accompanying mesenchymal and neural tumours

Lichen myxoedematosus

SYN. PAPULAR MUCINOSIS; LICHEN FIBROMUCINODOSIS; SCLEROMYXOEDEMA

Lichen myxoedematosus is a cutaneous myxoedematous state characterized by the formation of numerous lichenoid papules which coalesce together to form generalized plaques, causing extensive thickening and hardening of the skin [1,2] (Fig. 57.13). It is a rare disorder characterized by proliferation of fibroblasts with fibrosis and excessive deposition of acid glycosaminoglycans in the skin, and is distinct from scleroderma [3]. Montgomery and Underwood [2] divided it into four types:

1 a generalized lichenoid papular eruption (scleromyxoedema);
2 a discrete papular form;
3 a localized to generalized lichenoid plaque form; and
4 an urticarial plaque form.

However, a recent review of this area suggests that there are really only two main divisions of lichen myxoedematosus, a generalized papular and sclerodermoid form (scleromyxoedema) and a localized papular form [1]. Some atypical variants have also been suggested.

Scleromyxoedema is usually associated with a monoclonal gammopathy. Serum from patients with lichen myxoedematosus, even after elution of the IgG paraprotein, can stimulate synthesis of DNA and cell proliferation in cultured fibroblasts [4]. Localized forms of lichen myxoedematosus, without a demonstrable paraprotein, are recognized, and include a discrete papular form involving

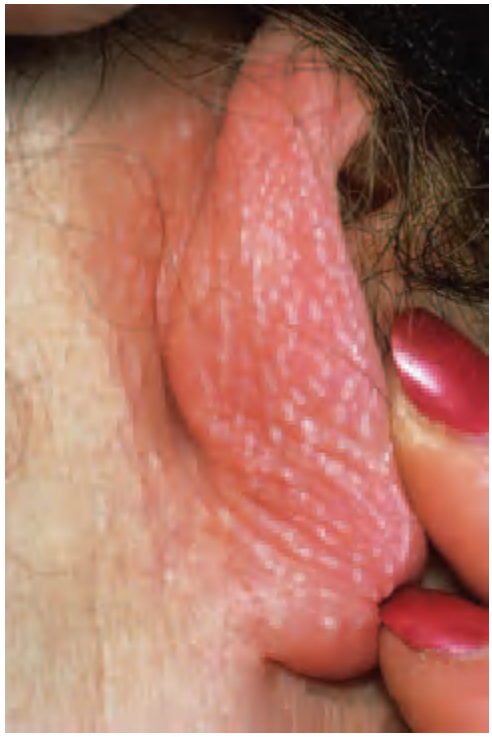

Fig. 57.13 Lichen myxoedematosus. Close up of micropapules behind earlobe. (Courtesy of St Thomas' Hospital, London, UK.)

any site; acral persistent papular mucinosis involving only the extensor surface of the hands and wrists; self-healing papular mucinosis, of juvenile and adult types; papular mucinosis of infancy, a paediatric variant of the discrete form or of acral persistent papular mucinosis; and a nodular form [1,5,6].

Histopathology [2,7–9]. Mucinous deposits occur in the middle and deeper layers of the dermis, where they displace collagen fibres, but do not involve the dermal papillae or accumulate around blood vessels. Histochemically, the mucinous deposits are heterogenous mixtures of acid glycosaminoglycans, which stain positively with alcian blue and toluidine blue. Large, stellate, elongated fibroblasts are present within the mucinous stroma [10]. Mucin deposition in the media and adventitia of vessels and in many organs including the myocardium is reported, and the skeletal muscles may be infiltrated with lymphocytes [11].

Clinical features [1,12]. In scleromyxoedema (the Arndt–Gottron syndrome) the pattern of lichen myxoedematosus is confluent, papular and sclerotic. Diffuse thickening of the skin underlies the papules. The facial features may be distorted by exaggeration of the facial ridges (Fig. 57.14), and flexion of the fingers may be limited. Multiple periorbital myxomas may progress to scleromyxoedema [13]. The involvement of the hands may simulate the sclerodactyly of scleroderma (Fig. 57.15), but the clinical appearance of numerous small papules of more or less uniform size, often in linear patterns on an erythematous and palpably thickened background, is very distinctive.

Fig. 57.14 Scleromyxoedema. View of forehead showing sclerodermoid appearance and linear papulation. (Courtesy of St Thomas' Hospital, London, UK.)

Fig. 57.15 Scleromyxoedema. Sclerodermoid appearance of finger. Same patient as shown in Fig. 57.14. (Courtesy of St Thomas' Hospital, London, UK.)

No endocrine abnormalities have been demonstrated, but cardiovascular abnormalities may occur in 10% of cases [7], whereas others may complain of extreme muscular weakness and lassitude due to myopathic or neurological involvement [13,14]. Occasionally, systemic involvement may occur in other internal organs; this has recently been reviewed [11,15].

An IgG class paraproteinaemia is almost always found on serum electrophoresis, although total serum protein values are usually normal [1,16]. Bone marrow studies may show a mild plasmacytic infiltration. Radiological survey of the skeletal system is normal. In one case, acid glycosaminoglycan levels in the serum were elevated [17].

Localized lichen myxoedematosus is characterized by small, firm, waxy papules of limited distribution [1], although a rare nodular form has larger lesions.

Diagnosis. Infiltrates appearing in and around old scars may simulate 'scar sarcoidosis'. Papules on the dorsa of the hands and ears may cause confusion with granuloma annulare. Systemic scleroderma may show many features simulating scleromyxoedema. However, in scleroderma the skin is thickened and bound-down, whereas in scleromyxoedema it is also thickened but moveable over the subcutis. Papules are absent in scleroedema and scleroderma, but common in scleromyxoedema.

Prognosis. The prognosis of scleromyxoedema is poor despite the introduction of treatment with cyclophosphamide and melphalan [11]. Death may result from non-specific complications such as bronchopneumonia, coronary occlusion or from haematological malignancies [11].

Treatment. The potential for spontaneous long-term regression renders treatment of severe lichen myxoedematosus or scleromyxoedema difficult to assess [18]. Systemic steroids alone are usually ineffective. Treatment with melphalan is probably the treatment of choice, although potentially toxic; long-term low-dose melphalan therapy resulted in the gradual resolution of skin lesions, with noticeable softening of sclerosis within 3 months [19]. However, the effect on the reversion of the monoclonal protein tended to be variable. Oral aromatic retinoids produce inconsistent but occasionally successful results [20,21]. Plasmapheresis can be beneficial if combined with pulsed corticosteroid and/or immunosuppressive therapy [22,23]. Other therapies reported to be successful in isolated cases of scleromyxoedema include topical betamethasone and dimethyl sulfoxide (DMSO) [24], extracorporeal photochemotherapy [25,26], intravenous immunoglobulin [27,28] and electron-beam therapy [29]. Aggressive surgical intervention for palliation of severe aesthetic and functional disability may be indicated [30].

Reticular erythematous mucinosis [1]

SYN. REM SYNDROME, PLAQUE-LIKE CUTANEOUS MUCINOSIS [2]

This syndrome comprises areas of reticular erythema on the trunk with a mucinous and round cell infiltrate in the dermis, and is frequently called the REM syndrome. Plaque-like cutaneous mucinosis is essentially the same disease process [3].

Aetiology. The aetiology is unknown, but there is some clinical and also experimental evidence that light is a factor in the pathogenesis of this disorder [4,5]. REM syndrome can be associated with the production of a monoclonal paraprotein, suggesting that the disease may

Fig. 57.16 Reticular erythematous mucinosis syndrome. View of anterior chest to show erythematous rash in photodistributed location.

involve disturbance of immune mechanisms [6]. Immunophenotypic studies have suggested a potential overlap between REM syndrome and Jessner's lymphocytic infiltration [7]. An hormonal influence may be operative [8].

Pathology. The epidermis appears normal. In the papillary and upper reticular dermis there is a perivascular, and occasionally perifollicular, infiltrate largely composed of small mononuclear cells and populations of FXIIIa+/ hyaluronan synthase 2+ dermal dendrocytes, which have been postulated to be responsible for accumulation of hyaluronan, rather than this being derived from fibroblasts [9]. There is separation of collagen bundles and fragmentation of elastic fibres. Histochemical stains show an increase in dermal mucin with a profile consistent with hyaluronic acid [4]. Direct immunofluorescence is usually negative for immunoglobulins, fibrin and complement [4], although granular basement-membrane deposits of IgM, IgA and C3 have been described in isolated cases [5,10].

Clinical features. Most affected patients are female [1,3,4,11] and usually middle aged, but the condition has been reported in children [12]. Areas of pink, reticulate or sheet-like erythema are present on the central part of the chest and back, particularly over the sternum and on the upper back (Fig. 57.16). There is usually no pruritus, although sometimes the areas become itchy following sun exposure, and the erythema may be then more apparent. The areas become infiltrated and then slowly increase in size. Coexisting disorders reported in association with occasional cases of REM syndrome include hyperthyroidism, hypothyroidism, discoid lupus erythematosus, carcinoma and thrombocytopenic purpura [13]. Evolution of REM syndrome to systemic lupus erythematosus has been reported [14].

Treatment. Topical steroids are ineffective, but fortunately antimalarials are almost invariably effective in controlling the eruption [1,4,11]. Ciclosporin appears to be of no value in treating REM syndrome [15]. UVB radiation combined with steroid impregnated tape [16], and use of the pulsed dye laser [17], have been beneficial.

Self-healing juvenile cutaneous mucinosis [1–4]

Self-healing juvenile cutaneous mucinosis is a rare disorder characterized by an early age of onset accompanied by inflammatory phenomena and spontaneous resolution over a few months. The condition has also been reported in a child undergoing chemotherapy for nephroblastoma [5], and in two brothers [6]. Clinically, there are papules, nodules or plaques with a predilection for the head and trunk rather than the extremities. Histologically, there is

dermal mucinosis and a mild increase in fibroblasts and mast cells. It is postulated that a temporary alteration of fibroblast synthetic function occurs, possibly as a result of a viral infection [3]. Rare cases of self-healing cutaneous mucinosis have been reported in adults [7,8].

Cutaneous mucinosis of infancy [1–4]

In this rare condition, opalescent papules may be noted at birth [2] or develop a few months later [1,3]. The papules are scattered on the dorsa of the hands or around the elbows, and may have a linear distribution [2]. Focal mucinous material is deposited in the papillary dermis without overt fibroblast proliferation. It is not clear what the long-term outlook of cutaneous mucinosis of infancy is, but some cases appear to progress [3]. Thus, certain cases of cutaneous mucinosis of infancy are in fact the infantile presentation of lichen myxoedematosus [5].

Papulonodular mucinosis associated with systemic lupus erythematosus [1–5]

Papulonodular mucinosis is a distinct but rare cutaneous manifestation occurring in patients with systemic lupus erythematosus or chronic cutaneous lupus erythematosus [6]. It presents as indolent, flesh-coloured papulonodules or plaques [7] on the neck, trunk and upper limbs due to diffuse mucinosis in the dermis. It differs from the diffuse mucinosis that may be found in lesional skin of lupus erythematosus in that it occurs in areas free of specific lupus erythematosus lesions. Clinical recognition is important because in one-third of cases it precedes both clinical and serological evidence of systemic lupus erythematosus, sometimes by several years. Cutaneous mucin deposition in papulonodular lupus erythematosus is associated with increased glycosaminoglycan production by dermal fibroblasts, which appears to be due to an unidentified serum factor [8].

Cutaneous mucinosis in the toxic oil syndrome [1]

Toxic oil syndrome occurred in Spain in 1981 related to the ingestion of adulterated oil. During the late recovery stages, an asymptomatic papular eruption developed on the arms, thighs and legs due to dermal mucin deposition. The papular eruption gradually resolved but sometimes led to sclerodermoid changes.

Cutaneous focal mucinosis [1–3]

Cutaneous focal mucinosis has been accepted as a distinct entity, although recently it has been classified as a superficial angiomyxoma [4,5] (see also Chapter 53). Clinically, it is characterized by a solitary, asymptomatic, flesh-coloured papule or nodule that can occur on the face, trunk or extremities. Histologically, there is localized accumulation of mucin in the dermis with an increased number of fibroblasts. The fibroblasts appear to function as mucoblasts with many large condensing vacuoles or secretory granules in their cytoplasm [2]. It is suggested

that cutaneous focal mucinosis arises as a result of a dysfunction of the fibroblasts in a localized area only. If treatment is required, local excision is satisfactory, since recurrence is unusual. The condition may show some overlap with other mucinoses, for example REM syndrome and scleromyxoedema [6].

Focal cutaneous mucinosis forms part of the Birt–Hogg–Dubé syndrome, where it is associated with multiple fibrofolliculomas and a predisposition to renal cancer [7].

Oral focal mucinosis of the tongue, causing a clinically elevated mass, is an uncommon clinicopathological entity which is considered to be the oral counterpart of cutaneous focal mucinosis [8].

Acral persistent papular mucinosis

Acral persistent papular mucinosis has been proposed as a distinct form of cutaneous mucinosis [1–3]. The characteristic findings include discrete papules or annular lesions on the extensor surfaces of the hands and wrists, mucinous deposits within the dermis, persisting for several years, and usually an absence of systemic abnormalities. Familial occurrence has been reported in two sisters [4]. The accumulation of lysosomal structures in acral persistent papular mucinosis may be a distinctive feature of the disorder [5]. However, it is still debatable whether acral persistent papular mucinosis is a distinct entity [6] or whether it is a variant of the discrete papular form of lichen myxoedematosus [1]. A case resembling acral persistent papular mucinosis has been described in which transient carpal tunnel syndrome appeared, suggesting that extracutaneous involvement might occur [7].

Mucinous naevus

The association of dermal mucinosis in association with a congenital plaque-like lesion in the interscapular area was first reported in a 16-year-old female [1]. In the absence of an overt connective tissue naevus and associated systemic disease, it was felt the lesion represented a congenital cutaneous mucinosis (mucinous naevus). Analysis of further cases suggests that these lesions may be a connective tissue naevus of proteoglycan type, and the only type to contain hyaluronic acid [2].

Follicular mucinosis [1]

SYN. ALOPECIA MUCINOSA

Definition and nomenclature. Follicular mucinosis is an inflammatory disorder characterized clinically by infiltrated plaques with scaling and loss of hair, and histologically by the accumulation of acid glycosaminoglycans in the sebaceous gland and the outer root sheath of the hair follicles. The condition was first described by Pinkus in 1957 [2] under the name alopecia mucinosa, but alopecia is not always evident, especially when only vellus follicles are involved.

Aetiology [3–6]. The cause of follicular mucinosis is unknown, but cell-mediated immune mechanisms may play a role in its pathogenesis [7]. Follicular mucinosis may be subclassified into three groups. The first and largest group consists of patients with solitary or only a few lesions, clearing spontaneously in 2 months to 2 years. In a second group are patients in whom the lesions persist, or new lesions continue to develop over many years. In the third group (about 15% of cases [3]) the mucinosis is associated with a lymphoma [5,6]; in such cases, histological evidence of the lymphoma is present from the onset, but it may be overlooked until the sections are later re-examined with hindsight.

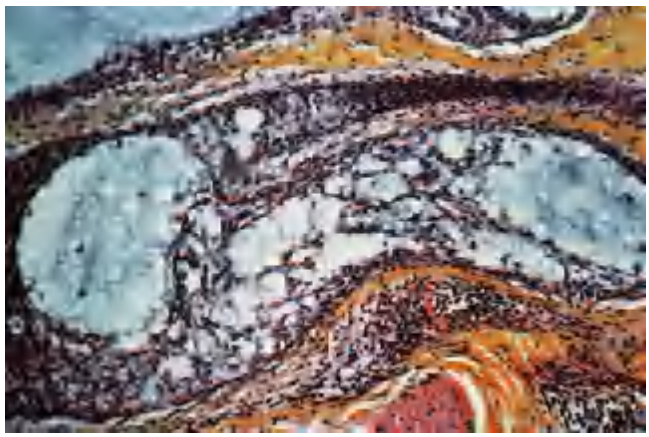

Fig. 57.17 Follicular mucinosis. Marked spongiosis and mucinous degeneration of outer root sheath of a follicle. Alcian blue, H&E, × 50. (Courtesy of St John's Institute of Dermatology, London, UK.)

Fig. 57.18 Follicular mucinosis. 'Boggy' erythematous plaque on forehead. (Courtesy of St John's Institute of Dermatology, London, UK.)

Patients with lymphoma-associated follicular mucinosis tend to be older (age 20–70 years; average 45 years) than those with benign disease (age 2–75 years; peak between 20 and 40 years), but there is no absolute distinction in age incidence [3,8,9].

Some authorities regard follicular mucinosis as a non-specific follicular reaction [4], as similar changes have been observed in association with lupus erythematosus [10], angiolymphoid hyperplasia [11], Hodgkin's disease [12] and alopecia areata [13].

Pathology [3,4,14]. The earliest change appears to be oedema of the outer root sheath and sebaceous gland, with formation of cystic spaces in which mucin accumulates. The entire depth of the follicle may be involved, but the degree of damage to the hair matrix is variable. Later, the sebaceous glands may appear to be absent, or the whole follicle may be converted into a cystic cavity containing mucin and degenerate root-sheath cells (Fig. 57.17). Dermal inflammatory changes are variable, and may become granulomatous. Electron-microscopic studies [15,16] have shown changes in the keratinocytes of the follicular epithelium. Autoradiographic studies [17] have failed to show increased synthesis of glycosaminoglycans in affected follicles.

Histopathological findings may not allow clear-cut differentiation between idiopathic and lymphoma-associated follicular mucinosis [5]. In general, the presence of large numbers of eosinophils in the inflammatory infiltrate and marked mucinous changes in the follicular epithelium favour a benign form, whereas lymphocytic epidermotropism and a dense perifollicular infiltrate with atypical cells suggests an associated lymphoma. Similarly, monoclonal rearrangement of the T-cell receptor (TCR) gamma gene on polymerase chain reaction analysis does not reliably differentiate the benign and lymphoma-associated forms. In one study, TCR gene rearrangements were found in about 50% of tested cases from both idiopathic primary and lymphoma-associated groups of patients [5], whilst a study of patients with primary follicular mucinosis found no evidence of progression to cutaneous T-cell lymphoma despite the presence of a clonal TCR gene rearrangement [18]. When a lymphoma is demonstrated, this is usually of T-cell type [19–21], although B-cell lymphoma has been reported [22]. A follicular variant of mycosis fungoides is being increasingly recognized, although overt mucinous spongiosis is not necessarily present [6,23]. Syringolymphoid hyperplasia with alopecia and anhidrosis is a syringotropic variant of follicular mucinosis and should be viewed as a facultative precursor lesion of mycosis fungoides [24].

Clinical features [3,25]. In the acute benign form, the earliest changes are grouped, skin-coloured papules or erythematous plaques, with some scale, and with prominent follicles. Each plaque, commonly 2–5 cm in diameter but sometimes larger, changes little in appearance. Multiple lesions may be present from the onset or may develop within a period of a few weeks. The face, scalp, neck and shoulders are commonly affected. The hairs are shed from the affected follicles, so that alopecia may therefore be the presenting symptom when the scalp or eyebrow region is involved. Spontaneous recovery usually takes place within a few months, but may be delayed for a year or more.

In the chronic form, the lesions are often more numerous and more widely distributed and their morphology tends to be more variable. There may be elevated, flat or domed plaques or nodules, some of which may ulcerate. The plaques and nodules are often of soft, gelatinous consistency; sometimes mucin can be squeezed out of affected follicles (Fig. 57.18). Non-infiltrated, red, scaly plaques, patchy scaling, alopecia (Fig. 57.19) and indurated plaques

Fig. 57.19 Follicular mucinosis. Circumscribed patch of hair loss associated with erythematous plaque on forearm. (Courtesy of St John's Institute of Dermatology, UK.)

may all be present. In some cases, leprosy may be simulated [26]. Presentation with an unusual acneiform eruption has been recorded [27].

Rarely, follicular papules may be generalized without obvious grouping. Irritation may be troublesome and persistent. Destruction of follicles may give rise to patches of permanent alopecia, which may be studded with horny plugs. This chronic form may persist for many years without any evidence of associated disease. An unusual case associated with erythroderma and boggy plaques on the scalp and face, associated with alopecia and purulent paronychia and nail loss, has been described [28].

Unfortunately, no single clinical feature distinguishes lymphoma-associated cases from the chronic benign form. Extensive cystic changes have been recorded in the lymphoma-associated type [29]. Contrary to earlier opinion [3,7] lymphoma-associated follicular mucinosis has been reported where the lesions occurred on the head and neck [19,30]. The temporal relationship between lymphoma and follicular mucinosis is very variable. Gross manifestations of the lymphoma may have been present for some time before the mucinosis develops; in other cases, the first indication of the lymphoma is uncovered by histology.

Diagnosis. The loss of hair in plaques with prominent follicles but minimal inflammatory changes should suggest the diagnosis. Sometimes, mucin can be expressed from the follicle. Eczema, seborrhoeic dermatitis, lichen simplex, pityriasis rosea, traumatic alopecia and tinea capitis can all be closely simulated. Biopsy and serial sectioning of the tissue should confirm the diagnosis.

Treatment. There are no clear guidelines for treating follicular mucinosis. Some improve spontaneously, while treatment with topical and intralesional steroids has been claimed to be of benefit. Superficial radiotherapy may be beneficial in some of the lymphoma-associated cases [19,30], but some cases fail to respond [31]. A case of follicular mucinosis responding to dapsone has been reported [32]. Low dose systemic steroids may benefit widespread pruritic follicular mucinosis [28] and interferon therapy, with or without acitretin, has also proved successful [33,34].

Urticaria-like follicular mucinosis

Urticaria-like follicular mucinosis appears to be a variant of follicular mucinosis, largely confined to middle-aged men, in which urticarial pruritic papules or plaques appear on the head and neck on an erythematous 'seborrhoeic' background [35]. The lesions tend to fade but recur for months to years leaving neither follicular plugging or alopecia. Sun exposure may temporarily clear the eruption. The histopathological features are identical to follicular mucinosis but the prognosis is good with a long benign course.

Secondary mucinoses [1]

The number of diseases in which dermal mucinosis may be associated to a greater or lesser extent with histopathological features otherwise typical of the disease in question continues to grow [1]. In some, the mucinous deposition may be so striking as to suggest the diagnosis, e.g. Degos' disease [2].

Collagen vascular diseases

Dermal mucinosis in lupus erythematosus and dermatomyositis has been linked in some patients to parvovirus B19 infection [3]. Marked periorbital oedema from massive mucinosis has been reported in a patient with discoid lupus erythematosus [4]. Infiltrated erythematous plaques on the back progressing to erythematous and elastic soft tumorous masses over 20 cm in diameter were recorded in a patient with systemic lupus erythematosus [5]. Dermatomyositis may present as plaque-like mucinosis [6,7]. Papular and nodular mucinosis has been recorded as a presenting sign of progressive systemic sclerosis [8], and development of multiple large soft skin lesions over the interphalangeal joints of both hands, resembling cutaneous focal mucinosis, has also been reported [9]. Lesions typical of papular mucinosis without evidence of paraproteinaemia occurred in a patient with generalized morphoea [10]. Dermal mucinosis has been associated with severe chronic cutaneous graft-vs-host disease of the sclerodermoid variety [11].

Hereditary progressive mucinous histiocytosis [12]

Hereditary progressive mucinous histiocytosis (MIM 142630) is a rare, probably autosomal dominant, disease in which small skin-coloured papules or nodules begin to appear anywhere in the first decade of life. In contrast to other benign histiocytic skin diseases there is no spontaneous resolution, so that a steadily increasing number of papules is noted. To date the disease has been confined to females. Histologically, the disease is associated with a progressive proliferation of histiocytes (non-X type) and dermal mucinosis but there is no evidence of any known lysosomal storage disease.

Papular mucinosis in L-tryptophan-induced eosinophilia–myalgia syndrome [13]

The L-tryptophan-related eosinophilia–myalgia syndrome, due to ingestion of contaminants of L-tryptophan, was first recognized in 1989 [4]. The skin lesions include a diffuse morbilliform eruption, urticaria and angio-oedema, dermographism, alopecia and cutaneous induration. Papular mucinosis may coexist for a while, although the lesions slowly regress after cessation of L-tryptophan ingestion [13]. There is associated weakness, fatigue, arthralgias and pneumonitis.

Mucopolysaccharidoses [1,2]

The mucopolysaccharidoses (MPS) are a group of genetically determined lysosomal storage diseases that are associated with deficiencies of lysosomal enzymes required for the normal sequential degradation of glycosaminoglycans (formerly known as mucopolysaccharides; mainly dermatan sulphate, heparan sulphate and keratan sulphate). The accumulation of glycosaminoglycans in a wide variety of tissues results in a complex and progressive disease leading to death in the first or second decade in most patients [3]. Multiple different enzymes known to degrade glycosaminoglycans have been implicated, resulting in a number of clinical syndromes of variable severity, which may share certain clinical features. Apart from the characteristic facies, the hypertrichosis and some thickening of the skin, dermatological changes are not prominent.

All are inherited as autosomal recessive traits except for Hunter's syndrome, which is sex linked. Mucopolysaccharidosis type I (MPS I) is caused by a deficiency of the lysosomal enzyme α-L-iduronidase. MPS I covers a broad spectrum of clinical severity ranging from severe Hurler's syndrome characterized by skeletal abnormalities, hepatosplenomegaly and severe mental retardation, through intermediate Hurler–Scheie syndrome to mild Scheie's syndrome, where there is aortic valve disease, corneal clouding, limited skeletal problems, but no mental retardation. There is molecular heterogeneity in mutations in MPS I [4–6]. MPS II (Hunter's syndrome) is caused by deficiency of the enzyme iduronate-2-sulphatase [7]. MPS III (Sanfilippo's syndrome) is characterized by progressive nervous system involvement with mental retardation, behavioural problems and seizures, associated with deficiency in one of the four enzymes involved in the degradation of heparan sulphate [8–11]. Details of these enzymes, and the deficient enzymes and clinical features of the other MPS [12–15], are listed in Table 57.4 [1].

Clinical features. The main types are summarized in Table 57.4. In some syndromes, the emphasis is on mental retardation with little somatic change; in others, mental development may be normal but somatic changes predominate. Children are generally born normal, and the changes develop over the first 2 or 3 years. There may be an early phase of increased growth, followed by growth retardation. Mental retardation occurs progressively, with hyperactivity and loss of skills. There may be severe mental retardation later, with almost complete paralysis and marked contractures. Bony changes (dysostosis multiplex) are pronounced in some syndromes, including pectus carinatum, thoracic kyphoscoliosis and hip dysplasia [16]; joint changes also occur. The head is large, the facies characteristically coarse and the tongue large. Umbilical and inguinal hernias are frequent and the abdomen protuberant. Corneal clouding is found in some syndromes and may lead to loss of vision, and deafness may also occur. Cardiac involvement, with or without aortic valve lesions, is one of the commoner causes of death, which usually comes before the age of 20 years. Respiratory infections are also common. The simultaneous occurrence of glycosaminoglycan type II (Hunter's) disease and systemic lupus erythematosus has been reported [17].

Skin lesions. Luxuriant hair or generalized hypertrichosis are found in several of the syndromes, and may be one of the very earliest clinical signs. Ivory-white nodules or ridges may occupy symmetrical areas between the angles of the scapulae and posterior axillary lines [18–23]. Individual nodules range from 1 to 10 mm in size and are especially found in Hurler's and Hunter's diseases, but also in Hurler–Scheie syndrome [24]. In some cases, they have also been found on the upper arms, forearms, pectoral regions and outer thighs. Thickening of the digits may simulate acrosclerosis [25]. Telangiectases have been found in Morquio's syndrome. Cases of extensive mongolian spots in infants with Hurler's and with Hunter's syndromes have been reported [26,27].

Histology [28–30]. There may be distinctive changes even in the absence of any clinical skin abnormalities. The occasional Malpighian cell in the epidermis develops a pale distended cytoplasm, which may displace the nucleus to one side. Large, vacuolated cells (gargoyle cells) are prominent just below the epidermis and in sweat glands [12,31] and, to a lesser extent, in the external root sheaths of hair follicles. Fragmentation and hyalinization of collagen, and increased tissue mucin, have been demonstrated in biopsies of scleroderma-like skin. Pooling of metachromatic material between the collagen bundles of the lower reticular dermis is sometimes especially marked [21,28].

Ultrastructurally, the presence of membrane-limited cytoplasmic vacuoles containing fibrillogranular material in dermal connective tissue and Schwann's cells has been demonstrated in all varieties of the MPS syndrome [12,28,29,31].

Table 57.4 Classification of the mucopolysaccharidoses (MPS). (Data from Neufeld and Muenzer [1].)

Number (& MIM no.)	Eponym	Clinical manifestations	Enzyme deficiency	Glycosaminoglycan affected
MPS I H (*252800)	Hurler	Corneal clouding, dysostosis, multiplex, organomegaly, heart disease, mental retardation, death in childhood	α-L-iduronidase	Dermatan sulphate, heparan sulphate
MPS I S (*252800)	Scheie	Corneal clouding, stiff joints, normal intelligence and life span	α-L-iduronidase	Dermatan sulphate, heparan sulphate
MPS I H/S (*252800)	Hurler–Scheie	Phenotype intermediate between I H and I S	α-L-iduronidase	Dermatan sulphate, heparan sulphate
MPS II (*309900)	Hunter (severe)	Dysostosis multiplex, organomegaly, no corneal clouding, mental retardation, death before 15 years	Iduronate sulphatase	Dermatan sulphate, heparan sulphate
	Hunter (mild)	Normal intelligence, short stature, survival to 20s to 60s	Iduronate sulphatase	Dermatan sulphate, heparan sulphate
MPS III A (*252900)	Sanfilippo A	Profound mental deterioration, hyperactivity, relatively mild somatic manifestations	Sulphamidase	Heparan sulphate
MPS III B (*252920)	Sanfilippo B	Phenotype similar to III A	α-*N*-acetyl-glucosaminidase	Heparan sulphate
MPS III C (*252930)	Sanfilippo C	Phenotype similar to III	Acetyl-CoA: α-glucosaminide acetyl-transferase	Heparan sulphate
MPS III D (*252940)	Sanfilippo D	Phenotype similar to III A	*N*-acetyl-glucosamine 6-sulphatase	Heparan sulphate
MPS IV A (*253000)	Morquio A	Distinctive skeletal abnormalities, corneal clouding, odontoid hypoplasia; milder forms known to exist	Galactose 6-sulphatase 6-sulphate	Keratan sulphate, chondroitin
MPS IV B (#253010)	Morquio B	Spectrum of severity as in IV A	β-galactosidase	Keratan sulphate
MPS V	No longer used	—	—	—
MPS VI (*253200)	Maroteaux–Lamy	Dysostosis multiplex, corneal clouding, normal intelligence; survival to teens in severe form; milder forms known to exist	*N*-acetyl-galactosamine 4-sulphatase	Dermatan sulphate
MPS VII (*253220)	Sly	Dysostosis multiplex, hepatosplenomegaly; wide spectrum of severity	β-glucoronidase	Dermatan sulphate, heparan sulphate, chondroitin 4-, 6-sulphates
MPS VIII	No longer used	—	—	—

Diagnosis. The diagnosis is usually suspected clinically, but the onset may be insidious and can readily be missed at an early stage. It can be confirmed and the exact syndrome clarified by finding the abnormal glycosaminoglycan in the urine, although this is not always easy biochemically at an early stage. The enzyme defect may be demonstrable in fibroblasts, white blood cells or serum. X-rays of bones may be helpful. Prenatal diagnosis is available for several of the diseases.

Treatment. Symptomatic treatment for the many symptoms can be very valuable but there is no effective cure. Clinical studies of enzyme replacement therapy are currently underway for MPS I, II and VI [3,32,33]. Bone marrow transplants, with all their hazards, can stabilize and to some degree reverse the pathological features [34–36], and currently remain the only hope for a long-term remission. Gene therapy offers hope for the future; lentiviral vector may prove useful for the delivery and expression of the α-L-iduronidase gene to cells *in vivo* for treatment of MPS I [37].

Mucolipidoses

The term mucolipidoses refers to a number of Hurler-like syndromes in which there is no accompanying mucopolysacchariduria but in which both polysaccharides and sphingomyelin and related lipids are stored. Dense cytoplasmic inclusions arise in cultured fibroblasts [1] and skin biopsy may reveal several types of lysosomal residual bodies, membrane-bound vacuoles, cytoplasmic bodies, and a diverse spectrum of lipopigments [2]. Mucolipidosis III (MIM *252600) has been reported in association with a large connective tissue naevus [3].

Leroy's syndrome

This is a rare lipoglycosaminoglycan disorder showing skin thickening and bone changes. The X-ray appearances mimic Hurler's disease. No corneal opacities are seen and fibroblast cultures show nuclear inclusions [1].

Amyloid and the amyloidoses of the skin

[S.M. Breathnach, pp. 57.36–57.51]

Amyloidosis is a generic term, originally coined by Rudolf Virchow in 1854, which denotes extracellular deposition of a proteinaceous substance composed of one of a family of biochemically unrelated proteins, depending on the underlying condition, and which is usually associated with considerable tissue dysfunction [1–6]. A classification based on the biochemical nature of amyloid fibril proteins is shown in Tables 57.5 and 57.6. Amyloidosis now tends to be classified on the basis of characterization of the fibril proteins rather than according to clinicopathological features [7]. Fibrils in primary and myeloma-associated systemic amyloidosis are composed of immunoglobulin protein AL, whereas in secondary systemic amyloidosis they are composed of a non-immunoglobulin protein termed protein AA.

Amyloid proteins, regardless of biochemical constitution, share certain characteristic physicochemical properties, tinctorial properties (Congophilia and green birefringence under polarized light) and a fibrillar ultrastructure. Paired, 7.5–10.0 nm, rigid, linear, non-branching, aggregated, hollow fibrils of indefinite length constitute the bulk of amyloid deposits, regardless of clinicopathological type or the tissue involved, and are arranged in a loose meshwork. Amyloid fibrils have been shown by X-ray diffraction crystallography and infrared spectroscopy to have, at least in part, a beta-pleated sheet configuration; this probably accounts for their ability to bind Congo red and for the low solubility and resistance to proteolytic digestion of amyloid.

Non-fibrillar amyloid proteins

All types of amyloid contain small amounts of a protein termed amyloid P component (AP) derived from and identical to serum amyloid P component (SAP), present in the blood of all normal individuals [1]. SAP prevents proteolysis of the amyloid fibrils of Alzheimer's disease, of AA amyloidosis and of AL amyloidosis, and may contribute to persistence of amyloid *in vivo* [8]. AP is constantly associated with the microfibrillar sheath of elastic fibres throughout the body in normal adults [9]. AP binds to isolated amyloid fibrils *in vitro* in a calcium-dependent manner, which may account for the frequent observation of amyloid deposition in the vicinity of elastic fibres [10]. Amyloid deposits also contain extracellular

Table 57.5 Biochemical nature of fibril proteins in systemic amyloidosis.

Clinical type of amyloidosis	Amyloid fibril protein	Precursor substance
Primary (immunocyte dyscrasia)	AL	Monoclonal immunoglobulin light chains
Myeloma-associated	AL	Monoclonal immunoglobulin light chains
Secondary (chronic active disease)	AA	Serum amyloid A protein (SAA)
Haemodialysis-associated (periarticular, bony and renal)	β_2-microglobulin	
Heredofamilial		
Predominantly nephropathic		
Familial Mediterranean fever	AA	SAA
Muckle–Wells syndrome	AA	SAA
Predominantly neuropathic		
Familial amyloid polyneuropathy	Transthyretin variant or Apoliprotein A1 or Gelsolin	
Non-neuropathic forms (Ostertag)	Apoliprotein A1 or Lysozyme or Fibrinogen α chain	
Predominantly cardiomyopathic	Transthyretin variant	
Cardiomyopathy with persistent atrial standstill	Unknown	
Senile systemic	Transthyretin from plasma	

Table 57.6 Biochemical nature of fibril proteins in organ-limited (localized) amyloidosis.

Nodular (skin, lung, genitourinary)	AL
Primary localized cutaneous	
Nodular	AL
Macular amyloid and lichen amyloidosus	?Altered keratin
Secondary localized cutaneous amyloidosis	?Altered keratin
Hereditary syndromes	
Hereditary cerebral haemorrhage with amyloidosis	
Icelandic type	Cystatin C
Dutch type	β-protein
Cerebral amyloid angiopathy and cortical plaques (Alzheimer's disease, senile dementia, Down's syndrome)	β-protein
Sporadic Creutzfeld–Jakob disease, kuru	Prion protein
Focal senile amyloidosis	
Heart atria	Atrial natriuretic peptide
Joints	Unknown
Seminal vesicles	Seminal vesicle exocrine protein
Prostate	β_2-microglobulin
Ocular deposits (corneal, conjunctival)	Unknown
Endocrine amyloidosis (APUD organs, APUDomas)	
Elderly non-insulin-dependent diabetics, benign insulinomas of the pancreas, normal aged pancreas	Islet amyloid polypeptide (homology with calcitonin gene-related peptide)
Medullary carcinoma of the thyroid	Precalcitonin-related

APUD, amine precursor uptake and decarboxylation.

matrix components, including glycosaminoglycans and proteoglycans, which may be involved in the pathogenesis [2,4,11].

Staining reactions [1–3]

Special stains for amyloid include the triphenyl-methane dyes methyl and cresyl violet for the demonstration of metachromasia, the PAS method, the substantive cotton dyes Congo red and Sirius red with or without fluorescence [4] or polarized light microscopy (Fig. 57.20), and fluorescence with thiazole dyes such as thioflavine T (Fig. 57.21). Immunohistochemical staining with anti-SAP has also been advocated [5].

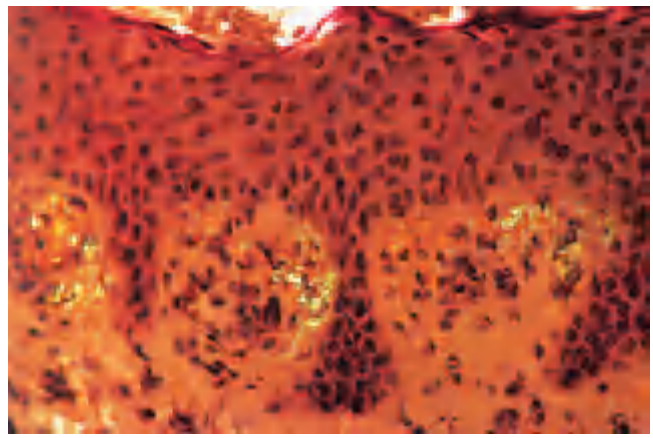

Fig. 57.20 Lichen amyloidosus. Alkaline Congo red, × 100. View under polarized light to show specific green fluorescence in amyloid deposits in papillary dermis.

The staining properties depend to some extent upon the duration of fixation in formalin and tend to be far brighter on frozen fixed material. Congophilia is the most specific. Unfortunately, methyl violet and Congo red staining may be equivocal and inadequate for detecting small deposits of amyloid; false positive results occur in colloid milium and lipoid proteinosis. False positive staining with thioflavine

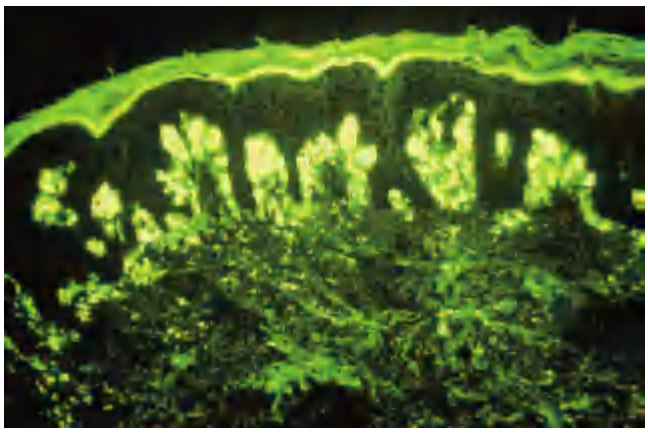

Fig. 57.21 Cutaneous amyloidosis. Thioflavine T, × 50. Viewed under fluorescence microscopy to show bright-yellow staining of amyloid deposits.

T is seen with stromal hyaline deposits, collagen fibres and colloid bodies in lichen planus: anti-SAP also stains colloid bodies and elastotic elastic fibres. Use of a battery of stains is therefore recommended. In some cases it may be necessary to resort to electron microscopy to look for the characteristic ultrastructure of the fibrils. *In vivo* scintigraphy techniques using ^{123}I-labelled human SAP component can be used to delineate amyloid deposits in systemic amyloidosis and to monitor the effects of therapy [6].

AL type amyloid, unlike AA type amyloid, retains its affinity for Congo red and its typical polarization characteristics after exposure to potassium permanganate [7]. Immunohistochemical staining with specific antisera [8,9], or either amino acid sequencing or mass spectroscopy of material extracted from fibrillar deposits (using sections of formalin-fixed, paraffin-embedded biopsy specimens) [10], are used to differentiate between the various types of fibril protein in amyloid deposits. Immunohistochemical staining with antikeratin antibody EAB-903 using formalin-fixed tissue appears to be a useful method in the differential diagnosis of primary localized cutaneous amyloidosis [11].

Primary localized cutaneous amyloidosis

In primary localized cutaneous amyloidosis (PLCA) there is deposition of amyloid in previously apparently normal skin, with no evidence of deposits occurring in internal organs. Various subtypes of PLCA are recognized, including the more common macular and papular (lichen amyloidosus) types and the rare nodular (tumefactive) form. Both macular and papular lesions can occur in the same patient.

Aetiology. Nodular PLCA may be regarded as a form of extramedullary plasmacytoma, since the fibrils are of immunoglobulin AL type, and are thought to arise as a result of local aberrant light chain material production by clonally expanded plasma cells [1,2].

The aetiology of other forms of PLCA remains unknown. Lichen amyloidosus is commoner among the Chinese [3]. Macular amyloidosis is rare in Europe and North America, but is much more common in Central and South America, the Middle East and Asia, suggesting the importance of genetic factors [3–8]. The occurrence of rare familial cases reinforces this view [8–15]. Primary cutaneous amyloidosis has been described in identical twins who also had numerous congenital abnormalities [16]. A review of the current literature has revealed no instance of systemic deposition of amyloid.

Fibrils in lichen amyloidosus and macular amyloidosis do not bind antibodies to protein AA or prealbumin [17], and although immunoglobulins, κ and λ light chains, and complement are frequently observed in deposits of macular and papular PLCA [18], they are not thought to be integral constituents of the fibrils, since they are readily eluted. The close proximity of the amyloid deposits to the lower epidermis in macular amyloidosis and in lichen amyloidosus suggests that the epidermis plays a role in its pathogenesis [19,20]. It has been proposed that focal epidermal damage and filamentous degeneration of keratinocytes is followed by apoptosis and conversion of filamentous masses (colloid bodies) into amyloid material in the papillary dermis [21,22]. There may be a contribution from the dermal–epidermal junction [23]. In support of this

theory is the fact that dermal amyloid deposits in these forms of PLCA react immunohistochemically with anti-human keratin antibody [24,25]. It is not clear why colloid (keratin) bodies produced in other dermatoses such as lichen planus are not transformed into amyloid. It has been proposed that in lichen amyloidosus specific immunological tolerance to the presence of colloid bodies in the papillary dermis favours their transformation into amyloid by macrophages or fibroblasts, whereas in lichen planus a brisk inflammatory response ensures their removal [26].

PLCA is associated with chronic friction, perhaps causing epidermal damage, as in the so-called friction amyloidosis seen especially in the Japanese as a result of rubbing the skin vigorously with a nylon towel or brush, bath sponge, towel, plant sticks or leaves [27–30], and in nodular prurigo and lichen simplex chronicus [31]. The association of macular amyloidosis with notalgia paraesthetica strengthens the role of chronic pruritus [32,33]. In the dyschromic forms of primary cutaneous amyloidosis, hypersensitivity to UVB with a possible DNA-repair defect may be significant [34]. The association of maculopapular amyloidosis with chronic active Epstein–Barr viral infection has recently been reported [35]. The patient's skin improved after treatment with aciclovir and interferon-α, suggesting that the viral infection may have played a role in inciting the keratinocytes to produce amyloid.

Pathology. In papular and macular forms of PLCA, the amyloid deposits are confined to the papillary dermis, and do not involve blood vessels or adnexal structures [1,2]. In macular amyloidosis, the deposits of amyloid are composed of small multifaceted amorphous globules, similar in size to the hyaline bodies found in lichen planus. They may be so sparse that more than one biopsy is necessary to confirm the diagnosis, and are easily missed without the use of special stains. The epidermis is usually of normal thickness but pigmentary incontinence with melanophages is a notable feature. In papular lichen amyloidosus, focal deposits of amyloid are often large enough to expand the dermal papillae and displace the elongated rete ridges laterally (Fig. 57.22). The overlying epidermis shows considerable irregular acanthosis and hyperkeratosis. The amyloid deposits are in close apposition to the

basal layer of the epidermis and contain a few melanophages. Near the amyloid deposits, there is usually a sparse lymphohistiocytic perivascular infiltrate.

By contrast, in the nodular or tumefactive forms of PLCA the dermis, subcutis and blood vessel walls are diffusely infiltrated with amyloid as seen in primary systemic amyloidosis (Fig. 57.23). However, there is usually a perivascular infiltrate of plasma cells [3–5].

Clinical features [1–5]. Several distinctive clinical forms of PLCA have been described (Table 57.7). Because macular amyloid and lichen amyloidosus may coexist in an affected individual (biphasic amyloidosis), they are regarded as variants of a single pathological process [6].

The papular form (lichen amyloidosus) is perhaps the best known. It usually presents as a pruritic eruption of multiple discrete hyperkeratotic papules, scaly and often hyperpigmented, distributed principally on the shins (Figs 57.24 & 57.25). The calves, ankles, dorsa of the feet and thighs, and the extensor aspects of the arms and abdominal or chest wall, may also be involved. Papules may coalesce to form thickened plaques, closely simulating hypertrophic lichen planus or lichen simplex chronicus. The condition usually persists for many years with localized pruritus as the prominent symptom.

The predominant sign in macular amyloidosis is clusters of small, pigmented macules, about 2 or 3 mm in diameter, which may coalesce to produce macular hyperpigmented areas. A reticulate or 'rippled' pattern of pigmentation is a characteristic diagnostic feature in many cases (Figs 57.26 & 57.27). The lesions tend to be associated with mild to moderate pruritus, but pruritus may be absent in 18% of cases. The lesions may be confined to the interscapular area (Fig. 57.26), but more commonly are extensively distributed over the back or chest [7,8]. Macular amyloidosis on the back has been reported to follow prolonged chronic friction (see above). Lesions may also occur on the extensor aspect of extremities, and occasionally on the chest and buttocks. Hypopigmented areas may produce a 'poikilodermatous' appearance. The condition usually presents in early adult life and persists for many years; both sexes are equally affected. Macular amyloidosis can be misdiagnosed as post-inflammatory pigmentation, resolving lichen planus or neurodermatitis, or as the reticulate hyperpigmentation of the neck ('dirty neck') that has been described in association with atopic eczema [9–11]. Amyloid-like material has been demonstrated by electron microscopy, but not at light microscope level, in the atopic dirty neck [12].

Fig. 57.27 Macular amyloidosis. Close up to show characteristic reticular or 'rippled' pigmentation over deltoid region. (Courtesy of St John's Institute of Dermatology, London, UK.)

Unusual variants of PLCA include: macular forms with widespread diffuse hyperpigmentation without papules but with poikiloderma-like facial involvement [13]; causing periocular hyperpigmentation [14]; simulating naevoid hyperpigmentation [15]; following Blaschko's lines [16]; resembling incontinentia pigmenti [17]; and a poikiloderma-like form [18,19]. Amyloidosis cutis dyschromica is assumed to be a congenital disorder with hypersensitivity to UVB radiation, with possible DNA repair defects; hyperpigmented and hypopigmented xerotic lesions with deposits of amyloid in the papillary dermis occur in sun-exposed skin [20]. Primary cutaneous amyloidosis of the auricular concha, in which small papules are grouped on the concha of the ear, is also believed to be a variant of PLCA, and may coexist with lichen amyloidosus [21,22].

Fig. 57.28 Nodular or tumefactive cutaneous amyloidosis. Close up of tumour on side of nose. (Courtesy of St John's Institute of Dermatology, London, UK.)

Associations of PLCA in a few kindreds with pachyonychia congenita [23], dyskeratosis congenita [24], familial palmar–plantar keratoderma [25] and multiple endocrine neoplasia type 2a have been described; in the latter, lichen amyloidosus is confined to the interscapular region [26,27]. Cases of PLCA have also been described in association with a variety of connective tissue disorders: systemic lupus erythematosus [28], systemic sclerosis [29], dermatomyositis [30], primary biliary cirrhosis and scleroderma [3,31], and Raynaud's phenomenon with livedo reticularis [32].

Anosacral cutaneous amyloidosis is a rare syndrome described in Japanese and Chinese males, in which pigmented macules and glossy hyperkeratotic lesions radiate out from the anus [33]. Fifty per cent of patients present below the age of 60 years, and the disease may be misdiagnosed as lichen simplex chronicus, post-inflammatory hyperpigmentation or tinea cruris.

The nodular or tumefactive form is a rare variant of PLCA (Fig. 57.28). Most reported patients have been females. Single or more commonly multiple nodules or plaques, indistinguishable from those associated with plasma cell dyscrasia-related systemic amyloidosis, may occur on the face, trunk, limbs or genitalia [1,3,5,34–41]. They vary in size from a few millimeters to several centimetres. The overlying skin is often atrophic, and there may be petechial haemorrhages within the nodules. The condition may follow a prolonged benign course over many years [38]; however, some patients later develop paraproteinaemia and overt systemic amyloidosis [1,3]. Some cases are associated with diabetes mellitus and Sjögren's syndrome [37]. Rare familial cases of nodular cutaneous amyloidosis have been reported [42].

Treatment. In general, the treatment of PLCA is disappointing. Milder cases can be helped by using potent topical corticosteroids with or without occlusive dressings, but usually in the short term only. Calcipotriol or phototherapy are similarly of limited use [1,2]. There have been reports of response to topical DMSO therapy in some [3–7] but not all [8] cases. Etretinate or acitretin therapy has been beneficial in a proportion of [9–12] but not all [13] patients; the condition soon relapses after the etretinate is stopped [14]. A trial of long-term cyclophosphamide 50 mg daily in lichen amyloidosus found that itching was markedly decreased within 4 months [15]. Ciclosporin given to treat atopic eczema coincidentally improved lichen amyloidosus [16]. Dermabrasion may have a long-term beneficial effect on papular lichen amyloidosus of the shins [17].

Nodular PLCA shows a good response to shave removal [18], curettage and cautery [19], cryotherapy, dermabrasion [20] or the carbon dioxide or pulsed dye laser [21–23], but subsequent recurrence is likely.

Secondary localized cutaneous amyloidosis [1–3]

Microscopic deposits of amyloid material have been described in association with a variety of cutaneous tumours, including intradermal melanocytic naevus [4], sweat gland tumours, pilomatrixoma, dermatofibroma, seborrhoeic wart, photosensitive annular elastolytic giant cell granuloma [5], solar keratosis, porokeratosis of Mibelli [6,7], Bowen's disease [8,9], basal cell carcinoma [10,11] and trichoepithelioma [12,13]. The amount of amyloid material in tumours is usually clinically insignificant but massive deposits may occur and cause diagnostic difficulty [14]. A similar phenomenon has been noted following PUVA therapy [15,16].

Systemic amyloidosis

Systemic types of amyloidosis include those associated with plasma cell dyscrasia, either overt as in multiple myeloma, or occult as in 'primary' systemic amyloidosis, amyloidosis secondary to a variety of chronic diseases, and in the heredofamilial amyloidoses. Clinically evident involvement of the skin is frequent in 'primary' systemic and myeloma-associated systemic amyloidosis, but occurs only rarely, if at all, in secondary systemic amyloidosis. Although there is a degree of overlap, primary and myeloma-associated systemic amyloidosis typically involve the tongue, heart, gastrointestinal tract, skeletal and smooth muscle, carpal ligaments, nerves and skin, whereas secondary systemic amyloidosis affects the liver, spleen, kidneys and adrenals [1]. Skin manifestations are associated with a number of systemic heredofamilial syndromes of amyloid deposition including familial Mediterranean fever [2], the Muckle–Wells syndrome [3] and heredofamilial amyloid polyneuropathy [4].

Primary and myeloma-associated cutaneous amyloidosis

Aetiology. In primary and myeloma-associated amyloidosis, the fibrils are composed of 'protein AL' (amyloid L-chain protein) and appear to be a consequence of plasma cell dyscrasia, although bone marrow aspiration may not reveal any abnormality. Amino acid sequence analysis has demonstrated that protein AL consists of fragments of immunoglobulin polypeptide light chain, particularly the variable (amino-terminal) region, or of an intact immunoglobulin light chain, or of both [1–4], and is usually associated with a similar abnormal immunoglobulin light chain in the serum, commonly of λ class. Abnormal light chain material is almost always present in the serum or urine, even in so-called primary systemic amyloidosis, and can be demonstrated on tissue culture of bone marrow cells from affected patients. Only a proportion of Bence-Jones proteins produce amyloid fibrils on digestion [5], which may account for the fact that amyloidosis develops in only about 15% of patients with myelomatosis. Amyloidogenic immunoglobulin AL monoclonal proteins appear to be preferentially of λ type, of lower molecular weight, and of lower isoelectric point [6]. Domains may be destabilized by specific amino acid residue changes due to point mutation, rendering them susceptible to the formation of ordered, fibril-like aggregates *in vitro* [7]. The organ tropism (i.e. whether there is predominant renal, cardiac or hepatic involvement) in AL amyloidosis may reflect germ-line gene use and plasma cell burden [8].

Histopathology [1–5]. In primary and myeloma-associated amyloidosis, deposits of amyloid are usually superficially placed in the papillary dermis as amorphous, faintly eosinophilic, often fissured masses, with associated thinning or obliteration of the rete ridges, accounting for the papules seen clinically. Amyloid deposits in the deep

reticular dermis and subcutis give rise to the clinical appearance of nodules and tumefactions, and infiltration of blood vessel walls correlates with the clinical finding of purpura. Marked thickening of blood vessel walls due to amyloid infiltration has been described [6]. Usually, there is little in the way of any inflammatory infiltrate, unlike nodular PLCA in which infiltration of plasma cells is a significant feature [3,4]. In areas of alopecia, amyloid deposits may surround and compress pilosebaceous units with resultant atrophy and loss of hair from the shafts. Amyloid may also be deposited in arrector pili muscles, the lamina propria of sweat glands and ducts, and around individual fat cells in the subcutis as characteristic 'amyloid rings'. Amyloid deposition in the nail fold and bed of dystrophic nails has been reported [7]. An affinity for amyloid to coat elastic fibres has been noted [8].

Clinical features [1–8]. The mean age of onset of primary amyloidosis is about 65 years, and there is a slight male preponderance. Presenting symptoms may be rather nonspecific, and include fatigue, weight loss, paresthesiae, hoarseness, oedema, dyspnoea, and syncope secondary to orthostatic hypotension. These features may predate the histological diagnosis by up to 2 years. The classical presentation with symptoms of carpal tunnel syndrome, macroglossia, specific mucocutaneous lesions which occur in up to 40% of cases, hepatomegaly and oedema should always alert the clinician to the presence of an underlying plasma cell dyscrasia.

Amyloidosis is the commonest cause of macroglossia in adults [9], and occurs in about 10% of cases. The tongue is usually diffusely enlarged and firm (Fig. 57.29), but it may also be fissured, with haemorrhagic papules, nodules, plaques or even bullae on its surface. There may be permanent tooth indentations along its lateral borders. Macroglossia may be so extensive as to cause dysphagia.

The commonest skin lesions are those related to intracutaneous haemorrhage due to infiltration of blood vessel walls by amyloid deposits (Table 57.8). Petechiae, purpura and ecchymoses may occur spontaneously or after minor trauma on normal or clinically involved skin, especially in the body folds, for example eyelids, sides of neck, axillae, umbilicus, oral and anogenital regions. Purpuric

Table 57.8 Cutaneous lesions in primary and myeloma-associated systemic amyloidosis.

Common	Less common
Petechiae, purpura, ecchymoses	Pigmentary changes
Waxy, translucent or purpuric papules	Scleroderma-like infiltration
Nodules	Bullous lesions
Plaques	Alopecia
Tumefactive lesions	Cord-like blood vessel thickening
	Nail dystrophy
	Cutis laxa; localized redundant skin folds and depressions

Fig. 57.30 Primary systemic amyloidosis. Prominent eyelid purpura following coughing. (Courtesy of St John's Institute of Dermatology, London, UK.)

haloes may occur around long-standing Campbell de Morgan spots [10]. Eyelid purpura after pinching, and periorbital purpura after proctoscopy ('post-proctoscopic palpebral purpura'), coughing (Fig. 57.30), vomiting or the Valsalva manoeuvre, are characteristic. Pigmentary changes include jaundice due to hepatic disease, cardiac failure or severe haemorrhage, pallor due to anaemia and hyperpigmentation due to haemorrhage.

Smooth, shiny, waxy papules or plaques, often with a haemorrhagic component, may also be found (Fig. 57.31). Translucent areas may resemble vesicles. Flexural areas are sites of predilection, including the eyelids, retroauricular region, neck, axillae, umbilicus, inguinal and anogenital regions. Lesions may also be found on the central face, lips, tongue and buccal mucosa. Widespread nodules may occur, coalescing to form large tumefactions. They may resemble condylomata lata on perianal and vulval skin [11,12], and when widespread may appear like xanthomas [13]. Diffuse infiltration of large areas, especially on the face, hands and feet, may simulate scleroderma [14,15], or on the face produce a myxoedema-like appearance. Alopecia may be patchy or widespread [16], and the scalp skin may be thrown into longitudinal folds resembling cutis verticis gyrata. Nail involvement due to infiltration of the nail matrix by amyloid may produce longitudinal striation (Fig. 57.32), crumbling, brittleness and partial anonychia, and may be a presenting sign [17–19]. Chronic paronychia with palmodigital erythema has also been described [20]. Signs which occur rarely include bullae of the skin or mucous membranes as a result of shearing within dermal amyloid deposits, resulting in changes resembling porphyria cutanea tarda or epidermolysis bullosa acquisita (Fig. 57.33) [21–25]. Extensive amyloid infiltration may lead to cord-like thickening of superficial blood vessels [26]. Amyloid elastosis is an unusual, recently recognized, syndrome in which papulo-

nodular cutaneous lesions are associated with widespread amyloid infiltration of visceral and cutaneous blood vessels, particularly in relation to elastic fibres [27,28]. Acquired cutis laxa has also been reported [29,30]. Localized elastolytic cutaneous lesions may present as soft, loose folds or indentations on the fingertips [31]. Other cases of cutis laxa may reveal fibrillar extracellular deposits, which are different from amyloid fibrils [32].

Hepatomegaly occurs in about 50%, and splenomegaly in about 10% of patients. The nephrotic syndrome or congestive cardiac failure (both of which occur in about 30% of cases), and rarely protein-losing enteropathy from amyloid involvement of the small bowel, may cause pitting oedema. Ascites may develop. Cardiac infiltration results in angina, infarction, congestive cardiac failure, orthostatic hypotension or arrhythmias [33]; it accounts for death in about 40% of cases of AL type systemic amyloidosis. Pulmonary involvement is common but usually asymptomatic. Amyloid infiltration of blood vessels may lead to claudication of the legs or jaw. Gastrointestinal tract involvement may simulate inflammatory bowel disease with haemorrhage; malabsorption is found in 5% of cases. The carpal tunnel syndrome [34] has been reported in up to 25% of patients with 'primary' systemic amyloidosis. Peripheral neuropathy [35], initially of the lower extremities, tends to pursue a chronic course; there may be superimposed autonomic neuropathy leading to orthostatic hypotension, diarrhoea, loss of bladder control or impotence. Muscle weakness may be caused by neuropathy, or by amyloid infiltration of muscle or its vascular supply; infiltration between muscle fibres leading to pseudohypertrophy is reported. Lymphadenopathy occurs in about 10% of patients [36]. Sjögren's syndrome or sicca syndrome due to amyloid infiltration of lacrimal and parotid glands [37] are occasional presenting features. Amyloid deposition in joints may mimic rheumatoid arthritis, and deposition around the shoulders may cause extensive soft-tissue enlargement (the shoulder-pad sign) [38]. Giant cell arteritis and polymalgia rheumatica are recorded [39], as are isolated factor X deficiency [40], disseminated intravascular coagulation and fibrinolysis with severe bleeding.

Diagnosis. The diagnosis should always be considered when a patient presents with the triad of carpal tunnel syndrome, macroglossia and mucocutaneous skin lesions [1,2]. Biopsy of classical mucocutaneous lesions should be the procedure of first choice. Biopsy of even clinically normal forearm skin has been reported positive in up to 50% of cases of primary and myeloma-associated disease. Fine-needle biopsies of the subcutaneous fat from clinically normal abdominal skin have a high positive yield in AL- and AA-type amyloidosis as well as in heredofamilial amyloidoses [3–5]. Rectal biopsy is positive in up to 80% of cases of AL or AA amyloidosis, jejunal biopsy in about two thirds, but gingival biopsy in only 19%. Gastric biopsy may produce a higher yield than rectal biopsy. Ninety-six per cent of hepatic, and 90% of renal and of splenic percutaneous needle biopsies, as well as carpal tunnel tissue biopsies at the time of decompression, are positive. Bone marrow aspiration may be positive in up to 45% of cases. Electrocardiography, echocardiography, angiocardiography, technetium scanning and endomyocardial biopsy are useful in the diagnosis of amyloid heart disease [6,7]. Computed tomography, ultrasound examination, and Doppler analysis of blood flow may be useful in renal amyloidosis. Sural nerve biopsy in patients with peripheral neuropathy [8], and synovial fluid analysis in patients with arthropathy, may be helpful. Scanning with ^{123}I-labelled SAP component enables specific localization and imaging of amyloid deposits *in vivo* [9,10].

Immunoelectrophoresis of both serum and concentrated urine is essential if the clinical presentation suggests the presence of a plasma cell dyscrasia, as conventional urine heat tests and simple electrophoresis of serum and urine may not detect small amounts of paraprotein or Bence-Jones protein. Protein electrophoresis of serum shows a spike pattern in just under half of patients with primary AL, and in about two thirds of those with myeloma. Immunoelectrophoresis of serum reveals a monoclonal protein in two thirds of patients with AL amyloidosis; only 45% have a monoclonal heavy chain, while 20% have free monoclonal light chains (Bence-Jones proteinemia). Immunoelectrophoresis of concentrated urine reveals a monoclonal light chain in about two thirds of cases (λ to κ ratio 2 : 1). When screening of both serum and urine is performed, the frequency of patients with an identifiable monoclonal protein rises to about 86%. A combination of immunofixation on agarose gel electrophoresis and bone marrow plasma cell light chain κ to λ ratio analysis improves diagnostic sensitivity [11]. Nevertheless, in some cases with the clinical features of AL amyloidosis it is not possible to demonstrate a paraprotein, even after prolonged follow-up for as long as 24 years [12].

Skeletal survey may be useful, as 50% of patients with myeloma-associated amyloidosis have radiological abnormalities, compared with only 6% of those with primary amyloidosis. Most myeloma cases, but no primary systemic amyloidosis cases, have more than 15% plasma cells in the marrow. In general, myeloma is not present if a patient has no lytic bone lesions, hypercalcaemia or anaemia, has only a small serum or urine monoclonal component, and has less than 25% bone marrow plasma cells.

Prognosis. Prognosis in primary systemic and myeloma-associated amyloidosis is poor, the major causes of death being cardiac and renal failure, and is linked to degree of plasma cell clonality and marrow infiltration [1]. The median survival of patients with myeloma-associated amyloidosis is only 5 months. The median survival of 859 patients with primary systemic amyloidosis seen at the Mayo Clinic from 1982 to 1992 was 2.1 years [2]; actuarial survival for 810 patients seen from 1966 to 1987 was 51% at 1 year, 16% at 5 years and 4.7% at 10 years [3]. Prognosis also depends on response to therapy and the extent of disease: the median survival of patients with primary amyloidosis with response to chemotherapy was 18–29 months, compared to 8.5 months in those receiving colchicine alone [4,5]. Cardiac involvement indicates a very poor prognosis, with a median survival of 1.08 years from diagnosis and 9 months from onset of heart failure [6–8]; cardiac transplantation improves survival to 60% at 2 years and 30% at 5 years [7,8]. Occasional patients surviving longer than 10 years have been recorded [3,9–11]. Patients presenting with amyloid neuropathy without associated cardiac, renal or hepatic involvement have a significantly better prognosis (median survival 40–50 months; 5 years survival 31.6%) [12]. Survival for more than 10 years has been recorded in a patient with primary systemic amyloidosis with sensorimotor polyneuropathy only [13].

Treatment. Most patients receive a trial of chemotherapy, most often using melphalan, prednisone and/or colchicine, with or without autologous bone marrow transplantation [14–19]. There is a relatively high risk of development of leukaemia or a dysmyelopoietic syndrome [20]. Cardiac [6–8] or renal transplantation can prolong survival; renal amyloidosis is not an absolute contraindication to transplantation, although amyloid may re-accumulate in the transplanted kidney. A recently developed competitive inhibitor of SAP binding to amyloid fibrils, *R*-1-[6-[*R*-2-carboxy-pyrrolidin-1-yl]-6-oxo-hexanoyl]pyrrolidine-2-carboxylic acid, also cross-links and dimerizes SAP molecules, leading to their very rapid clearance by the liver and marked depletion of circulating human SAP. This mechanism of drug action potently removes SAP from human amyloid deposits in the tissues and may provide a new therapeutic approach to both systemic amyloidosis and diseases associated with local amyloid [21].

Secondary systemic amyloidosis

In secondary systemic amyloidosis, the fibrils are composed of a non-immunoglobulin protein designated protein AA [1,2]. A precursor of protein AA, known as serum

amyloid A protein (protein SAA), is present in the serum of normal individuals as an apolipoprotein of high-density lipoprotein, and behaves as an acute phase reactant.

Secondary amyloidosis occurs as a complication of many chronic inflammatory diseases in which the immune system is stimulated [3,4]. These include acute recurrent and chronic infections, rheumatoid arthritis [5], juvenile chronic arthritis, ankylosing spondylitis [6], Reiter's syndrome, Behçet's syndrome, Sjögren's syndrome, dermatomyositis, scleroderma, systemic lupus erythematosus (very rarely) [7], inflammatory bowel disease [8], Hodgkin's disease and some solid non-lymphoid tumours, as well as Castleman's disease [9] and Rosai–Dorfman disease [10]. Secondary systemic amyloidosis may also arise as a complication of a number of dermatoses [11], such as venous ulceration [12], generalized psoriasis and psoriatic arthritis [13–15], pustular psoriasis [16], lepromatous leprosy [17], hidradenitis suppurativa, chronically infected burns, chronic skin infection in drug addicts [18,19], nodular non-suppurative panniculitis [20], giant, ulcerated or metastatic basal cell carcinoma [21], acne conglobata [22], epidermolysis bullosa of dystrophic [23–25] and aquisita types, and X-linked anhidrotic ectodermal dysplasia.

Secondary systemic amyloidosis rarely produces specific skin lesions, but commonly involves the kidneys (causing the nephrotic syndrome), spleen, alimentary tract and adrenals; the diagnosis should be confirmed by rectal or renal biopsy. Needle aspirates of abdominal wall subcutis may yield positive histological identification of amyloid [26]. Small or minute amyloid deposits are most often found around the adnexae, sometimes in small blood vessels and in the subcutis around fat cells: 'amyloid rings'.

There is no specific treatment, and many die from progressive renal failure. Treatment of the primary disease may arrest progression of the amyloidosis; estimated survival at 10 years was 90% in patients whose median protein SAA level was under 10 mg/L, and only 40% among those whose median SAA level exceeded this in one study [27]. Renal disease has responded to colchicine therapy or cyclophosphamide [5,28]. Renal transplantation is certainly worthy of consideration.

Dialysis-related amyloidosis

In systemic amyloidosis related to haemodialysis, the major constituent protein of amyloid firbrils is β_2-microglobulin. Most of the clinical findings are related to amyloid deposition in osseo-articular tissues [1,2]. Extensive tissue deposition of β_2-microglobulin may rarely present as masses in the buttocks [3], or as lichenoid lesions [4].

Inherited systemic amyloidosis

Several distinct genetic types of amyloidosis are recognized, which may be associated with mutations in a number of plasma proteins including transthyretin (MIM *176300), apolipoprotein AI (MIM *107680), fibrinogen A α chain (MIM *134820), lysozyme (MIM *153450), gelsolin (MIM *137350) and the 55-kDa tumour necrosis factor (TNF) receptor [1–3]. The kidney, peripheral nerves and spinal ganglia, or the heart are predominantly affected. Skin manifestations are associated with a number of systemic heredofamilial syndromes of amyloid deposition, including familial Mediterranean fever [4], the Muckle–Wells syndrome [5] and heredofamilial amyloid polyneuropathy [6]. Familial Mediterranean fever, inherited as an autosomal recessive disorder, may involve erysipelas-like lesions on the lower legs, urticaria, Henoch–Schönlein purpura and vasculitic nodules [4]. Associated features are intermittent fevers with abdominal pain and joint effusions, and a tendency to peritonitis, pleurisy, synovitis and renal amyloidosis. The Muckle–Wells syndrome, which has autosomal dominant inheritance, is characterized by periodic attacks of urticaria, fever and limb pains, associated with progressive perceptive nerve deafness and renal amyloidosis [5]. Trophic skin changes may develop in heredofamilial amyloid polyneuropathy [6]. The Finnish type of heredofamilial neuropathic amyloidosis, a gelsolin-related systemic amyloidosis characterized by cranial neuropathy and corneal lattice dystrophy, may be associated with cutis laxa, blepharochalasis and lichen amyloidosus [7].

Angiokeratoma corporis diffusum

[S.M. Breathnach, pp. 57.51–57.56]

Angiokeratoma corporis diffusum is the dermatological hallmark of several rare inherited lysosomal disorders, which include the following:
1 Anderson–Fabry disease (deficient α-galactosidase A; MIM 301500) [1];
2 fucosidosis (deficient α-L-fucosidase; MIM *230000) [2,3];
3 deficient lysosomal α-*N*-acetyl-galactosidase activity with glycopeptiduria (Kanzaki's disease; MIM *104170) [3–6];
4 aspartylglycosaminuria (deficient glycosylasparaginase; MIM *208400) [7];
5 adult-onset GM1 gangliosidosis (deficient β-galactosidase; MIM *230500) [8];
6 galactosialidosis (combined β-galactosidase and sialidase (neuraminidase) deficiency; MIM *256540) [9];
7 cases with no specific enzyme deficiency.
In each of these disorders, the skin lesions slowly develop as clusters of individual telangiectases or small angiomas. The larger and older lesions may become hyperkeratotic. The characteristic cutaneous eruption is often accompanied by a varied degree of vasomotor disturbances, neurological features, cardiovascular episodes and, sometimes, renal failure. Glycoproteinoses (fucosidosis, α-*N*-acetylgalactosaminidase deficiency and aspartylglycosaminuria) belong to the lysosomal storage disorders group, the common feature of which is deficiency of a lysosomal protein enzyme that hydrolyses glycoprotein (glycan) carbohydrate chains by stepwise removal of terminal monosaccharides. Deficiency of a single enzyme causes blockage of the entire pathway, and induces storage of incompletely degraded substances inside the lysosome. Different mutations may be observed in a single disease [3].

Anderson–Fabry disease (MIM *301500) [1–3]

Aetiology. Angiokeratoma corporis diffusum is an X-linked disorder, in which deficiency of lysosomal hydrolase α-galactosidase A results in the progressive deposition of uncleaved, neutral glycosphingolipids—predominantly α-galactosyl-lactosyl-ceramide (trihexosylceramide, globotriaosylceramide)—within the lysosomes of endothelial, perithelial and smooth muscle cells, leading to severe painful neuropathy with progressive renal, cardiovascular and cerebrovascular dysfunction and early death. Physical stigmata, such as angiokeratomas in skin and mucous membranes and characteristic benign corneal abnormalities, facilitate identification of Fabry's disease. Men are predominantly affected; most women who are carriers are symptomless, but they may have clinical evidence of the disease, and in a few this may be as severe as in men including increased risk of stroke [1,4]. The gene responsible for expressing α-galactosidase A has been localized to the middle of the long arm of the X chromosome [5,6], but the mutations involved are heterogeneous [7–10].

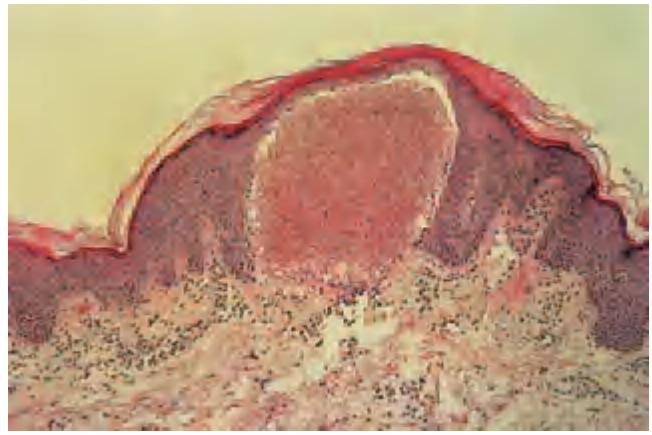

Fig. 57.34 Angiokeratoma corporis diffusum: H&E, × 4. Dilated blood-filled vessels in papillary dermis.

Histopathology [1]. Light microscopy of cutaneous lesions of angiokeratoma corporis diffusum shows dilated blood-filled vessels in the upper dermis lying beneath a thinned epidermis (Fig. 57.34), with or without hyperkeratosis. Detection of lipid in the skin necessitates the use of special fixation and lipid-staining techniques. The characteristic and diagnostic feature of the disease is the presence of vacuolated cells in the walls of capillaries, arterioles and venules. Glycolipid material can be demonstrated by polarized light as a double refractile substance in frozen sections, in the media and intima of smaller skin blood vessels. The diagnosis can be made more easily with the electron microscope than by light microscopy [2]. Electron-dense cytoplasmic inclusion bodies with a lamellar internal organization, consisting of alternating electron-opaque and electron-light regions with a periodicity of 4–6 nm are found in endothelial (Fig. 57.35) and muscle cells of blood vessels, perithelial and perineural cells, arrectores pilorum muscles and dermal macrophages. They may represent lipid deposits within lysosomes [3,4]. Inclusion bodies have been reported in the skin of adult patients even in the absence of clinically evident angiectases [5,6], and have also been found in 'normal' skin from an infant with the disease [7]. Characteristic cytoplasmic inclusions were observed in eccrine sweat glands and in their associated unmyelinated nerve fibres in a patient with hypohidrosis [8]. Ultrastructural study of kidney biopsies reveals typical concentric lamellation bodies in the cytoplasm of all types of renal cell [9].

Clinical features [1–5]. Cutaneous involvement [6–8] usually first appears shortly before puberty. The initial lesion is a dark-red or black telangiectatic macule or papule up to 4 mm across, remaining unchanged on diascopic pressure; overlying hyperkeratosis is not always obvious. Occasionally, skin lesions may be minimal or even absent. Grouping tends to occur, and in mild cases telangiectatic spots may be seen only on the thighs, scrotum or around the umbilicus (periumbilical rosette). In severe cases, widespread lesions are present, particularly on the limbs, hips, buttocks (Fig. 57.36), lower trunk and shaft of the penis. The association of Anderson–Fabry disease with perioral telangiectases has been noted [9]. The skin is often dry, lax, hypohidrotic or even anhidrotic [10,11].

A symptomless superficial corneal dystrophy (cornea verticillata) is a frequent ophthalmic finding, and is of diagnostic importance, since it can only be mimicked by chloroquine keratopathy [6]. It is often present in carrier females. Dilatation and tortuosity of the conjunctival and retinal vessels are common and may be present in childhood. The upper eyelids may be oedematous. A variety of oral and craniofacial abnormalities are described, including an increased prevalence of cysts/pseudocysts of the maxillary sinuses and the presence of maxillary prognathism [12].

Fig. 57.36 Angiokeratoma corporis diffusum. Clusters of telangiectatic spots. Micropapules are present on the buttocks. (Courtesy of St John's Institute of Dermatology, London, UK.)

Episodic attacks of pain [13,14] mainly in the skin of the fingers and toes (acroparaesthesia), often of an excruciating and apparently unique character, and usually beginning between the ages of 5 and 15 years, occur in 90% of males and in fewer than 10% of females. High-frequency sensorineural deafness may be present [3]. Vasomotor disturbances appear later, probably as a result of involvement of the autonomic nervous system. The hands may be blue or blanched, or there may be flushing of the extremities. Mild arthritis of the terminal phalanges is frequent.

Patients with angiokeratoma corporis diffusum are often mildly hypertensive, and liable to coronary artery disease and other cardiac abnormalities, including disturbances in conduction, valvular disorders and hypertrophic cardiomyopathy [15,16]. Varicose veins and stasis oedema are fairly common. Cerebrovascular disease and strokes are an important cause of premature death [2–5,17]. Renal dysfunction is a major complication; end-stage renal failure, requiring dialysis or transplantation, usually occurs between 40 and 50 years of age, but may occur much earlier [2,3,18,19]. Gastrointestinal involvement, including achalasia of the oesophagus, is common. Other reported presenting features include fever and generalized lymphadenopathy [20].

The full syndrome occurs predominantly in men. In women, there may be only corneal opacities, retinal vessel tortuosity and urinary signs of renal involvement, but sometimes the disease is as severe as in men [5].

Prognosis. The median cumulative survival was reduced to 50 years due to cerebrovascular or renal disease in one series, and attendance at school, sports and social activity were significantly affected, with only 57% of patients being employed [3]. Cerebral lesions did not appear until 23 years of age in another series, but were present in all patients by 55 years of age; the peak onset of proteinuria occurred in the fourth decade, and the peak onset of end-stage renal disease occurred in the fifth decade [2]. Prolonged survival without impairment of renal function is, however, possible.

Diagnosis. A skin biopsy may confirm the clinical diagnosis. Albuminuria, haematuria and specific lipophages may be seen in the urine as a result of lipid infiltration of the glomerular vessels; PAS-positive, 'mulberry-like' cells in urinary sediment can be used as a diagnostic aid [1]. The finding of a decreased level of α-galactosidase A in plasma, leukocytes and cultured skin fibroblasts is diagnostic. Slit-lamp examination of the cornea and renal biopsy should be performed in doubtful cases. The differential diagnosis includes purpura, angioma serpiginosum and other types of angiokeratoma: circumscriptum, scrotal (Fordyce type) and Mibelli type.

Treatment. Males with Anderson–Fabry disease recorded significantly lower health-related quality-of-life scores compared with males in the general population and individuals with severe haemophilia; the scope for improvement in quality of life as a result of treatment with an appropriate agent is therefore large [2]. Management has been largely symptomatic. Laser therapy may be helpful for the angiokeratomas [3]. Painful crises may respond to phenytoin or carbamazepine, either alone or in combination [4,5]. Early use of antiplatelet agents, for example aspirin, may mitigate embolic or thrombotic cerebrovascular events due to platelet activation caused by deposition of sphingolipid in vascular endothelium. Renal or cardiac transplantation have been undertaken for end-stage disease [6,7], but there is a tendency for reaccumulation of ceramide in transplanted organs. Enzyme replacement therapy using human recombinant α-galactosidase A has resulted in symptomatic improvement, as well as documented lessening of globotriaosylceramide deposits, and improvement in renal, cardiac and cerebrovascular function [8–14]. However, the future lies with gene therapy [15–17].

Glycoprotein lysosomal storage disorders

Glycoprotein lysosomal storage disorders that may have cutaneous features include fucosidosis, glycopeptiduria due to deficient lysosomal α-*N*-acetyl-galactosaminidase activity, and aspartylglycosaminuria.

Fucosidosis (MIM *230000)

Fucosidosis is an autosomal recessively inherited lysosomal storage disease caused by a deficiency of α-L-fucosidase, leading to accumulation of fucose-containing glycolipids and glycoproteins in various tissues. It is extremely rare; less than 100 patients have been reported worldwide, although the disease occurs at a higher rate in Italy, in the Hispanic-American population of New Mexico and Colorado, and in Cuba [1]. Fucosidosis is characterized by progressive psychomotor deterioration, angiokeratoma and growth retardation [1–4]. Other clinical features include coarse facies, recurrent infections, visceromegaly and epilepsy. The clinical spectrum varies between a rapidly progressive infantile type (type I) and a less severe adolescent or adult type (type II). The angiokeratomas are more frequent in the less severe type and possibly imply a better prognosis. The angiokeratomas may also occur on the tongue and be associated with increased vascular markings on the palms and soles [2]. The genetic mutations causing fucosidosis are heterogeneous [1,5]. Bone marrow transplantation has been recorded as an effective treatment [6,7].

Ultrastructure of melanocytes, endothelial cells, sweat glands and fibroblasts reveals numerous empty storage vacuoles, which enables ready differentiation from Anderson–Fabry disease [8].

Glycopeptiduria due to deficient lysosomal α-*N*-acetyl-galactosaminidase activity (MIM *104170) [9–12]

SYN. KANZAKI'S DISEASE

This very rare type of angiokeratoma corporis diffusum was first delineated in 1989 in a Japanese woman [10]. The disease overlaps with infantile neuroxomal dystrophy [11] so that infantile and adult-onset subtypes have now been identified [9]. The angiokeratoma lesions may be very diffuse and slowly spread to involve the face and extremities. The lesions tend to be most dense on the axillae, breasts, lower abdomen, groins and buttocks. Telangiectases have been noted on the lips, inside the oral cavity and on endoscopy in the gastric mucosa [9]. Dilated, corkscrew-like, tortuous, vessels occur in the ocular fundi [9]. In adults, the disease can be associated with impairment of intellect and features compatible with peripheral neuroaxonal degeneration [9].

Aspartylglycosaminuria (MIM *208400)

SYN. DEFICIENT ASPARTYLGLYCOSAMINIDASE

The main symptom is progressive mental retardation. Facial angiofibromas and oedema of the buccal mucosa (leukoedema) with gingival overgrowths have been described [13].

Angiokeratoma corporis diffusum with no overt enzyme deficiencies

Isolated cases of angiokeratoma corporis diffusum without overt enzyme deficiencies continue to be reported

rarely [1–4]. The association of angiokeratoma corporis diffusum with normal enzyme activities and Turner's syndrome has been observed [5]. It is unclear at the present time whether such cases may ultimately be proved to have other enzymatic deficiencies that have yet to be identified.

Lipoid proteinosis (MIM #247100)

SYN. URBACH-WIETHE DISEASE [1–3];
HYALINOSIS CUTIS ET MUCOSAE [4];
LIPOGLYCOPROTEINOSIS [5]
[S.M. Breathnach, pp. 57.56–57.57]

Lipoid proteinosis [6,7] is a very rare, autosomal recessive, genetic disorder characterized by infiltration of hyaline material into the skin, oral cavity, larynx and internal organs. It usually presents in infancy with hoarseness. The sexes are equally affected. Large kindreds of lipoid proteinosis have been reported in South Africa, where most of the cases can be traced back to a German immigrant [8,9].

Aetiology. Very recently, the disorder has been mapped to chromosome 1q21 and has been shown to be caused by mutations in the extracellular matrix protein 1 gene [10]. The exact nature of the hyaline material is still unknown.

Histopathology [2,11,12]. Epidermal hyperkeratosis and irregular acanthosis overlies a considerably thickened dermis. The upper dermis contains extracellular hyaline material, at first deposited along the course of capillaries and concentrically around sweat coils, and in older lesions tends to be orientated vertically in broad bands. The hyaline material stains strongly with PAS, implying the presence of glycoproteins. Mucosubstances can usually be demonstrated but the histochemical characteristics of the hyaline deposits may vary from site to site and with time [11]. Around the blood vessels and appendages, accumulations of type IV and V collagen occur [12]. Elsewhere, type III collagen is abnormally distributed and there is a reduction in type I collagen.

Ultrastructurally [13–15], hyaline material with a granular appearance is interspaced between collagen bundles.

Fig. 57.37 Lipoid proteinosis. Typical 'beaded' papules present along the margins of the upper eyelids. (Courtesy of Dr R.C.D. Staughton, Chelsea and Westminster Hospital, London, UK.)

Immediately surrounding blood vessels, there is reduplication of basal laminae in an 'onion skin' arrangement.

Clinical features [16–21]. Lipoid proteinosis develops early in life. Scarring from mild skin inflammation and injury is marked. Hoarseness develops in infancy; it becomes prominent within the first few years of life, and can progress to complete aphonia but fortunately usually without breathing difficulties [6]. The mucosae of the pharynx, tongue and lips soon develop firm yellow-white infiltrates; the lingual frenulum may be short. The soft palate, pillars of the tonsils, uvula and under-surface of the tongue show extensive yellow irregular infiltrations. The tonsils are covered with a hard, white mass. The larynx is involved to a severe degree, with nodules in the epiglottis and vocal cords [22]. The tongue is enlarged and feels firm on palpation; its range of movement is decreased, so that the patient is usually unable to protrude it beyond the margins of the lips. Occasionally, there is similar involvement of the mucosa of the labia and vagina.

Skin changes frequently become prominent in early life with the development of yellow-brown nodules appearing on the face and lips. Involvement of the scalp leads to loss of hair. Very typical 'beaded' papules are present along the margins of the upper and lower eyelids (syn. moniliform blepharosis) (Fig. 57.37) and there may be total loss of eyelashes. Scattered, atrophic, pock-like scars are often seen on the face [16]. Nodular lesions on the elbows resemble xanthomas. Deposits may appear in the skin and mucous membranes after trauma. Later, the colour of the skin darkens and the lesions become hyperkeratotic or warty. Small nodules are sometimes present on the finger joints, in the axillae and on the knees and scrotum. Dental abnormalities [23], intracranial (e.g. bilateral temporal) calcification [20] and epilepsy are often associated with lipoid proteinosis, and recurrent parotitis

can occur. Widespread visceral involvement is described, and indeed virtually every organ in the body can be involved [24].

Diagnosis. A combination of hoarseness from early childhood, thickening and stiffening of the tongue and characteristic cutaneous nodules makes the diagnosis relatively easy. In erythropoietic protoporphyria, which causes waxy papules and depressed scars, there is solar sensitivity and the scarred areas are confined to exposed skin; on histology, the hyaline material is not so extensively deposited, is never found around sweat coils, and fine droplets of lipid can be demonstrated. Xanthomatosis and amyloidosis can also be excluded by the histological appearances. In adult life, differential diagnosis from lichen myxoedematosus, and myxoedema with hoarseness, have to be considered.

Prognosis. Lipoid proteinosis is progressive until early adult life, but in general the prognosis is good [24]. Involvement of the larynx only occasionally leads to respiratory difficulties in childhood, resulting in tracheotomy.

Treatment. Microlaryngoscopy and dissection of the vocal cords can be successful. Dermabrasion [25], chemical skin peeling, blepharoplasty and carbon dioxide laser therapy [26] may be helpful. Remarkable clearance of skin and laryngeal lesions was reported in a single case of lipoid proteinosis after 3 years of continuous oral dimethyl sulfoxide therapy [27]. However, no improvement was demonstrated in a further three patients [28]. Beneficial effects of etretinate [29,30] and of penicillamine [31] have also been reported.

Neutral lipid storage disease (MIM 275630)

SYN. DORFMAN–CHANARIN SYNDROME

[S.M. Breathnach, pp. 57.57–57.58]

This rare autosomal recessive genetic lipid disorder is briefly mentioned because it may be associated with congenital ichthyotic erythroderma [1–4]. Lipid-filled vacuoles may be identified in neutrophils and basal keratinocytes, fibroblasts, Schwann's cells, smooth muscle cells and sweat glands [5]. The prognosis depends on the pattern and degree of systemic involvement. Etretinate may help the ichthyosis [2].

Farber's disease [1] (MIM *228000)

SYN. DISSEMINATED LIPOGRANULOMATOSIS

[S.M. Breathnach, p. 57.58]

Farber's disease is a rare and fatal lipid-storage disease of infants, probably inherited in an autosomal recessive fashion, in which there is deficiency of lysosomal acid ceramidase and an accumulation of ceramide [2]. Most cases have been sporadic.

Histopathology. In the skin and subcutaneous tissue, dense areas of mixed granulomatous infiltration are found among a fibrovascular stroma. Groups of large, foamy histiocytes are found towards the centre of the granulomas. At systemic sites (especially the brain) the presence of vacuolated cells is similar to the pathology encountered in other metabolic storage diseases.

Histochemical studies indicate that the deposited material is an acid glycolipid [3] of which ceramide is probably the most important [2]. It has been suggested that estimation of acid ceramidase in cultured fibroblasts or amniotic fluid cells may provide a means of early diagnosis [4]. Ultrastructurally, curvilinear bodies (Farber's bodies) have been described in the cytoplasm of fibroblasts [5,6].

Clinical features. Involvement of the laryngeal joints and the adjoining tissue produces dysphonia, laryngeal stridor, hoarse cry and noisy respiration. Erythematous papules and nodules appear close to joints and tendons of the hands and feet, leading to painful and progressively deformed joints. The ears, the occipital region and the trunk are other sites of predilection with infiltrated papules, plaques and nodules predominating. Gross mental and motor retardation are features of the disease. Cherry-red spots may be noted at the macula [3]. The lungs, heart and lymph nodes may also be affected.

Gaucher's disease (MIM *606463)

[S.M. Breathnach, pp. 57.58–57.59]

Definition. A rare inborn error of metabolism characterized by the accumulation of complex lipid substances in macrophages (Gaucher's cells) within liver, spleen and bones.

Aetiology [1,2]. This congenital and familial disorder of lipid metabolism is transmitted as an autosomal recessive disorder, and is due to a deficiency of the lysosomal hydrolase, acid-β-glucosidase (glucocerebrosidase) [3–5]. The abnormal lipid that results, kerasin, accumulates in the cells of the reticuloendothelial system leading to enlargement of the spleen, liver and lymph nodes. This condition may also be associated with a thrombocytopenia and coagulation defect [6,7]. Even patients and siblings with the same mutation, including monozygotic twins, may exhibit marked variability in disease expression and severity, illustrating our lack of understanding of the phenotype–genotype relationship in the sphingolipidoses [4].

Pathology. The classical feature of the disease is the presence of numerous characteristic histiocytes (Gaucher's cells) which infiltrate the pulp of the spleen, the liver and bone marrow, lymph nodes, sinuses and sometimes other organs. Gaucher's cells are large cells with a small nucleus and a voluminous pale-staining cytoplasm, which differ from other lipid-containing cells because of the delicate, striated, tissue-paper appearance, best seen in thicker sections (10 μm). Ultrastructurally, Gaucher's cells contain elongated residual bodies containing tubular structures composed of twisted microfibrillar elements [1,8]. These structures probably represent aggregated glucocerebroside molecules within distended lysosomes, and contain acid phosphatase [9]. In the juvenile neuropathic form, the brain shows loss of neurones and some perivascular accumulation of PAS-positive cells, but typical Gaucher's cells are few or absent.

Clinical features. The adult type (type I) is the most common form and shows an insidious onset with only slow progression. In the adult, the initial complaint is usually that of weakness or perhaps of minor bleeding tendencies [7]. Dull pain in the bones is another early feature. Common cutaneous features include diffuse pigmentation, which may be due to haemosiderosis or to deposition of melanin, easy tanning and pigmented macules [10,11]. Telangiectasia may be noted when there is marked liver

involvement [11]. Anaemia as part of a pancytopenia is an almost constant finding. Generalized osteoporosis of bones due to infiltration by Gaucher's cells leads to gross deformity of the skeleton with collapse of thoracic and lumbar vertebrae. The finding of Gaucher's cells in sternal marrow is important diagnostically [12].

The infantile type (type II), comprising 10% of all cases of Gaucher's disease, begins during the first 6 months of life and ends fatally before the second year [13]. The symptoms of the acute infantile form are predominantly neurological, and include neck rigidity, increased muscle tone, catatonia and laryngeal spasm. The infant dies of acute respiratory infection complicated by laryngospasm, cyanosis and cachexia. Splenomegaly and hepatomegaly are prominent, but there are no specific skin lesions. Some cases are capable of more prolonged survival and this has been referred to as the juvenile form (type III). A rare association between type II Gaucher's disease and congenital ichthyosis presenting as the collodion baby phenotype has been noted [14–16].

Prognosis. This depends very largely on the age of onset. If the symptoms appear in the first decade of life, the prognosis is poor. If in the third or later decades of life, the progress of the disease is much slower, and survival to old age is not unusual.

Treatment. There is no specific treatment. Splenectomy is indicated as a palliative measure to reduce abdominal distension and on occasions to try and relieve anaemia and thrombocytopenia. However, the benefits of splenectomy are rather variable and depend on the extent of marrow destruction by Gaucher's cells. X-ray therapy to the bones may relieve pain. Little can be done for the infantile or juvenile form of Gaucher's disease. Liver transplantation can disperse tissue glucocerebroside deposition and this effect has been explained by the mechanism of microchimerism (migration of cells from the allograft) [17]. Enzyme replacement therapy has been the most successful therapeutic approach for lysosomal storage disorders, and reverses systemic manifestations of Gaucher's disease but does not effectively treat the neurological complications [18,19]. Bone marrow transplantation continues to be effective in Gaucher's disease, but it has high morbidity and mortality that limits its use. Drugs that slow the rate of formation of accumulating glycolipids are being developed and one of them, OGT-918 (*N*-butyldeoxynojirimycin), is showing promise in Gaucher's disease [18]. Gene therapy requires much more development before clinical efficacy trials.

Niemann–Pick disease (MIM *257200) [1,2]

[S.M. Breathnach, pp. 57.59–57.60]

Definition. Niemann–Pick disease refers to a group of congenital lipidoses (sphingolipidoses) bearing a wide spectrum of clinical symptoms. It is usually fatal in early childhood and is characterized by emaciation, hepatomegaly and splenomegaly.

Aetiology. Niemann–Pick disease is inherited as an autosomal recessive lack of sphingomyelinase [3]. Six types of Niemann–Pick disease have been described, of which only types B and E are consistently free of neurological manifestations [4]. They are characterized by the accumulation of enormous quantities of sphingomyelin in histiocytes, macrophages and reticulum cells of all organs. The sex incidence is approximately equal, and the condition is said to be more common in Jewish infants. At least 96% of all Niemann–Pick disease type C patients link to *NPC1*, which encodes for a lysosomally targeted protein [5].

Pathology. There is massive enlargement of the liver, spleen, lymph nodes and infiltrations in lungs and bone marrow. Niemann–Pick cells are readily demonstrated in all organs including the skin [6]. In the brain and central nervous system, a variety of degenerative features similar to those of Tay–Sachs disease have been described. The Niemann–Pick cell is usually mononucleate, large, pale and foamy, but accompanied by neither granulomatous nor inflammatory cells. In cryostat sections, they stain readily with Sudan stains and contain doubly refractile material. PAS positivity is less marked as compared with Gaucher's cells. Circulating lymphocytes frequently also show lipid inclusions [7]. Ultrastructurally, the Niemann–Pick cell is similar to a histiocyte, with cytoplasm containing variably sized lipid cytosomes, many with concentrically arranged whorled features [8]. The diagnosis can also be confirmed by finding a very low level of sphingomyelinase activity in the leukocytes [9].

Clinical features. An apparently normal infant begins to lose weight about the second or third month of life. The abdomen becomes protruberant from massive enlargement of liver and spleen. Lymph nodes are increased in size. The infant becomes progressively more emaciated and apathetic, and the face appears mongoloid. Muscle weakness increases, the child is unable to sit or raise the head, and all muscle tone is lost. Deafness and blindness are common features. Death takes place usually before the age of 2 years and often earlier. Older survival has been recorded [10] in the absence of severe liver involvement.

The skin involvement in Niemann–Pick disease has been described as waxy induration with transient xanthomas overlying enlarged cervical nodes [10,11]. Other skin lesions described include papular [12], papulonodular [13] or suppurative lesions on the face, associated with foamy cell infiltration, indurated discoloured patches on cheeks [6], purpuric lesions, café-au-lait spots and dark-bluish mongolian spots on skin and oral mucosa [8].

Treatment. Allogenic bone marrow transplantation has been tried in Niemann–Pick disease type B [14].

Xanthomas and abnormalities of lipid metabolism and storage

[C.A. Seymour, pp. 57.60–57.77]

Classification of lipid disorders can be based on clinical assessment, including family history, levels of fasting plasma lipids and lipoproteins. The World Health Organization (WHO) classification of lipoprotein phenotypes has been superseded by a more useful classification, which now provides a basis for indicating which lipoproteins are in excess in patients, but does not specifically indicate genetic forms of the disease. The Fredrickson classification of hyperlipidaemia (Table 57.9) is based on plasma lipoprotein patterns associated with increased concentration of cholesterol and/or triglyceride (TG; triacylglycerol), and provides a useful basis for characterizing which specific lipoprotein is increased in patients. Such a classification is not diagnostic and does not include a high-density lipoprotein (HDL) cholesterol category. HDL is an important lipoprotein, since low levels of HDL are associated with an increased risk of cardiovascular disease. This risk is increased if the low HDL is associated with increased total cholesterol and/or TG. Recent advances in our knowledge of lipoprotein metabolism have resulted in a more functional classification, which recognizes that dyslipidaemias are more often polygenic and multifactorial in origin. This classification is not an aetiological one and does not specifically differentiate primary (genetic) from polygenic and secondary hyperlipidaemias. Establishing a lipoprotein phenotype does not substitute for making a diagnosis of the underlying cause. About 60% of the variation in plasma lipids is genetically determined, most being polygenic with interaction with environmental factors. Familial forms of hyperlipidaemia, where the family history is important in the clinical assessment, may have monogenic influences

Table 57.9 Classification of hyperlipidaemia.

Primary hyperlipidaemia (new terminology)	Frederickson lipoprotein phenotype (WHO classification)	Lipid changes				
		Plasma cholesterol	LDL cholesterol	Plasma TG	Lipoprotein changes	Secondary causes
Hypercholesterolaemia		Raised or normal	Raised	Normal	Excess LDL	Hypothyroidism
Familial hypercholesterolaemia	IIa, IIb					Primary biliary cirrhosis
Polygenic hypercholesterolaemia	IIa					
Combined hypercholesterolaemia		Raised	Raised	Raised	Excess LDL	Acute intermittent porphyria
Familial combined (mixed) hyperlipidaemia	IIa, IIb (IV)				Excess VLDL	Anorexia nervosa Cushing's syndrome Diabetes Hepatoma Nephrotic syndrome
Remnant particle disease (dysbetalipidaemia)	III	Raised	Low or normal	Raised	Excess CM remnants Excess IDL	Diabetes Hypothyroidism Monoclonal gammopathy Obesity
Hypertriglyceridaemia		Raised or normal	Normal	Raised	Excess VLDL	Alcoholism Chronic renal disease Diabetes Lipodystrophies Monoclonal gammopathy Uraemia
Familial hypertriglyceridaemia	IV					
Familial combined hypertriglyceridaemia	V	Raised	Normal	Raised	Excess CM Excess VLDL	Alcohol Diabetes Drugs: β-blockers Diuretics Oral contraceptives Retinoids
Chylomicronaemia syndrome	I	Raised	Low/normal or raised	Raised	Excess CM	SLE (rarely)
Lipoprotein lipase deficiency						
Apoprotein CII deficiency						
HDL abnormalities not classified						Androgenic steroids
Hypoalphalipoproteinaemia						
Hyperalphalipoproteinaemia						

C, cholesterol; CM, chylomicrons; HDL, high-density lipoproteins; IDL, intermediate-density lipoproteins; LDL, low-density lipoproteins; N, normal; TG, triglycerides; VLDL, very-low-density lipoproteins.

that are variably expressed; for example, familial hypercholesterolaemia (FH), which is expressed independently of environmental factors, and familial dysbetalipoproteinaemia (type III), where the gene defect may only be expressed by interaction with the environment.

Primary hyperlipidaemias

Clinical classification of hyperlipidaemia and hyperlipoproteinaemia (lipoprotein phenotypes) is based on measurement of levels of non-fasting total cholesterol, fasting TG, low-density lipoprotein (LDL) and HDL cholesterols, the ultracentrifugation pattern of plasma lipoproteins and, increasingly, the measurement of apolipoproteins, particularly apo-A1 (in HDL), apo-B (in LDL) and apo-C (in VLDL). The classification is still divided into six categories [1–4], but most usefully in terms of treatment into pure or combined hypercholesterolaemia, or pure or combined hypertriglyceridaemia (Table 57.9).

Secondary hyperlipidaemias [1,2]

There are a variety of disorders that may produce or exacerbate a pre-existing hyperlipidaemia (Table 57.10) and of these diabetes mellitus, alcoholism and ingestion of oestrogens are the most commonly encountered. Where hyperlipidaemia occurs in association with certain acquired systemic diseases, treatment of the systemic disorder results in normalization of the circulating lipoprotein profile, unless the hyperlipidaemia is also due

Table 57.10 Secondary hyperlipidaemia.

	Cholesterol ↑	Cholesterol ↑ LDL ↑	Triglyceride ↑ VLDL ↑	Triglycerides HDL ↑	LDL↑ VLDL ↑
Common	Primary biliary cirrhosis Biliary cirrhosis	Nephrotic syndrome (IIA/IIB) Hypothyroidism (IIA or IIB) Drugs: Thiazide diuretics Ciclosporin	Chronic renal failure (IV) Maturity onset Diabetes mellitus (IV) Juvenile onset (less commonly (V)) Alcoholism (IV)	Oral contraceptives Pregnancy Oestrogens Prostatic carcinoma (treated) Drugs: β-blockers Epanutin Retinoids (IV) Cimetidine (V, I)	Sex hormones (exogenous) Myeloma (III)
Rare		Hepatoma (IIA) Acute intermittent porphyria (IIA) Cushing's syndrome (IIB) Anorexia nervosa (IIA)	Monoclonal gammopathy (IV) Lipodystrophy (all forms, IV or V) Gout (V) Obesity Occasional alcohol Polycythaemia (V) SLE (I)	Gaucher's disease Glycogen storage disease Regular/heavy alcohol	

HDL, high-density lipoproteins; LDL, low-density lipoproteins; SLE, systemic lupus erythematosus; VLDL, very-low-density lipoproteins.

to a coincident primary hyperlipidaemia, when the increase is more marked. The abnormal lipoprotein pattern in secondary hyperlipidaemia may not be clearly diagnostic although it can mimic a primary lipoprotein disorder. For example, the hyperlipidaemia of uncontrolled diabetes mellitus and that of lipoprotein lipase deficiency may appear similar (Table 57.9); this may be because of similarities in underlying mechanisms. However, there are others, for example the hyperlipidaemias associated with chronic biliary obstruction and monoclonal gammopathy, which have unique patterns (i.e. pure hypercholesterolaemia). In chronic renal disease, varying lipoprotein profiles may occur that mimic all types of primary hyperlipidaemia. In addition, a number of systemic disorders may modify primary hyperlipidaemia, for example diabetes mellitus and familial hypertriglyceridaemia.

While any hyperlipidaemia may be a major risk factor for coronary artery disease (CAD), a number of other factors may be equally important. These include increased risk of thrombosis due to increased fibrinogen, elevated plasma lipoprotein (a) (Lp(a)) and, in patients with insulin resistance, diabetes mellitus and microalbuminuria.

Other risk factors that can complicate and exacerbate an underlying lipoprotein abnormality are obesity, smoking and hypertension. It is also recognized that some factors are associated with an increased risk of atherogenesis, and some with an increased risk of thrombogenesis (such as Lp(a), factor VII and plasminogen activator inhibitor 1 (PAI-1)). Some of these are also independent risk factors for CAD. In addition to lifestyle factors, common causes of secondary hyperlipidaemia are shown in Table 57.9. Some drugs such as those used in the treatment of psoriasis (retinoids) may precipitate a combined hyperlipidaemia picture. More recently treatment of HIV with protease inhibitors may produce a marked hypertriglyceridaemia (increase in VLDL).

Lipid metabolism [1–10]

In the last two decades there has been an improvement in knowledge of the component parts of lipid metabolism and a more integrated understanding of the pathophysiology of lipid transport. It is well established that lipoproteins are derived from an *exogenous* pathway, where diet will have a large influence, and an *endogenous* pathway, which will involve lipoprotein production, processing and catabolism.

Lipids are essential as energy stores and respiratory substrates, and are structural components of cell walls. Lipids are transported in the blood and extravascular body fluids in combination with proteins, usually apoproteins. Lipoprotein particles are globular and vary in

composition, but contain an outer polar component of phospholipid and free cholesterol enclosing the core of hydrophobic lipids (cholesterol esters and TGs, also termed triacylglycerols). In addition, apoproteins, also enclosed in the core but with charged groups (polar regions) exposed to the surface, have a role both in the lipoprotein structure and in regulation.

Exogenous transport in chylomicrons (chylomicron pathway) [5,6,9,10]

The exogenous pathway transports the products of fat digestion from the gut and liver to peripheral tissues. Triglyceride-rich chylomicrons (CMs) from the gut and VLDL from the liver are processed in similar ways. The major difference is that, in the gut, CMs contain an edited form of apolipoprotein B (apo-B48), while the liver secretes the full apo-B100 in VLDL. Absorbed dietary TG (absorbed as free fatty acids and monoglycerides), free cholesterol and phospholipids are packaged within the enterocyte with intestinal apo-B48 to form CMs. Nascent CMs are secreted from intestinal villi to lymph (chyle) and enter lacteals, reaching the blood through the thoracic duct. In the circulation, CMs (which carry dietary fat and cholesterol) acquire further apolipoproteins, mainly apo-C, and apo-E from HDL. The apo-CII component of these particles activates the enzyme lipoprotein lipase found on the capillary endothelium of skeletal and cardiac muscle (providing energy) and adipose tissue (where it is stored). This leads to the rapid hydrolysis of the core of TG and entry of the resultant fatty acids and glycerol to peripheral tissues. Thus CMs become remodelled and smaller; VLDLs share this common catabolic pathway, and produce CM 'remnants'. The CM 'remnant' (rich in cholesterol ester containing both apo-B48 and apo-E) re-enters the circulation (reverse cholesterol transport) and is taken up by the liver via specific apo-E receptors (which, unlike the LDL receptor, are not affected by entry of free cholesterol into the hepatocyte) and catabolized in lysosomes. This transport system is efficient and as a result dietary cholesterol remains in the plasma for only a few minutes and can enter hepatic metabolic pathways, including excretion to bile.

Endogenous transport from the liver (VLDL–LDL pathway) [7–10]

Triglyceride-rich lipoproteins (VLDLs) are produced continuously in large amounts by the liver in a similar way to CMs in the enterocyte, with the exception that in humans the liver synthesizes and secretes the full-length apolipoprotein, apo-B100, rather than the truncated enterocyte form, apo-B48. The VLDL particles are secreted to provide tissues with VLDL in the absence of CMs (e.g. in the fasting state) and to prevent hepatic steatosis. Nascent VLDL particles (containing both TG, surplus fatty acid, cholesteryl esters and apolipoproteins B, CII and E) compete with CMs for lipolytic sites on endothelial cells, but have a lower affinity for the enzyme (lipoprotein lipase) than CMs. Again, as with CMs, hydrolysis occurs outside the liver by lipoprotein lipase to yield 'remnant' particles. The apo-B-containing lipoproteins (VLDL, intermediate-density lipoprotein (IDL) and LDL) are all involved in a process of delipidation, mediated in larger particles by lipoprotein lipase and in the smaller particles by hepatic lipase (IDL, dense LDL). Delipidation of large VLDL with cofactor apo-CII results in remnant particles $VLDL_2$, IDL and LDL, and direct catabolism of these particles occurs through uptake by apo-B and apo-E receptors on cells. The LDL receptor facilitates endocytic uptake of VLDL, IDL and LDL. Hepatocyte LDL receptors recognize apo-E on VLDL 'remnants' and allow some endocytosis and uptake into the cell, while some 'remnant' particles are processed by surface lipase to LDL, which can then be taken up by the apo-B100 receptors on hepatocytes. 'Remnant' particles, unlike LDL particles, have a short half-life in circulation [9].

LDL particles consist mainly of a core of cholesterol, cholesteryl esters and apolipoproteins B100 and E (about two thirds of the plasma cholesterol is in the LDL form). These lipoproteins bind to receptors that recognize apo-E and apo-B100, enter the liver and are metabolized, providing cholesterol for membrane and steroid hormone synthesis. LDL particles are metabolized slowly over a matter of days. The uptake of LDL regulates both the circulating levels of this lipoprotein and the synthesis of cholesterol. The number of cell receptors and rate of cholesterol synthesis are regulated by the cholesterol concentration in the cell. Cells also take up LDL via unregulated processes, such as through the scavenger pathway involving macrophages, which is dependent on the extracellular LDL concentration. These become more important when the circulating level of LDL is increased by the presence of dense LDL particles.

In normal and hyperlipidaemic individuals, LDL particles are heterogeneous, existing in three distinct forms (I, II, III). Pattern A, on a gel electrophoresis, is associated with low TG and larger LDL-I and -II, whereas pattern B has higher levels of TG and small, dense LDL (III) [9]. LDL-I and -II are converted to LDL-III by the action of cholesteryl ester transfer protein (CETP), which allows exchange of cholesteryl ester in LDL for TG in TG-rich lipoproteins. Subsequently LDL-III is hydrolysed by hepatic lipase to produce dense LDL, which are not metabolized through the usual LDL receptors.

LDL catabolism in the cell occurs in lysosomes after internalization, cell surface receptors recognizing lipoproteins with apo-B and apo-E. These LDL particles undergo lipolysis to cholesteryl esters, free cholesterol, apo-B and amino acids. Free cholesterol can regulate expression of

more cell surface LDL receptors (except in FH) and also regulates intracellular cholesterol synthesis via 3-hydroxy-3-methylglutaryl coenzyme A—the HMG-CoA reductase pathway. Subsequently activity of another enzyme (cholesterol-*O*-acyl transferase) resynthesizes cholesteryl ester from free cholesterol for storage within the cell. LDL can also enter cells in a non-receptor-mediated pathway, which is more important in atherosclerosis. At low concentrations of plasma LDL, this would be insignificant but is increased with increasing plasma LDL concentrations (important in individuals taking a high fat diet) and with lack of HDL, which can competitively inhibit non-receptor LDL (i.e. dense LDL uptake). This predisposes to atheroma in the FH patient (with reduced LDL-receptor uptake), in the high-fat-intake individual (with increased plasma LDL concentration) and where plasma HDL concentrations are low (lack of competition for the non-receptor pathway). Monocyte uptake of LDL, oxidized LDL and dense LDL (LDL-III) may also occur, which also predisposes to an increased risk of atheroma.

High-density lipoprotein and transport of cholesterol from tissues to liver (reverse cholesterol transport) [11]

Apolipoproteins AI and AII are the main protein components of plasma HDL, which also consists of cholesteryl esters and a phospholipid bilayer. They are secreted from the intestine as part of the nascent CMs. Some nascent HDL is also derived from hepatocytes. The core of cholesteryl esters is derived from the esterification of cholesterol from lipoproteins with a fatty acyl residue to form lecithin (phosphatidyl choline), catalysed by the liver enzyme lecithin cholesterol acyltransferase (LCAT). The conversion of polar cholesterol to non-polar cholesteryl esters creates a gradient that allows cholesterol to be continually transferred to HDL. HDL particles increase in size with increased lipolysis, reflecting transfer of surface components from TG-rich lipoproteins to HDL and stimulation of cholesterol esterification (the reverse process to delipidation of other lipoproteins during lipolysis). HDL particles are constantly exchanging components with other larger lipoproteins (VLDL, LDL) through lipolysis mechanisms and action of the enzyme LCAT.

The main role of HDL is to accept cholesterol and remove excess from cell surfaces and transport it as cholesteryl ester. Clearance of HDL is partly through reverse cholesterol transport through uptake by the liver, either as HDL or via transfer of cholesteryl ester from HDL to VLDL through CETP transfer to apo-B-containing particles, which are then taken up by the liver and possibly through a smaller HDL cleared through the liver. Thus HDL is not catabolized as a whole particle, and its components are redistributed continuously.

HDL plays an important role in preventing the accumulation of cholesterol in the body. It should be noted that high concentrations of HDL may contribute to an increase in total plasma cholesterol producing a mild hypercholesterolaemia and is not associated with an increased risk of CAD. Thus specific measurement of HDL should be undertaken to indicate whether it is an independent risk factor for CAD (i.e. low HDL concentrations).

Apoproteins [1,5,8,10]

These are lipid-free protein components of plasma lipoproteins. They form amphipathic helical structures, which allow the formation of stable structures with polar phospholipids at the surface of the plasma lipoproteins and so solubilize cholesterol esters and TG for transport (Table 57.11). The role of these proteins as components of lipoproteins and in lipid metabolism is now better understood (Table 57.11).

Table 57.11 Apolipoproteins.

Class	Origin	Function (where known)
Apo-AI	Liver, intestine	LCAT activator
Apo-AII	Liver, intestine	?
Apo-AIV	Liver, intestine	
Apo-B48	Intestine	CM production
Apo-B100	Liver	Receptor-mediated catabolism of LDL
Apo-CI	Liver	LCAT activator
Apo-CII	Liver	LpL activator
Apo-CIII	Liver	Inhibits catabolism of TG-rich Lp
Apo-D	?	?
Apo-EII	Liver	Receptor-mediated catabolism of apo-E-containing Lp
Apo-EIII	Liver	
Apo-EIV	Liver	

CM, chylomicrons; LCAT, lecithin cholesterol acyltransferase; LDL, low-density lipoproteins; LpL, lipoprotein lipase; TG, triglycerides.

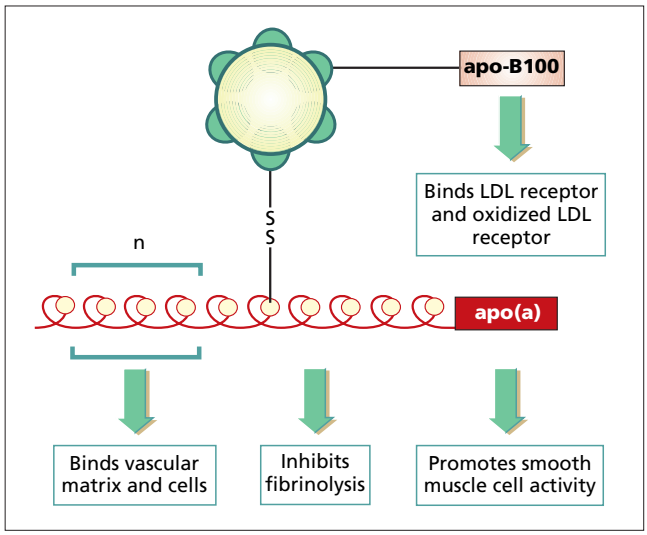

Fig. 57.38 The role of lipoprotein (a). (Redrawn from Sterling [15].)

Lipoprotein (a) (Lp(a)) [12–15]

This lipoprotein varies in concentration, and its physiological function has only recently been determined. It is larger and more dense than LDL but has a similar lipid composition. It is thought to come from the liver but not via the VLDL pathway. It seems to correlate well with atheroma [7] as does apo-B and LDL, but also to have a wider role in thrombogenesis. It consists of an LDL-like particle with apo-B100 enclosing a lipid core but with an additional side chain of a highly glycosylated protein, apolipoprotein (a) (apo(a)). The latter is linked to apo-B by a disulphide bridge (Fig. 57.38). Apolipoprotein (a) has homology with the fibrinolytic system protein precursor, plasminogen, in the presence of kringle structures; one of which is increased in apo(a). The molecular weight of Lp(a) varies due to the variation in the number of kringle repeats (usually four) within apo(a). The gene locus for apo(a) is encoded on chromosome 6 near that for plasminogen. The concentration of circulating Lp(a) varies in different populations largely due to differences in expression of the apo(a) gene and apo(a) isoforms [14]. The latter vary inversely with plasma Lp(a), and small, fast-moving isoforms are associated with higher Lp(a) concentrations. Circulating Lp(a) particles are regulated more by synthesis than by catabolism, which appears to occur only in the liver.

Lipoprotein (a) has a role in atherogenesis because of its LDL (apo-B) content, and because it does not bind as well as LDL to receptors—it therefore becomes oxidized (ox-Lp(a)) and can be taken up by the scavenger macrophage pathway. It also has a role in thrombogenesis by virtue of the homology with plasminogen. In the apo(a) structure, specific areas are identified that bind with the vascular matrix and cells, inhibit fibrinolysis and promote smooth muscle activity [13]. Family studies indicate that Lp(a) may also be affected by inherited factors independent of apo-B (FH) and apo(a) gene size. There is still controversy as to its precise importance in predicting CAD risk, but increased Lp(a) concentrations occur with increase in acute phase proteins, in renal disease. High Lp(a) concentrations have also been found in CHD, early myocardial infarction, stroke and peripheral vascular disease.

Xanthoma

Xanthomas are a common presentation of disorders of lipid metabolism usually associated with abnormalities of cholesterol metabolism, for example FH (type IIa), combined hyperlipidaemias (both combined hypercholesterolaemia type IIb, III) and combined hypertriglyceridaemia (type V); and may be associated with increased risk of arteriosclerotic vascular disease (type II) and occasionally with pancreatitis (type V). Discrete xanthomas affecting tendons are typical of FH, whereas eruptive xanthomas affecting the skin are typical of type V. However, it is the skin manifestations that will bring the patient to the

Fig. 57.39 Extensive xanthelasmas palpebrarum. (Courtesy of Addenbrooke's Hospital, Cambridge, UK.)

Fig. 57.40 Tuberous xanthomas. (Courtesy of Addenbrooke's Hospital, Cambridge, UK.)

Fig. 57.41 Eruptive xanthomas. (Courtesy of Addenbrooke's Hospital, Cambridge, UK.)

dermatology clinic and therefore these are dealt with separately [1–3].

Xanthelasma palpebrarum. These usually appear as bilateral and symmetrical, soft, velvety papules and plaques arranged around the eyelids. The upper eyelid and the region around the medial canthus are the most common sites of involvement, although in severe hypercholesterolaemic conditions (e.g. FH) they may occur circumferentially or on the outer aspects of the eye (Fig. 57.39). They may represent a localized cutaneous phenomenon, but they may more usually signify a systemic hyperlipidaemia and are then associated with elevation of LDL as in pure hypercholesterolaemia (such as FH) or type III hyperlipoproteinaemia. They may also be associated with mixed hyperlipidaemia (type IIb or IV) or as an isolated finding in certain apo-E phenotypes, particularly E2/E2 [3], or in chronic biliary obstruction (e.g. primary biliary cirrhosis) [4,5]. Generalized plane xanthomas may be seen in normolipidaemic patients.

Tuberous xanthoma (Fig. 57.40). These lesions vary in size and shape, from small papules 0.5 cm in diameter to lobulated tumours 2.5 cm or more across. These are firm and yellow or orange in colour, often with an erythematous halo. Usually they are painless but larger lesions may be tender on direct pressure. They develop slowly and are seen on pressure areas, such as the extensor aspect of the limbs, particularly over knees, elbows and buttocks. These xanthomas are commonly seen with hypercholesterolaemia and increased levels of LDL (e.g. FH [3,4]) and familial dysbetalipoproteinaemia (type III) as well as in secondary hyperlipidaemias (e.g. those associated with hypothyroidism, chronic biliary disease, and very rarely in association with a monoclonal gammopathy [6,7]).

Tendinous xanthoma. These appear as slowly enlarging subcutaneous nodules attached to tendons, ligaments, fascia and periosteum. They are symptomless and the overlying skin appears normal. Although any tendon may be involved, most frequently the xanthomas are on the extensor tendons of hands and feet and the Achilles tendon. The latter often present to the orthopaedic surgeon, and may even be diagnosed on ultrasound as a fatty nodule. The subperiosteal lesions may involve bony prominences such as the malleoli and elbows but do not calcify. They are found in association with severe hypercholesterolaemia and elevated levels of LDL, typical of pure hypercholesterolaemia and FH (type II). Tendinous xanthomas may also be found but less frequently in secondary hypercholesterolaemia associated with prolonged cholestasis.

Eruptive xanthoma (Fig. 57.41). Eruptive xanthomas may occur at any site but are most commonly seen over the buttocks, shoulders and extensor surfaces of extremities.

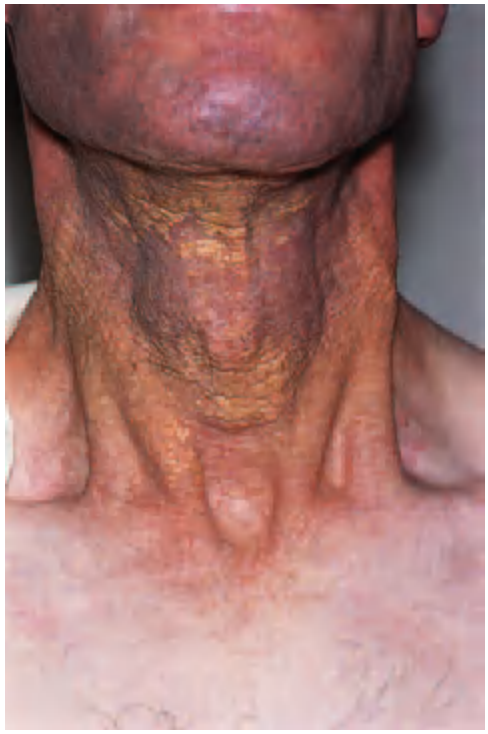

Fig. 57.42 Plane xanthomatosis. (Courtesy of Addenbrooke's Hospital, Cambridge, UK.)

The oral mucosa and face are very occasionally affected. They appear as pinhead or larger yellow papules with a reddish base; they may be fleeting in nature and occur in crops. They may cause pruritus. Occasionally, these papules may coalesce and overlie a tuberous xanthoma and are then called *tuberoeruptive xanthomas*.

These xanthomas are associated with pure or mixed hypertriglyceridaemia and a high concentration of VLDL or CMs (i.e. pure or combined hypertriglyceridaemia) in the modern classification (and Fredrickson types I, V and, less commonly, type IV hyperlipoproteinaemias (Table 57.9)). They may also be seen in secondary hyperlipidaemia, usually in association with diabetes [8].

Plane xanthoma (Fig. 57.42) [6,7,9,10]. Plane xanthomas appear as yellow or orange macules or slightly palpable plaques. They involve almost any site, but when plane xanthomas occur in palmar creases (xanthoma palmaris) they are pathognomonic of type III/familial dysbetalipoproteinaemia. Plane xanthomas may also be seen in the secondary hyperlipidaemias associated with conditions of chronic biliary obstruction or prolonged cholestasis such as primary biliary cirrhosis and, rarely, monoclonal gammopathy.

Generalized plane xanthoma. These plane xanthomas cover large areas of the face, neck and thorax, and also involve flexures and palms. Many patients with these diffuse plane xanthomas develop a monoclonal gammopathy [6,7] associated with either myeloma (with a type III pattern [3]), macroglobulinaemia or lymphoma, and even with normal plasma lipid levels. The latter are associated with a particular apo-E phenotype and are not associated with an increased risk of vascular disease [5]. Lipid metabolism may be disturbed, and approximately 50% of patients with IgA myeloma have hypolipidaemia with low plasma total and LDL cholesterol concentrations. Less commonly, endogenous hypertriglyceridaemia may be present and the lipoproteins may be in the density range of VLDL, LDL [9] or intermediate forms and CMs. It is not known how these monoclonal antibodies produce the lipid abnormalities, but at least some combine with the lipoproteins or interfere with receptor-mediated catabolism [7,10–12].

Pathology. Ultrasound of xanthomas indicates the presence of lipid, and histology of skin biopsies may show intracellular sudanophilic material in abnormal quantities, particularly around capillaries. Differential staining of this material often shows a characteristic reaction for cholesterol and polariscopic examination of frozen sections may show doubly refractile (anisotropic) droplets.

Treatment. Most xanthomas respond well to dietary control and/or to appropriate medical treatment for the underlying condition with lowering of LDL concentrations (details are given in the following sections). However, they may need to be removed surgically. Xanthomas are likely to recur unless dietary and other cholesterol-lowering measures are continued. If it is an isolated finding, xanthelasma palpebrarum may be destroyed with cautery, trichloroacetic acid or can be excised, but they are likely to recur over a period of years. Probucol, a recognized antioxidant, is associated with specific regression of xanthelasma [13,14], but this has recently been withdrawn from the market. Other antioxidants such as vitamin E may be effective in the long term.

Xanthomas in lymphoedema [1–4]

Xanthomas in association with lymphoedema are reported. Lymph stasis with intraluminar and periluminar retention of lipoproteins and ingestion by local histiocytes seems a likely explanation. Scattered, firm, yellowish papules are seen within lymphoedematous areas. Chylous exudation may be spontaneous or follow abrasion. Histologically, the epidermis shows irregular acanthosis and hyperkeratosis. Intralymphatic and perilymphatic collections of foam cells are characteristic. Alleviation of the lymph stasis by surgery or pressure bandaging is sometimes effective.

Xanthoma cells in inflammatory and neoplastic disease

Cholesterol deposition is not infrequent in inflammatory disorders, where it appears to result from the liberation of lipids in the tissues. These lipids are ingested by histiocytes producing the characteristic foam cell seen in histological sections. In some instances, there may be an abnormal production of cholesterol *in situ*.

Diffuse xanthoma may appear in previously inflamed skin [1,2]. Similar secondary xanthomatous infiltration is also seen in certain localized inflammatory and neoplastic disorders. The diseases in which xanthoma cells may be encountered are listed below.

1 Inflammatory disease:
  (a) histiocytoma;
  (b) juvenile xanthogranuloma.
2 Neoplastic disease:
  (a) multicentric reticulohistiocytosis;
  (b) eosinophilic granulomas [3];
  (c) Letterer–Siwe disease, Hand–Schuller–Christian disease;
  (d) mycosis fungoides.

Genetic primary hyperlipidaemia

There is no doubt that CAD is strongly associated with high concentrations of cholesterol and/or TG, although the circulating levels and incidence of CAD vary from country to country, with higher CAD incidence in northern Europe and lowest in Japan and rural Africa. An inverse relationship exists between HDL and CAD. Most causes of a high cholesterol and/or TG are due to a number of interrelating factors (risk factors) but some are due to a combination or solely to individual susceptibility involving either one or a number of genes [1–4]. Although monogenic hyperlipidaemias are rare in the general population as compared with polygenic hyperlipidaemias, they do enable an application of 'Garrod's legacy', to allow a useful classification on the basis of a well-defined clinical disease, which is helpful in deciding treatment. Large clinical trials (Scandinavian 4S Study [5], West of Scotland Coronary Prevention Study [WOSCOPS] [6,7] and many other studies [8]) have clearly established that reduction of cholesterol levels is effective in both primary and secondary prevention of ischaemic heart disease. Similar studies have claimed secondary prevention with the lowering of combined or pure hypertriglyceridaemia [9].

Evidence of the hereditary basis of these diseases is often presumptive, and detailed investigation of first-degree relatives can reveal partial metabolic defects suggestive of recessive inheritance [4].

Primary hypercholesterolaemia

Familial hypercholesterolaemia (FH) (MIM #143890) [1]

SYN. ESSENTIAL FAMILIAL HYPERCHOLESTEROLAEMIA

This is a common autosomal dominant disorder affecting approximately one per 500 of the European and American populations. It is characterized by an increase in the levels of LDL (and apo-B), and is the commonest cause of tendon xanthomas and xanthelasma.

Aetiology. The primary defect is a reduction in LDL catabolism because of an abnormality in the LDL receptor [2], leading to increased plasma LDL concentrations. The molecular defect was first described by Goldstein and Brown [3]. The gene for the LDL receptor is found on chromosome 19. Heterozygotes express half the number of LDL receptors, and homozygotes have between 0% and 25% of receptors found in normal individuals. Cultured fibroblasts have shown four mutant alleles at the LDL receptor locus [4]. The most common of these results in a non-functional gene product, and therefore reduces LDL receptor expression; the next most frequent results in a defective gene product that interferes with transport and binding of LDL; and the rarest produces a receptor that binds LDL normally but fails to transport cholesterol into the cells by preventing internalization after LDL binding, because of a mutation affecting the cytoplasmic domain of the receptor [3,4]. To date, some 200 or so mutations have been described. More recently, 3% of patients presenting with features of FH have a mutated apo-B due to a glutamine substitution for arginine at a position that affects LDL binding. This is known as *familial defective apo-B* [1,5], which presents in childhood with hypercholesterolaemia; tendon xanthomas appear in the 30s; and by the age of 80 years all heterozygotes have xanthomas.

In FH, homozygotes have two of these mutant alleles and therefore are unable to clear LDL from the plasma. They present in childhood with cutaneous xanthelasma and xanthomas. Heterozygotes have one normal allele and can remove about half of the plasma LDL.

Levels of plasma cholesterol correlate directly with the severity of LDL receptor deficit [1,6]. Polygenic hypercholesterolaemia is the commonest form. FH accounts for less than 3% of males dying from CAD under the age of 60 years [7].

The defect in *common polygenic hypercholesterolaemia* is usually due to overproduction of VLDL by the liver. There is rapid conversion to LDL, which initiates up-regulation of the LDL receptor, and an increase in dense LDL; the latter results in non-receptor-mediated uptake via macrophages to produce foam cells and an increase in atheroma. This is most commonly caused by excessive dietary intake and obesity.

Clinical features. Heterozygotes usually present in the third to fourth decades with premature onset of CAD, at least 20 years earlier in FH than the normal population. This can be avoided by cholesterol screening of children/siblings of an affected individual. Tendon xanthomas are a very common hallmark of the disease, and incidence increases with the age of the patient. The very rare homozygous condition usually presents in the first year of life with cutaneous planar or tuberose xanthomas, often at the site of trauma and on the palms of the hands. Tendinous and tuberous xanthomas, xanthelasma and corneal arcus are all commonly present [8]. CAD may become manifest before the age of 20 years due to atheromatous narrowing of the aortic root and coronary ostia. In addition, cholesterol deposits may give rise to supravalvular aortic stenosis.

Investigation. Plasma total cholesterol is elevated with a normal TG level. Lipoprotein ultracentrifugation shows a type IIA pattern with increased LDL cholesterol (increased apo-B) in the top five percentile cut-off for the control population, taking into account age and sex variations. Most patients with type IIA (pure hypercholesterolaemia), however, do not have FH but common polygenic hypercholesterolaemia (see above). The presence of tendinous xanthomas and family members with elevated plasma total LDL cholesterol help to establish the diagnosis. A few patients with FH have a combined but predominant cholesterol (type IIB pattern) with mildly raised TG levels (see also familial combined hypercholesterolaemia [FCH]). Again the presence of tendon xanthomas and family studies should help to separate these patients from 'multiple-type' hyperlipidaemia. A few centres can assay LDL apo-B receptors directly in both heterozygous and homozygous patients. DNA analysis is unlikely to be helpful on a routine basis since so many mutations have been described.

Familial combined hypercholesterolaemia (MIM #144250)

This was originally termed type IIb in the Fredrickson classification (Table 57.9) and initially described by Goldstein *et al*. [1]. It is a common phenotype associated with a combined hyperlipidaemia but predominant hypercholesterolaemia (increased cholesterol and slightly

increased TGs). However, the diagnosis cannot be made in a subject whose family members are not available, since the term FCH implies multiple-type hyperlipidaemia occurring in one family. Family studies show 50% of relatives of an affected individual to have either hypercholesterolaemia (type IIa), hypertriglyceridaemia (type IV or V) or both abnormalities (type IIb) [1,9] It is probably inherited as an autosomal recessive trait in which patients show variable increased plasma cholesterol, TGs and lipoprotein patterns. Thus individuals within a family could be type II, IV or even V, or a type IV patient when treated could appear to have a type II lipid profile. There are also non-genetic and polygenic causes of these lipid profiles; the latter exacerbated by environmental factors and lifestyle.

Metabolic abnormalities in these patients can allow a subclassification. They may have postprandial hyperlipidaemia, most have an increase in apo-B100, and genetic lipoprotein lipase deficiency can be demonstrated in some families. The metabolic and genetic basis of FCH is not entirely understood, and family studies of individuals presenting with a high cholesterol or high TG picture are important. Fasting hypertriglyceridaemia is frequently seen in an FCH subject with delayed clearance of the apo-B particle (atherogenic) and delay in postprandial clearance of CMs and CM remnants, also found to be associated with insulin resistance. The latter is termed Reaven's syndrome and is associated with a fasting hyperinsulinaemia, increased body mass index, systolic hypertension and dyslipidaemia (reduced HDL, increased fasting plasma VLDL and TG), with impaired free fatty acid metabolism. Increased plasma apo-B levels frequently coincide with small, dense LDL particles (subclass pattern B (see p. 57.63)), which has an increased risk of myocardial infarction. No clear pathogenic association has been established with the apo-B gene, lipoprotein lipase gene, apo-AI -CII -CIV gene cluster, or with the apo-E gene on chromosome 19 [10,11].

Aetiology. In FCH, increased cholesterol and/or TG reflect increases in LDL and/or VLDL particles due to increased production (mainly VLDL), decreased catabolism or a combination of these. It has been suggested that some heterozygotes could have deficiency of lipoprotein lipase or of the cofactor apo-C II (therefore causing reduction in VLDL lipolysis), and that FHC is a dominant disorder with onset in the third decade but the precise inheritance is unclear [10,11].

Clinical features. These will depend on the predominant lipid; thus, hypercholesterolaemia will produce a picture similar to FH and hypertriglyceridaemia will be similar to the pure familial hypertriglyceridaemias. Xanthelasma and xanthomas, for example, may be much less prominent and only evident in patients over the age of 30–40 years.

The diagnosis is, however, of great importance, since mixed hyperlipidaemia is the most commonly found lipid abnormality in survivors of myocardial infarction. Premature death and non-fatal myocardial infarction are also prevalent in FCH. Once the diagnosis is made within a family, an individual diagnosis can be made from a high TG, high LDL and low HDL level, or a combination of these lipoproteins.

Investigation. FCH is associated with an increase in TG and/or LDL/IDL within many family members.

Treatment of pure or combined hypercholesterolaemia [12–21]

In any patient with pure (familial, type IIa) or combined predominant hypercholesterolaemia (type IIb) the aim of treatment is to reduce the level of LDL to within the normal range. In all patients, attention should be paid to the diet, which should be low in saturated fats and high in poly- and mono-unsaturated fats [12]. Treatment of homozygous and heterozygous FH involves drug therapy, and starts in childhood. Cholestyramine or colestipol, non-absorbable anion exchange resins, may be most suitable in children, in young women of child-bearing age, during pregnancy and while breast feeding, and may lower the cholesterol by up to 25% [13,14]. Compliance is a problem with all resins. This medication has in all other patients been superseded by the now well-established HMG-CoA reductase inhibitors or 'statins' (e.g. lovastatin, simvastatin, pravastatin, fluvastatin, atorvastatin or rosuvastatin), which have greatly improved management. Results of large double-blind trials have shown the safety, efficacy and cost-effectiveness of the statins in lowering cholesterol [12–19]. The statins may be used alone or in conjunction with other agents such as cholestyramine [1,15] and more rarely fibrates. The net result is a dose-dependent reduction in cholesterol, but, more importantly, even when the cholesterol has normalized there is an overall reduction in CAD, mortality and morbidity with continued statin use [13–19]. It is recognized that there are many other beneficial effects (pleiotrophic) of statins on the microcosm of the arterial wall in reducing smooth muscle migration, fibrosis, increasing collagen formation and effects on endothelin-1 and nitric oxide [22]. These drugs work best in heterozygotes, who have a partial LDL-receptor deficiency. Homozygotes are less responsive to standard therapy.

For homozygotes, plasma exchange or LDL apheresis [19] is helpful in homozygous FH or familial defective apo-B, but treatment needs to be repeated at weekly intervals. Portocaval shunt has been used in cholesterol lowering therapy but liver transplantation in carefully selected homozygotes may be a more effective way to correct the hepatic deficiency of LDL receptors and normalize choles-

terol levels [19] until gene therapy becomes feasible. In the past, ileal bypass was thought to be helpful in severely affected patients, but has been superseded by the advent of the statins [21].

Treatment of FCH is the same as for pure or familial hypercholesterolaemia, and where TG is equally elevated, treatment will be as for familial hypertriglyceridaemia with fibrates (see p. 57.73).

Prognosis

This depends on the severity of the defect. Untreated homozygotes (FH) often die from heart disease by the age of 30 years, while many untreated heterozygotes (FH) have had a myocardial infarction by the age of 55 years.

Mixed hyperlipoproteinaemia

Familial dysbetalipoproteinaemia (MIM *107741)

SYN. FAMILIAL TYPE III HYPERLIPIDAEMIA; REMNANT PARTICLE DISEASE

This is a rare inherited disorder in which plasma cholesterol and TG are elevated (often to a similar degree) because of increased remnants of CMs and IDL (β-VLDL), which fail to be cleared by hepatic remnant (or apo-E) receptors [1].

Aetiology. The defect involves a polymorphic genetic locus for apo-E (apo-E3) [2]. Particles containing apo-E2 show no binding to the apo-B/E receptor. Most patients are homozygous for this form of apo-E2 but some are heterozygous with apo-E2/E3 or apo-E3/E4 phenotypes [1,3]. Patients with complete deficiency of apo-E4 have also been described. The presence of an E4/E4 phenotype has now been associated with other diseases (such as Alzheimer's disease). Apo-E3, a component of remnant lipoprotein derived from CMs and VLDL, is essential for uptake of these CM 'remnants' by the liver. All patients with this disorder are homozygotes (1% of the population for Ed allele, where d = deficient). Heterozygotes are common in the population (apo-E2/E2 phenotype, one per 100) but most individuals can compensate in some way for the abnormal apo-E, and it is only those who cannot do so that express the disease. Expression of the disease therefore depends on other genetic or metabolic factors, such as the inheritance of multiple type hyperlipidaemia, FH, insulin-dependent diabetes mellitus, hypothyroidism and obesity [1,4]. It rarely presents in premenopausal females or in childhood.

Clinical features [5]. Onset of symptoms is delayed to the second or third decade, although presentation may be later in women because of the effect of oestrogens on hepatic uptake of remnant particles. Xanthomas are a

Fig. 57.43 Xanthomatosis and yellow palmar creases. (Courtesy of Addenbrooke's Hospital, Cambridge, UK.)

common presentation, and patients may have tuberous, tuberoeruptive or plane xanthomas involving the palmar and digital creases (xanthoma palmaris) (Fig. 57.43) [6], as well as typical eruptive lesions over elbows, knees and wrists often surrounded by satellite lesions. Xanthelasma may also occur. Premature severe coronary, cerebral and peripheral vascular disease occurs and patients may in addition have hypothyroidism, central obesity or diabetes [7].

Investigation. Plasma cholesterol and TG levels are elevated to almost the same degree (i.e. cholesterol greater than 7.0 mmol/L and TG greater than 4.0 mmol/L). Lipoprotein electrophoresis shows type III pattern with a broad pre-β-band, and the IDL fraction obtained by ultracentrifugation shows a high cholesterol content. These changes are not diagnostic. The demonstration of the Ed allele on isoelectric focusing is diagnostic for familial dysbetalipoproteinaemia [2,8]. The diagnosis should also be confirmed by apo-E phenotyping, particularly of E2. Genotype testing is now available in some centres.

Treatment. Appropriate treatment will resolve the xanthoma lesions, which eventually disappear. Treatment of any other metabolic disease, such as obesity, diabetes mellitus or hypothyroidism, will contribute to lowering of the lipid levels. Most patients will respond to therapy with fibric acid derivatives (such as bezafibrate or gemfibrozil), either alone or in combination with nicotinic acid. Clofibrate is no longer used in the management of this disorder. HMG-CoA reductase inhibitors may be useful, particularly for double homozygotes (type III and FH) [1,7,9].

Primary hypertriglyceridaemias

Under this title will be considered patients presenting with a predominant increase in TG due to increases in fasting plasma CMs or VLDL, or both (type I, IV or V phenotypes).

Familial hypertriglyceridaemia (MIM *145750) [1,2]

SYN. ENDOGENOUS HYPERTRIGLYCERIDAEMIA

This category is usually subdivided according to whether the phenotype of individuals is type IV or V.

Familial pure hypertriglyceridaemia (type IV). This is a common autosomal dominant disorder with delayed penetrance, which gives rise to moderate hypertriglyceridaemia due to increased levels of VLDL and normal levels of LDL [3]. The frequency of this disorder in the population is of the order of 0.2–0.3% [3] and it is expressed in childhood [3]. The underlying mechanism for VLDL TG overproduction is not certain, but VLDL TG synthesis is increased more than VLDL apo-B synthesis and the catabolic rate of both VLDL components is decreased [4]. The pathogenesis of the condition is not clearly understood. Obesity, diabetes mellitus and alcohol are commonly exacerbating causes in the non-familial form but are not a part of familial hypertriglyceridaemia. They may exacerbate the condition by increasing VLDL production [1] and by insulin resistance [5].

Clinical features [1,6]. Typically, patients are obese, with glucose intolerance, hypertension and hyperuricaemia [6,7]. Severe exacerbations can be precipitated either by ingestion of oestrogen-containing oral contraceptives [6],

poorly controlled diabetes [6,7] or excessive alcohol intake [8], and under these circumstances CMs appear in the plasma and the patient develops a 'mixed hyperlipidaemia'. During such an exacerbation, patients occasionally develop eruptive xanthomas over buttocks or arms, but xanthomas are not normally a feature of the condition. The increase in TGs increases the risk of any associated increase in cholesterol, and, if the clinician assesses the risk of CAD to be high, treatment for lowering the TG should be started [9,10].

Investigation. A moderate increase in plasma TG (between 2.0 and 10 mmol/L) with normal cholesterol and type IV pattern ultracentrifugation should suggest the diagnosis, although these findings are found in other genetic and acquired hyperlipidaemias [1,11].

Occasionally patients may have severe triglyceridaemia with increased levels of CMs and VLDL [5,10]. Plasma LDL levels may appear within the normal range as are the LDL-apo B levels but TG levels in excess of 5.0 mmol/L interfere with LDL measurements. There are no other specific tests for familial hypertriglyceridaemia but study of the adult members of a family may show that 50% of them have increased TGs.

Treatment. Adherence to a modified low fat diet to achieve ideal body weight is essential, and the patient's weight, diabetes mellitus and thyroid disease (if present) should all be treated appropriately. Sucrose, alcohol and oral contraceptives should be avoided, and the diet should be low in total and saturated fats. If these dietary measures do not succeed, drug therapy with fibrates (bezafibrate, fenofibrate or gemfibrosil) or more rarely nicotinic acid can be effective in controlling this hyperlipidaemia. Use of a fish-oil preparation (ω-3 fatty acid), such as Maxepa® or Omacor®, can result in a rise of LDL and should be avoided [12].

Familial type V hyperlipidaemia (MIM 238400) [1–3]

Within some families there are individuals who in late adult life show mixed hyperlipidaemia. This is a disorder with features of both type IV and type I hyperlipoproteinaemias, due to increases in VLDL and CMs and where serum TG are in excess of 11 mmol/L. The condition is rare, approximately one in 1000 adults. Severe hypertriglyceridaemia occurs when CMs and VLDL compete for the same lipoprotein lipase and when there is an increase in hepatic VLDL synthesis. This can be genetic or exacerbated by alcohol, obesity, diabetes or oestrogen administration. Reduced VLDL clearance and reduced lipoprotein lipase activity, as in diabetes, will increase fasting plasma TG and absorbed CMs will be also cleared from the blood more slowly after a meal.

Clinical features. These patients present with eruptive xanthomas, abdominal pain and occasionally acute pancreatitis associated with a marked or severe increase in TG, even in the fasted state (TGs in excess of 11 mmol/L). Patients may often have other clinical features, such as hepatosplenomegaly due to fatty change or fatty infiltration of the liver; lipaemia retinalis (a white appearance of retinal arteries and veins) may also occur and is characteristic of the condition. Pseudohyponatraemia can occur in association with increased TGs. There is a risk of atheroma due to increased dense LDL secondary to increased VLDL (insulin resistance), which predisposes to CAD and peripheral vascular disease.

Investigation. Fasting TG concentrations will be excess of 11 mmol/L and the serum will appear cloudy due to the presence of CMs even when fasting.

Treatment. Treatment is essentially towards weight reduction by reducing carbohydrate and total fat intake but may be difficult because a low fat diet (less than 50 g/day) can increase VLDL synthesis. Use of medium chain TGs can be useful, as these are not incorporated into CMs. Use of heparin to stimulate lipoprotein lipase activity may be useful in the management of patients with acute pancreatitis due to increase in TGs. Gestational pancreatitis should be managed with intravenous carbohydrates and fat restriction to 10 g/day [3]. Lipolysis can be increased by oxandrolone in males and norethisterone in females,

and by nicotinic acid or by fish oils containing ω-3 fatty acids (Maxepa® or Omacor®) to reduce TG synthesis.

Familial lipoprotein lipase deficiency (MIM *238600) [1–5]

SYN. FAMILIAL TYPE I HYPERLIPOPROTEINAEMIA; FAT-INDUCED LIPOPROTEINAEMIA; BURGER–GRUTZ TYPE

This is a rare autosomal recessive disorder, which results in deficiency of extrahepatic lipoprotein lipase, the rate-limiting enzyme for hydrolysis and removal of CMs and VLDL TG from circulation, which results in accumulation of CMs in the plasma. Lipolysis initiates the cascade of conversion of lipoprotein particles, which results in reduction in circulating LDL and remodelling of HDL. Lipoprotein lipase facilitates binding of non-HDL lipoprotein to extracellular matrix and uptake of the lipoprotein by cell-specific receptors through mechanisms independent of lipolysis.

Clinical features. This condition presents in childhood with recurrent attacks of abdominal pain or acute relapsing pancreatitis and eruptive/tuboeruptive xanthomas (often occurring over the buttocks). Hepatosplenomegaly and retinopathy (lipaemia retinalis) are frequent findings. More rarely neurological abnormalities have been described: memory loss, dementia and peripheral neuropathy. The major threat to health in these patients appears to be acute pancreatitis.

Investigation. Lipaemic plasma in young individuals after a 12-h fast should suggest the diagnosis, and if the sample is left in the refrigerator (at 4°C) overnight a creamy layer collects at the top of the tube, while the infranatant remains relatively clear. The plasma TG level is markedly elevated in the region of 50–100 mmol/L [5] with plasma TG to cholesterol mass ratio often exceeding 9 : 1. VLDL levels are normal or decreased, and LDL and HDL levels are markedly reduced. As in other hypertriglyceridaemias, some blood tests may be inaccurate (pseudohyponatraemia, low plasma amylase and increased aspartate/alanine transaminases). Measurement of the lipoprotein lipase level [6] or apo-CII may occasionally be necessary to establish the diagnosis [6].

Treatment. Restriction of dietary fat to 20–30 g/day by decreasing the intake of long-chain TGs usually results in loss of the symptoms and signs of the hyperlipidaemia. Medium-chain TGs are not normally incorporated in CMs and therefore may be given in unrestricted amounts. In addition to dietary measures, use of fibrates, fish oils or nicotinic acid/acipimox can further lower TG concentrations. The risk of acute pancreatitis is significantly diminished if plasma TG concentrations are kept below 10 mmol/L.

Prognosis. Until recently, the risk of acute pancreatitis was thought to be most important, and early reports suggested that lipoprotein lipase deficiency did not predispose patients to accelerated atherosclerosis. The concept that atherosclerosis was not a feature of the genetic disorder was accepted because CMs were considered to be too large to penetrate the endothelial barrier. A recent case report has thrown this into doubt [3]. In addition, a low level of circulating LDL can be apparent because of difficulty in measuring cholesterol in the face of increased CMs.

Familial apo-CII deficiency (MIM *207750) [1,7–9]

This is a very rare autosomal recessive disease [7,8], which in the homozygous state (due to recessively inherited mutant genes) results in an absence of normal apo-CII [7], an essential cofactor for lipoprotein lipase. As a consequence of this defect, there is a functional lipoprotein lipase deficiency, since lipoprotein lipase cannot hydrolyse CMs or VLDL in the absence of normal apo-CII. This defect in lipolysis causes a rise in both CMs and VLDL.

Clinical features. These might be expected to be the same as for lipoprotein lipase deficiency, but patients usually present in adult life and do not show hepatosplenomegaly or eruptive xanthomas. Abdominal pain due to pancreatitis, however, remains a major threat to health [9].

Investigation. Plasma TG levels are markedly elevated in the range 17–107 mmol/L. By strict criteria, the lipoprotein ultracentrifugation pattern is type V, but many patients have an intermediate pattern between types I and V [10]. It also manifests in decreased post-heparin lipase activity, which normalizes with addition of apo-CII [10]. Deficiency of apo-CII can be measured by isoelectric focusing of de-lipidated VLDL.

Treatment. This is either by fat restriction, as in lipoprotein lipase deficient patients, or by replacement of the apo-CII by transfusion with normal plasma [10]. Synthetic apo-CII may become more widely available for treatment [1,7,11].

Sporadic hypertriglyceridaemia [1]

SYN. COMMON 'POLYGENIC' HYPERTRIGLYCERIDAEMIA

This heterogeneous group of patients have elevated plasma TG with or without increased levels of CMs. They differ from those with familial hypertriglyceridaemia and familial multiple type hyperlipidaemia in that their first-degree relatives are unaffected [2].

Lipid storage diseases

Two very rare lipid storage diseases are important to dermatologists in spite of their rarity, because these disorders characteristically present with xanthomas. Tangier disease is included but the skin involvement is usually minor.

Cerebrotendinous xanthomatosis (MIM #213700) [1,2]

SYN. CHOLESTANOLOSIS

This rare autosomal recessive condition is characterized by widespread tissue deposition of cholestanol and cholesterol, resulting in progressive neurological defects and premature death from arteriosclerosis [3,4].

Aetiology. The primary biochemical defect is due to a deficiency of hepatic mitochondrial enzymes catalysing the hydroxylation of cholestanol (27-hydroxylase deficiency). This deficiency affects bile acid synthesis by reducing feedback inhibition on cholesterol 7α-hydroxylase (a rate-limiting enzyme). This allows synthesis and accumulation of cholestanol [5]. The resulting deficiency of primary bile acids (chenodeoxycholic and cholic acids) probably leads to increased cholesterol and cholestanol synthesis by the liver [6,7].

Clinical features. Patients present in childhood or early adult life and sterol deposits are found throughout the body. Tendon xanthomas, especially in the Achilles tendon, are an early characteristic of the disorder and clinically are similar to those seen in FH. Xanthelasma and tuberous xanthomas may also be present. Central nervous system abnormalities occur early in childhood, and mental retardation and progressive spasticity develop. Patients often have a myopathic facies with open mouth and protruberant tongue. Neuropathological studies suggest that the enzyme defect leads to an accumulation of brain metabolites that are neurotoxic, causing axonopathy and non-specific lipid deposition in the injured tracts [8]. Thus neurological signs develop from extensive myelin destruction within the cerebellum, brainstem and peripheral neuropathy. Patients also develop juvenile cataracts (as early as 5 years old) due to deposition of cholestanol and cholesterol in the lens. Osteoporosis and bone fractures are common. They are also at risk from premature arteriovascular disease [1,4].

Investigation. Key biochemical findings are that cholestanol levels are diagonostically elevated in the plasma, tissues and bile. Xanthomas occur in association with low or normal plasma cholesterol levels. Also because of defective bile acid synthesis, reduced levels of cholic and chenodeoxycholic acids are found in bile.

Treatment. This is based on the concept that plasma cholestanol increases because of a block in bile acid synthesis. Use of chenodeoxycholic acid/ursodeoxycholic acid may be useful in lowering plasma cholestanol by suppression of endogenous bile acid synthesis. Correction of the bile acid deficiency with chenodeoxycholic acid produces a reduction in plasma cholestanol levels and improvement in the neurological signs [1]. This is a

life-long treatment. HMG-CoA reductase inhibitors have also been tried with some success in reducing cholesterol and cholestanol concentrations but with no deterrent effect on disease progression [9–11].

Sitosterol storage disease (sitosterolaemia) and xanthomatosis (MIM #210250)

This very rare condition inherited as an autosomal recessive trait is characterized by xanthomas in childhood or early adult life with tendon and subcutaneous xanthomas due to accumulation of plant sterols within the tissues [1–3].

Aetiology. The biochemical defect has not been clearly established but it has been suggested that absorption of plant sterols, β-sitosterol, campestanol and stigmasterol are increased. These are all related to cholesterol and may be converted to bile acids. However in homozygotes, intestinal absorption of sitosterol is increased two- to threefold over controls, and cholesterol synthesis was reduced due to markedly reduced HMG CoA reductase activity. Furthermore LDL-receptor expression was increased in the sitosterolaemic hepatocyte resulting in increased LDL uptake.

Clinical features. Tendinous xanthomas, particularly over the Achilles tendon and extensor tendons of the hand, have been present in all cases reported to date, and usually appear in early childhood. Less commonly, tuberous xanthomas and xanthelasma may be present. Haemolysis due to abnormal spherocytes as well as abnormal platelets are associated with an enlarged spleen. Arthritis and arthropathy also occur. Premature arteriovascular disease affecting coronary arteries and aorta has been noted particularly in young males.

Investigation. The diagnosis is made by the demonstration of increased amounts of these plant sterols by gas–liquid chromatography of plasma or xanthomas. These patients also have hypercholesterolaemia. Heterozygotes are clinically and biochemically normal although some may have slightly increased plasma sitosterol concentrations.

Treatment. This usually involves exclusion of plant and shellfish sterols from the diet and this, combined with bile acid sequestering agents (cholestyramine or colestipol) to reduce absorption from the gastrointestinal tract, results in reduction of sitosterolaemia and improvement in the clinical signs. Use of statins to reduce cholesterol levels is not effective in treating these patients. In fact a diagnosis of sitosterolaemia should be considered and excluded in patients with hypercholesterolaemia unresponsive to statins.

Tangier disease (MIM #205400)

SYN. FAMILIAL HDL DEFICIENCY; B-LIPOPROTEIN DEFICIENCY DISEASE

This is a very rare autosomal recessive disorder characterized by a deficiency or absence of normal HDL in the plasma [1–4].

Aetiology. Tangier disease is caused by mutations in the gene of the ATP-binding cassette transporter 1 (*ABC1*) located on the long arm of chromosome 9 (9q31) [5,6]. The primary biochemical defect is not known, but *ABC1* plays a role in the secretion of mature HDL and secretion of cellular lipids. Defective maturation underlies increased catabolism of apo-A1 and apo-AII and, as a result, HDL is

markedly reduced and of abnormal composition (apolipoproteins AI and C are present in only trace amounts [2–4]). This reduction in HDL results in the production of abnormal CM remnants and the accumulation of cholesteryl esters in many tissues [6].

Clinical features. Twenty-six patients have been reported to date [3]. Orange-yellow tonsils and adenoids are characteristic but hepatosplenomegaly and peripheral neuropathy are common features. Cholesteryl esters are found in the skin within foamy histiocytes [7–9]. Slit-lamp examination of the eye shows corneal infiltration in most patients as they age.

Investigation. The combination of a very low level of cholesterol and elevated plasma TG is almost diagnostic. Ultracentrifugation shows HDL to be absent or present in only trace amounts, and lipoprotein electrophoresis shows no α_2-protein. Plasma apolipoprotein A (apo-A1) is very low (less than 3% of controls).

Treatment [2,3]. There is no specific treatment for this disease as yet, although reduction in fat content of the diet may be logical, since remnants of TG-rich lipoproteins appear to accumulate in the plasma with normal fat intake.

Disorders of amino-acid metabolism

[C.A. Seymour, pp. 57.77–57.85]

The disorders of amino-acid metabolism are of growing importance. As well as abnormalities of skin, patients may show mental retardation, abnormalities of hair and impaired general body growth. These disorders are the result of inherited defects of enzymes that mediate the metabolism or transport of amino acids.

Hyperphenylalaninaemia syndromes

These syndromes are characterized by defects in hydroxylation of phenylalanine to tyrosine, or defects in the generation of tetrahydrobiopterin (BH_4), a coenzyme for hydroxylation, resulting in increased fasting plasma phenylalanine concentrations (normal range 40–80 mmol/L).

Phenylketonuria (MIM *261600)

SYN. HYPERPHENYLALANINAEMIA TYPE I; FOLLING'S DISEASE; PHENYLPYRUVIC OLIGOPHRENIA

Phenylketonuria (PKU) is a rare inherited disease in which a deficiency of the enzyme phenylalanine hydroxylase (PAH) leads to an accumulation of phenylalanine in the plasma (normal range: less than 2 mg/dL, 120 µmol/L: in PKU, plasma levels are greater than 1000 µmol/L) and to the excretion of phenylpyruvic (about 1 g is excreted daily) and phenylacetic acids in the urine. Known forms include primary deficiency of PAH (PKU and non-PKU phenylalaninaemia), and impaired synthesis of BH_4, guanosine triphosphate (GTP) cyclohydrolase or 6-pyruvoyl tetrahydropterin synthase (6-PTS; MIM *261640), or dihydropteridine reductases (DHPR; PKU2, MIM *261630). PKU is the commonest of these hyperphenylalaninaemias; however, not all are PKU, nor is it always due to PAH deficiency.

Aetiology [1,2]. PKU is inherited as an autosomal recessive disorder with overall incidence of one in 8000–12 000 live births. It accounts for 0.04–1.00% of residents in institutions for the mentally disabled. One in 50 individuals carries the mutant gene. It is a heterogeneous genotype, PAH deficiency being caused by over 400 mutations at the PAH locus on chromosome 12q22–q24.1 [1]. Other phenylalaninaemias include BH_4 deficiency caused by alleles at three other loci: one on chromosome 4 and the others unmapped to date [3,4]. The *DHPR* gene has been localized to chromosome 4 band 15.1p16.1 [1,3]. The clinical condition arises in the presence of the mutation alone (if due to deficient BH_4) or in combination with exposure to phenylalanine (in PKU and non-PKU PAH deficiency). The near complete deficiency of PAH impairs conversion of phenylalanine into tyrosine, leading to the accumulation and excretion of abnormal compounds. Heterozygotes have a high fasting serum phenylalanine level and some 'dilution' of hair colour. The usual gene dose effects are seen in heterozygotes.

In PKU, there are only abnormal concentrations of normal metabolites, and no abnormal metabolites. The metabolic block in the conversion of phenylalanine to tyrosine, carbon dioxide and water, which is the rate-limiting step, leads to the accumulation of phenylalanine,

phenylpyruvic acid and related metabolites. Phenylalanine has ketogenic (acetoacetate) and gluconeogenic (fumarate) intermediates that contribute to the glucose pool, which could play a role in normal brain development and function. The oxidation rate in the brain is probably diminished but, although degenerative changes have been described in the cortex and basal ganglia and in the liver, they are inconstant [5–7]. The reduction of melanin formation in the hair is probably due to the inhibition of tyrosine–tyrosinase reaction by phenylalanine, as the hair will darken if large amounts of tyrosine are ingested.

Clinical features [1,5–7]. The clinical phenotype of PKU is largely of historical interest, because with early diagnosis and treatment the damaging features of the disease can be reduced or prevented. In addition, genotype–phenotype expression can now be examined (with complementary DNA expression *in vitro*). The metabolic phenotype (hyperphenylalaninaemia with or without neurotransmitter deficiency) is the link between the gene and the disease. Affected infants are of average height and weight at birth, but thereafter show wide variation in the ages at which the developmental stages are passed. Unless diagnosis is made early, they present with psychomotor delay in early childhood due to an effect on brain development and function. Recent studies have suggested that the clinical features previously associated with PKU may not be linked. However, these patients almost invariably have fair skin and hair (due to the impairment of melanin synthesis), although in darker races the resultant skin pigmentation may be darker than in the average white person. If untreated in early life, there is nearly always mental retardation, and most of these patients will require special care. About 50% have epilepsy, and often extrapyramidal manifestations, such as athetosis and exaggerated tendon reflexes, may be found. The excreted amino acids can exude a musty odour. The electroencephalogram is abnormal in 80% of patients and correlates with the metabolic phenotype. Magnetic resonance imaging has demonstrated changes consistent with disturbance in the water content of the white matter. It is not clear whether these are of clinical significance [8], although brain phenylalanine concentrations may be lower than expected and are then associated with less effect on the IQ.

The fair and sensitive skin readily develops eczema. This may be of the atopic variety or of less distinctive type. Although clinical light sensitivity has been reported, the ability to tan and the erythematous response to UV radiation are normal [9]. The incidence of pyogenic infections is increased. Scleroderma-like lesions with involvement of the muscles have been described [10]. Eye abnormalities associated with hypopigmentation may occur [1,11]. Impaired physical growth affects the head circumference and height (abnormality in metaphyseal endplate of long bones) in the untreated condition [7,11].

There is some evidence that in mothers with PKU, phenylalanine crosses the placental barrier (along a concentration gradient) and may cause an embryopathy/fetopathy affecting growth, congenital malformations, microcephaly, epilepsy or mental deficiency in the fetus [6]. This diagnosis should therefore be considered in fair-skinned, light-sensitive individuals, especially in mothers of mentally retarded children.

Diagnosis. Newborn screening is the established way to determine hyperphenylalaninaemia (HPA). Although the urine may contain phenylpyruvic acid at birth, the urine test may be negative in the first months of life (ferric chloride test). The blood phenylalanine, however, is raised from an early date, and therefore it is recommended that screening is performed on blood samples during the first week of life [12]. This is now an established neonatal screening programme in the UK [13].

The most widely used method of screening is based on the Guthrie test [13]. The test is performed on a dried capillary blood sample collected on filter paper and analysed by microbiological inhibition assay (Guthrie) or by chromatography, fluorimetry or tandem mass spectrometry. The latter test has few false negatives. A method is described for differentiating the hyperphenylalaninaemias based on the response to phenylalanine content in the diet [4]. Some patients with hyperphenylalaninaemia do not have PKU (see also hyperphenylalaninaemia types II to V). Some patients with persistent HPA have impairment in synthesis or recycling of BH_4, which must also be screened for.

Prenatal diagnosis. Indications for this are uncertain, as treatment is experimental. Families at risk can have prenatal diagnosis by a combination of DNA analysis, enzyme activity, or amniocyte or chorion villus sample metabolite levels [1,3,12]. There are advantages to gene testing by DNA analysis, if alleles have been identified in an affected family member.

Treatment [5–19]. The aim of treatment is to normalize phenylalanine levels as early as possible and for as long as possible (i.e. throughout life) and particularly during pregnancy. It is of prime importance that the diagnosis is made early so that a low phenylalanine diet can be instituted as soon as possible, in order to avoid cerebral damage (assessed by IQ) produced by high blood phenylalanine levels. Blood phenylalanine levels are routinely measured to assess the effects of any treatment. The diet is selectively restricted in phenylalanine to about 250–550 mg/day to keep the plasma phenylalanine level below the toxic range [20]. The patient's diet may need supplementation with tyrosine/tryptophan. The aim is to keep the plasma level to less than 480 μmoL/L. Repeated monitoring of the blood phenylalanine levels (by the Guthrie

test) is required during treatment. Phenylalanine is monitored twice a week in the neonate, weekly in infants, 2–3 weekly in toddlers and ideally monthly thereafter even during adult life. During pregnancy, dietary measures should be adhered to as early as possible and preferably even before conception, but definitely from the fifth and sixth week of pregnancy. This is likely to reduce the risk of damage to brain development but is unlikely to avert congenital heart disease [21–23], which is only prevented by adhering to a strict diet before conception. Twice weekly sampling blood tests are ideal to maintain levels of 100–250 μmol/L. There is evidence that reduction in maternal phenylalanine levels during pregnancy results in neonates with a higher birth weight [24].

The diet is based on a synthetic substitute for most of the dietary protein and should be continued not only until the child has passed the main period of brain development but also during adult life, as it has now been established that neurological sequelae (long tract signs) can develop in the untreated affected adult [21]. The diet is often relaxed at about 8 years of age but some limitation of diet is still essential, otherwise there is a risk of relapse or of failing to develop the full IQ potential. Thus, contrary to previous practice, tight control of circulating phenylalanine is not only essential during pregnancy, but more recently has been shown to be advisable if not essential to continue throughout adult life [1,22,24,25]. Unfortunately, the response to dietary treatment is variable despite early and careful control, and the effectiveness of treatment varies with individual patients. The amount of phenylalanine supplied in the diet should be low enough to prevent its accumulation in the blood, but high enough to allow protein synthesis and growth. Foods are given on an exchange basis using tables to indicate food with 1 g protein (equivalent 50 mg phenylalanine). Enzyme therapy with phenylalanine ammonia lyase (PAL) can be given in enteric-coated capsules and has a beneficial effect on plasma phenylalanine levels. However enzyme replacement therapy can only be achieved at present with heterologous liver transplant. Enzyme substitution, using PAL, can lower blood phenylalanine if given orally but the effect is too short lived to be therapeutic.

Non-PKU hyperphenylalaninaemia (types II and III)

Not all infants with hyperphenylalaninaemia have PKU [1]. Types II and III represent a continuum, from those difficult to separate from typical PKU to those who are mildly affected. There is a general correlation between PAH activity and blood levels of phenylalanine [2]. Accurate classification usually requires testing with phenylalanine loading and measurement of metabolites [3,4]. Treatment needs to be modified according to the severity of the enzyme deficiency, but essentially is as for PKU.

Hyperphenylalaninaemia (types IV and V)

Types IV and V are due to deficiencies in the coenzymes DHPR [1] and dihydrobiopterin synthetase [1–5], respectively. The chromosomal locus encoding DHPR is assigned to human chromosome 4. Patients lacking DHPR are deficient in neurotransmitters whose synthesis is dependent on normal DHPR-tyrosine and tryptophan hydroxylase activities. They have low urinary and cerebrospinal fluid vanilyl mandelic acid and 5-hydroxyindole acetic acid. Other rarer forms, resulting in BH_4 synthesis disorders —GTP cyclohydrolase deficiency [6,7] and 6-PTS [5,8] deficiency—can be more easily detected by loading tests. These infants represent only 1.3% of all patients with hyperphenylalaninaemia but need accurate diagnosis, as their treatment is very different from that of typical PKU [1,6]. Treatment of DHPR deficiency needs dietary restriction of phenylalanine and restoration of the neurotransmitter levodopa (about 12 mg/kg/day) and 5-hydroxytryptophan (about 10 mg/kg/day), together with carbidopa to reduce peripheral breakdown of levodopa. Folate replacement or folinic acid treatment is also necessary, as DHPR plays a role in tetrahydrofolate homeostasis.

Prenatal diagnosis. It is now possible to measure DHPR in amniocytes and to detect the condition by DNA analysis by restriction length fragment polymorphism (RFLP) in informative families [5].

Tyrosinaemia

There are a number of inherited conditions that cause hypertyrosinaemia. These include inborn errors of metabolism (e.g. oculocutaneous and hepatorenal tyrosinaemia) and secondary causes (e.g. severe hepatocellular dysfunction, transient tyrosinaemia of the newborn and other diseases, for example hyperthyroidism). Tyrosine comes either from dietary intake or from hydroxylation of phenylalanine. It is degraded in the hepatocytes by the rate-limiting enzyme, tyrosine aminotransferase (TAT).

Tyrosinaemia I (hepatorenal) (MIM *276700) [1–3]

This is a rare but well-documented autosomal recessive disorder due to a deficiency in fumarylacetoacetoic hydroxylase (FAH). This enzyme has been located to chromosone 15. It can present as an acute or chronic form, and principally affects the liver, kidney and peripheral nerves.

The *acute form* presents in the first few weeks of life with failure to thrive, vomiting, diarrhoea and a cabbage-like odour. Hepatomegaly and a bleeding diathesis are common features and untreated patients die of hepatic failure.

The *chronic form* is characterized by chronic liver and renal disease (Fanconi-like syndrome) with death within the first decade. Some patients may develop hypertension, and hypertrophic cardiomyopathy and porphyria-like neurological crises (due to δ-aminolaevulinic acid (ALA)). Hepatoma is a late complication. Plasma tyrosine and methionine are elevated diagnostically and there is a global increase in urine amino acids, with particular increase in ALA [3].

Secondary deficiency of hepatic 4-hydroxyphenylpyruvate dioxygenase (HPDD) may occur and is important to note. Some patients develop hypermethioninaemia, the importance of which is uncertain, although it is also increased in cirrhosis and hepatoma. The episodes of porphyria-like peripheral neuropathy are thought to be due to succinylacetone, which inhibits the porphyrin synthetic enzyme, ALA dehydratase [3].

Prenatal diagnosis. This is either by direct determination of the FAH enzyme activity or detection of succinylacetone directly or from its inhibitory activity in amniocytes or chorionic villus samples [2,4]. Neonatal screening is aimed at detecting increased levels of tyrosine, methionine or succinylacetone from blood spots on filter paper, and more recently these have also been used for screening ALA dehydratase. Several different mutations have been reported, and where the mutation is known, molecular analysis should be carried out.

Treatment. This is with a low tyrosine and phenylalanine diet, which may reduce the succinylacetone excretion and

reduce the effects on the kidneys. Liver transplantation has been successful and is the treatment of choice [5–7] and gene therapy may be possible [8]. Treatment is with NTBC (2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione), which inhibits key enzymes in the degradation pathway reducing production of toxic metabolites [6,7].

Tyrosinaemia II (MIM *276710) [1–3]

SYN. RICHNER–HANHART OCULOCUTANEOUS SYNDROME [4]

This is a very rare disorder, inherited as an autosomal recessive trait, due to a deficiency of cytoplasmic TAT, now mapped to chromosome 16q22–q24, the rate-limiting enzyme for tyrosine catabolism [5]. Males and females are equally affected. The deficiency leads to tyrosinaemia, unique tyrosinuria and an increase in the urinary tyrosine metabolites. The eyes, skin and nervous system are the only organs affected. Mild but painful corneal herpetiform erosions and dendritic ulcers develop within the first few months of life and may lead to photophobia, corneal scarring [6,7] and glaucoma. Ulceration also has occurred on corneal transplants [7]. Skin lesions usually occur after eye lesions have developed, although in some families the skin lesions may exist without eye lesions [1,2]. Painful erosions may develop on palms and soles, especially the tips of digits, thenar and hypothenar eminences. Later, these areas become hyperkeratotic [4]. The skin biopsy, although showing hyperkeratosis and acanthosis, is not diagnostic, but electron microscopy shows intracellular granules and filaments, probably caused by tyrosine crystal-induced inflammation. Hyperkeratosis of the tongue has been reported [8]. In the original description of this disease [4], mental retardation occurred in fewer than 50% of patients. Disturbance of fine coordination and self-mutilation also occur [1,2].

Diagnosis. This is made by detection of increased blood tyrosine levels, normal phenylalanine and increased urinary metabolites of 4-hydroxyphenylacetic acid, *N*-acetyltyrosine and 4-tyramine.

Treatment. Most patients respond to dietary restriction of tyrosine and phenylalanine [2,9] by reducing protein to 2–3 g/kg/day, with the aim of reducing blood levels to less than 600 µmol/L, although the precise reduction in tyrosine required to control the skin and eye features is unknown.

Alkaptonuria (MIM #203500) [1,2]

This is a rare metabolic disorder first described by Garrod in 1902 [1], which results from a single gene defect. It is characterized by a discrete biochemical lesion, with deposition of oxidized homogentisic acid pigment throughout the body, particularly in fibrous and cartilaginous tissues. Dark urine (homogentisic aciduria), distinctive cutaneous pigmentation (ochronosis) and arthritis are characteristic. Generally, it is considered a benign degenerative disorder with normal life expectancy [2].

Aetiology [1–3]. It is inherited as an autosomal recessive condition. Its incidence in the population is one in 200 000. It is characterized by a constitutional deficiency of homogentisic oxidase (homogentisic 1,2-dioxygenase activity). This leads to an accumulation of homogentisic acid, an intermediate metabolite of phenylalanine and tyrosine catabolism. The enzyme is normally found in the liver and the kidney.

Ochronosis [4,5] describes the deposition of a melanin-like brownish-black pigment, derived from the oxidized product of homogentisic acid (benzoquinone acetic acid), in connective tissues and cartilage. The enzyme homogentisic acid oxidase contains an essential sulph-hydryl group, which is inhibited by certain chemicals. These include various drugs such as phenol, resorcin, mepacrine and perhaps other antimalarials that may cause acquired ochronosis. An exogenous ochronosis can also occur from hydroquinone-containing skin-bleaching creams [4].

Genetics. Alkaptonuria is an autosomal recessive condition. The gene locus (*AKU*) has been assigned to chromosome 3q by consanguinity and by comparative mapping. The gene has been cloned to 3q21–q23 with demonstration that the human 1890 gene harbours missense mutations and cosegregates with the disease [3]. The incidence is one in 200 000 but in areas of consanguinity it is higher [6].

Histopathology. There is deposition of black pigment in the cartilage, fibrous tissue, tendons and atheromatous areas. The intervertebral discs, larynx, tracheal rings and articular cartilages are jet-black as if 'dipped in Indian ink'. Differentiation of the ochronotic pigment from melanin is difficult, and stains do not consistently differentiate between the two pigments.

Clinical features [2,7]. Cardinal features are due to homogentisic acid in urine, and pigmentation of cartilage, connective tissue and joints. The patient with the hereditary type is symptom-free until adult life. The only manifestations in childhood are discoloration of the urine and 'spotting or staining' of the napkins or clothing due to alkaline pH. The clinical sequence of events is alkaptonuria, then ochronosis and lastly ochronotic arthropathy (fifth decade). The cutaneous manifestations appear in the fourth decade. One of the earliest signs is thickening of the ear cartilage, associated with blue-black or grey-blue discoloration. The pinna feels noticeably thickened and flexible, and in later stages there may be gross calcification. Cerumen is often brown or jet black. Scleral pigmentation is noted as early as the third decade; it appears as brown or grey deposits midway between the corneal margin and the medial canthus. The skin of the eyelids and forehead is also pigmented and the tarsal plates often appear blue on transillumination. All the tendons are similarly discoloured; the dark discoloration over the extensor tendons on the knuckles is best seen when the patient makes a fist. Widespread dusky cutaneous pigmentation may be noted, but this feature is particularly marked over the cheeks, forehead, axillae and genital regions. The buccal mucosa and larynx are also affected and the nails are sometimes distinctly coloured brown. Ochronotic changes affecting the ear drum and ossicles may produce deafness; prostatic concretions and black renal calculi, as well as calcific aortic disease, have been recorded. The urine is of normal colour but darkens on exposure to air or within seconds of adding an alkaline solution. Patients sometimes observe that both their sweat and urine discolour clothing.

Ochronotic arthropathy follows a fairly consistent clinical pattern. There is low back pain with stiffness early in the fourth decade; during the next 10 years the knees become involved and, later, the shoulders and hips. The friable articular cartilages lead to prolapsed intervertebral discs or a ruptured nucleus pulposus with accompanying acute pain. Spondylosis spreads to the thoracic spine; patients then assume a stooping posture and can lose up to 15 cm in height. Limitation of expansion of the chest provokes dyspnoea. The spinal X-ray appearances are diagnostic.

Marked atherosclerosis is common in the older age groups as well as valvulitis and calcification of aortic and mitral valves. In spite of their marked disability, many patients reach old age.

Diagnosis. The diagnosis is by demonstration on gas–liquid chromatography of homogentisic acid in the urine (by its reducing ability), or with specific enzyme tests [8].

Differential diagnosis. An incorrect diagnosis of glycosuria or diabetes can be made if the urine is tested with Fehling's solution (but this is rarely used now). The pigmentation of acquired ochronosis from exogenous foreign chemicals or drugs is identical to the genetic disorder, but is unaccompanied by homogentisic acid in the urine or by arthropathy.

The overall clinical picture and the localization of pigment thus distinguish the genetic disease from other pigmentation disorders such as Addison's disease, haemochromatosis, argyria, chronic photosensitivity pigmentation, cutaneous porphyria and pellagra. The ferric chloride urine test gives variable results; other phenolic compounds give similar colour reactions and thus, when the test is positive, the urine should be examined by chromatography.

Treatment [2]. Since the major damage induced by the metabolic defect is pigmentation and joint changes, treatment is directed towards reducing connective tissue damage by ascorbic acid (acting as an antioxidant), and by analgesics and physiotherapy for the arthropathy. A low protein diet limiting the amount of phenylalanine and tyrosine is not practicable as a long-term measure, although it could be used intermittently. Use of vitamins (B_{12}, C) may be helpful (for example ascorbic acid in reducing homogentisic acid oxidation).

Homocysteinurias [1–5]

SYN. HOMOCYSTINURIAS

Homocystinurias are a group of rare, inborn errors of amino-acid metabolism first reported in 1962 [4]. They also encompass hypermethioninaemia and cystathioninuria. The defects arise when there is abnormality in transfer of the sulphur of methionine to serine in the synthesis of cysteine.

Aetiology. Initially homocysteinuria was thought to be due to deficiency of cystathionine-β synthase (CBS; MIM *236200), but it is now apparent that homocysteine accumulation may also result from inherited (MIM #236250) or acquired blocks in the 5-methyltetrahydrofolate–homocysteine methyltransferase reaction [1,3,6]. The enzyme deficiency is involved in homocysteine to cystathione conversion or in homocysteine to methionine conversion, which is dependent on 5-methyltetrahydrofolate and leads to an increase in homocysteine in the blood and in the urine. These can be distinguished because there is an increase in urine methionine in the CBS deficiency, and methionine is low in the secondary form. Secondary forms of homocystinuria can occur in vegetarians with vitamin B_{12} deficiency, or with treatment with isonicotinic acid.

Clinical features. CBS deficiency is inherited as an autosomal recessive trait, with a world prevalence of one in 344 000 and detection of one in 58 000–100 000, depending on the country [1]. Four major organs are affected: the eye, skeletal system, central nervous system and the vascular system. The underlying cause of tissue changes is because accumulated homocysteine interferes with collagen cross-links. The newborn infant may appear clinically normal, but lens dislocation, mental deficiency, growth disorder and cutaneous signs develop slowly over the next few years. Other clinical features include epilepsy, genu valgum and growth changes resembling Marfan's syndrome. There is often an abnormal glucose tolerance test and increased growth hormone levels. The hair is fine, sparse and brittle, and the malar area flushed. In some cases, hair examination shows no fluorescence with acridine orange, indicating abnormality of disulphide bonds. The cysteine content is normal. Livedo reticularis of the legs and tissue-paper scars on the hands may be present.

Osteoporosis of the spine is common and predisposes to scoliosis. Other features include hepatomegaly (secondary to fatty change) and myopathy. Psychiatric abnormalities occur in about 50% of such patients, with episodic depression (10%), and chronic behavioural disorders (17%) [7]; chronic obsessive–compulsive disorders (5%); personality disorders (19%), usually with an IQ of less than 79. Some children develop spontaneous venous and arterial thrombosis due to increased platelet stickiness [6,8]. In the vascular system, thrombosis with embolic abnormalities is a frequent cause of mortality. This affects any vessel and patients are at an increased risk of post-operative thromboembolism. More recently this association of homocysteine with vascular disease has been more clearly recognized [9,10].

Differential diagnosis. Marfan's syndrome, an hereditary mesodermal dysplasia, exhibits visceral manifestations without mental deficiency. The hair is normal and homocysteine is absent from the urine.

Diagnosis. This is by detection of urinary homocysteine by a positive urinary cyanide–nitroprusside reaction. Recently, plasma homocysteine measurement (with increases of 50–200 μmol/L), confirmed by changes after methionine loading, is regarded as a more accurate assessment. Heterozygotes can be detected by assaying for the enzyme in the liver, phytohaemagglutinin-stimulated lymphocytes and in cultured fibroblasts. In addition, the presence of abnormal sulphur-containing metabolites can be detected in the urine after an oral load of L-methionine. CBS deficiency can be diagnosed by hypermethioninaemia or by detection of increased homocysteine in urine or blood. Methods for detecting heterozygotes rest on enzyme assays, metabolite measurements or a combination using liver tissue, cultured fibroblasts or phytohaemagglutinin-stimulated lymphocytes. Newer techniques include tandem mass spectrometry [11].

Treatment [1,12]. There are two aims of treatment: (i) control/elimination of the biochemical abnormality; and (ii) treatment of complications. Patients are usually divided into pyridoxine-responsive or non-responsive individuals, detected after the newborn period. For the newborn, diets restricting methionine and supplemented with cysteine have been used with encouraging results when started early in life. Large doses of vitamin B_6 (pyridoxine) in the form of pyridoxine hydrochloride 150–300 mg/day produce complete reversal of the biochemical abnormality in some cases. Some may become folate deficient; administration of vitamin B_{12} and folic acid improves

clinical symptoms. For the non-pyridoxine responsive patients, a low protein diet with methionine-free amino acid supplements and exchanges, and minerals and vitamins may be helpful. In non-responsive patients diagnosed after birth (non-responsive after a trial of 500–1000 mg/day for several weeks), the use of betaine as a methyl donor agent to lower homocysteine levels could be a useful adjunct in combination with a low-methionine diet.

Prognosis. Prognosis is more favourable than might be thought, with recent surveys showing that fewer than 5% die by the age of 20 years [1–3].

Hartnup disease (MIM *2345000) [1–3]

This is a very rare hereditary recessive metabolic disorder of neutral amino-acid transport, which is characterized by a pellagrous eruption, a temporary and intermittent cerebellar ataxia, and a characteristic renal amino-aciduria with excessive indicanuria [1].

Aetiology [1,4]. The defect is due to a failure of the transport of tryptophan and is limited to the small intestine and kidney [5–7]. The defect is believed to be caused by a genetic defect in the specific system for transport of neutral amino acids across the brush border epithelium of the intestine and kidney, leading to hyperamino-aciduria and urinary indolic compounds due to bacterial action on the unabsorbed tryptophan. It is likely that Hartnup disorder is a monogenic defect which interacts with polygenic and environmental factors giving a wide clinical spectrum [8]. The failure of absorption of tryptophan results in a deficiency in the synthesis of nicotinamide causing a pellagra-like syndrome.

Clinical features. The onset is usually in childhood between 3 and 9 years, but the first signs are occasionally encountered as early as 10 days after birth. The cutaneous signs precede the neurological manifestations. The rash is dry, scaly and well marginated, affecting the light-exposed areas, notably the forehead, cheeks, periorbital regions, the uncovered areas of the arms and the dorsal surface of the hands. After exposure to sunlight, the skin reddens and an exudate may occur.

Cerebellar ataxia is the most commonly encountered neurological feature. It usually follows the skin lesions. Other signs of cerebellar origin include nystagmus and diplopia, and occasionally tremor of the hands and tongue. Early reports suggested mental retardation, but this has not been the case with most patients. Minor cognitive defects have been reported. Less commonly, there are associated psychiatric disturbances such as depression, delusions and hallucinations. Exacerbations are most frequently seen in the spring or early summer [2], cutaneous manifestations being accompanied by transient ataxia. Rarely, the attacks are provoked by febrile illness. Other somatic abnormalities include oedema and hypoproteinaemia with fatty change in the liver [2], fever, diarrhoea and atrophic glossitis.

Intravenous tryptophan is metabolized normally and the serum amino acids are normal. The urine contains increased amounts of amino acids of the monoamine monocarboxylic groups [5], and it is the pattern of the amino-acid excretion that confirms the diagnosis.

Differential diagnosis. The eruption in mild cases closely simulates infantile atopic eczema, seborrhoeic eczema or pityriasis alba; in Hartnup disease the covered areas are usually spared. Florid cases closely mimic nutritional pellagra.

The congenital poikilodermas, particularly the light-sensitive hereditary disorders such as Cockayne's syndrome, may present diagnostic difficulties.

Treatment [2,3]. The rationale for the treatment is to replace the defect by giving nicotinamide (50–300 mg/day) orally. Treatment usually results in amelioration of the rash and may improve ataxia and psychotic behaviour. A high-protein diet may be a useful adjunct. Intravenous nutrition may be necessary in severely affected patients.

Prognosis. Symptoms become milder with increasing age.

Gout

[C.A. Seymour, pp. 57.85–57.86]

This heterogeneous group of purine metabolism abnormalities is characterized by hyperuricaemia, and recurrent attacks of acute arthritis in some cases, with the deposition of monosodium urates in the articular cartilage and urate deposits in the skin (tophi) (Fig. 57.44). Arthritis may be progressive and nephropathy is common. Nephrolithiasis due to uric acid may precede arthritis.

Aetiology [1–4]. Uric acid is the degradative product of purine metabolism in humans. Increased circulating levels of uric acid arise because of overproduction or underexcretion of uric acid. Primary gout has long been recognized as a heterogeneous disorder with up to 40% of patients in whom pedigree analysis suggests an inherited cause [4]. Population studies suggest that the disorder is multifactorial and attributable to a combination of genetic and non-genetic factors [1]. There are two very rare specific enzyme deficiencies associated with gout, which have X-linked inheritance. These are partial deficiency of hypoxanthine–guanine phosphoribosyl transferase (HGPRT; HPRT-related gout, MIM #300323) and increased activity of phosphoribosyl-pyrophosphate (PRPP) synthetase. Most patients with primary gout appear to have reduced excretion of uric acid [5,6] but the metabolic abnormalities are poorly understood. Fewer than 10% of patients with primary gout have an increase in the rate of purine biosynthesis [7]. A number of defects have been suggested but only partial deficiency of HGPRT and increased PRPP synthetase activity are of importance [8].

Fig. 57.44 Gouty tophi. (Courtesy of Dr R.H. Champion, West Suffolk Hospital, Bury St Edmunds, UK.)

Secondary gout may result from decreased excretion of uric acid. The most important cause of this is diuretic therapy but it may also occur in a number of disease states, especially renal disease. Increased uric acid production is commonly secondary to increased turnover of nucleic acid in conditions such as polycythaemia rubra vera, lymphoma, myeloma and in patients with leukaemia receiving active chemotherapy. A number of other disorders may not uncommonly occur with increased uric acid and gout. Eighty-two per cent of patients with pure or combined hypertriglyceridaemia have increased uric acid levels, and conversely 74% of patients with gout have raised lipoproteins (TG, VLDL [8,9] and Lp(a) [10]); it may be associated with combined hypertriglyceridaemia (types IIb, and IV hyperlipidaemia) and with insulin-resistance (hyperinsulinaemia and glucose intolerance). Although associated with coronary heart disease, the role of uric acid is controversial [9]. Hypertension, obesity, diabetes mellitus and ethanol consumption in susceptible persons may also be associated with gout [11].

Histopathology. Sodium urate crystals may be found in joint fluid. The crystals can be identified by microscopic examination and by their ability to polarize light strongly. In the dermis and medulla of the kidney, the urate crystals provoke a giant cell reaction [11,12].

Clinical features [1,3,4,6]. Hyperuricaemia appears at about the age of puberty in males and later in females, often after the menopause. Patients remain asymptomatic until the fourth to sixth decades when the first attack of acute gouty arthritis occurs. Recurrent, self-limiting attacks usually follow after a period of about 6 months to 2 years. Initially single joints, and classically the great toe, are involved, but later the condition may become polyarticular and then usually involves the joints of the lower extremities. Later in the disease, a chronic tophus state develops with deposits in cartilage, synovial membranes, tendons and soft tissues. The classical localization for tophi is in the helix and antihelix of the ear, and on the index fingers (Fig. 57.44). Criteria for clinical diagnosis of acute gout have been reported [3,13].

Acute uric acid nephropathy results from precipitation of uric acid crystals in the collecting ducts of the kidney and is most commonly seen in patients with leukaemia

undergoing aggressive chemotherapy. Renal stones develop in up to one-quarter of patients [12] and renal colic may be a presenting manifestation of gout. Chronic urate nephropathy is a common manifestation [6,14] and contributes significantly to the morbidity and mortality of gout [14]. Uric acid has been suggested as a risk factor for CAD [15].

Differential diagnosis. Pseudogout [2,16] (calcium pyrophosphate deposition disease) shows close similarities to gout (particularly the acute attacks), familial incidence and later chronic arthropathy, pseudotophi and precipitation by surgical operations and diuretic therapy. The serum uric acid is normal, calcium pyrophosphate is found in synovial fluid and X-rays show articular calcification [2].

Multicentric reticulohistiocytosis frequently shows papules and nodules on the ears and fingers with an associated arthropathy.

Rheumatoid arthritis with necrobiotic nodules is usually sufficiently characteristic to avoid confusion with gout. Psoriatic arthropathy may cause diagnostic difficulties.

Treatment [1,3,14,17,18]. All patients with gout or a raised uric acid level should be investigated for its cause. Acute attacks are treated by rest of the affected joint and with regular anti-inflammatory treatment, such as indometacin. Colchicine (0.5 mg 6-hourly until symptoms subside, or maximum oral dose of 6 mg has been reached) may also be useful in acute episodes. Side effects of diarrhoea, renal and hepatic damage need to be carefully monitored. It is a matter of clinical judgement whether to treat asymptomatic gout with anything other than antiuricaemic therapy.

Antiuricaemic therapy using allopurinol, a xanthine oxidase inhibitor, is effective after the acute event and in prophylaxis. Drugs such as probenecid and sulfinpyrazone may be used to increase uric acid excretion, but are usually less effective prophylaxis. The newer, non-steroidal anti-inflammatory agents may be used. Treatment must be tailored to the needs of individual patients [7,19].

Lesch–Nyhan syndrome (MIM #300322) [1–6]

[C.A. Seymour, pp. 57.86–57.87]

This syndrome is probably determined by a sex-linked recessive gene. The underlying metabolic defect is a complete lack of the purine salvage enzyme HGPRT resulting from mutations in the gene. HGPRT is coded for by a single gene on the X chromosome (Xq26–q27), and is expressed in all tissues. Eighty-five per cent of mutations are point mutations or small deletions rather than major gene changes. This enzyme catalyses the salvage of hypoxanthine and guanine to inosine monophosphate (IMP) and guanosine monophosphate (GMP). It is characterized by choreoathetosis, spasticity, mental retardation and self-mutilation, particularly biting of the lower lip in childhood. Patients are normal at birth, but by 6 months developmental abnormalities are apparent. Choreiform movements occur within the first year. There may also be a macrocytic/megaloblastic anaemia. Increased levels of HGPRT causing neurotransmitter imbalance are found in the basal ganglia, but their relevance to the clinical disease is uncertain. HGPRT-deficient mice do not show abnormal neurological behaviour. The origin of the neurological abnormality in humans is still unknown but is likely to be due to accumulation of purine metabolites rather than deficiency of purine nucleotides, which in some way interfere with brainstem neurotransmitter function. Secondary changes in terminal arborization of dopaminergic neurones have been suggested because of reduced concentrations of dopamine homovanillic acid, dopa and tyrosine decarboxylase in dopaminergic neurones in the putamen. Blood uric acid levels are high and, although there are no reports of gouty arthritis, renal function is impaired by deposit of urates. Patients with partial

deficiency of HGPRT may develop gouty arthritis and/or uric acid calculi without the neurological and behavioural features.

Prenatal diagnosis. HGPRT analysis can be carried out on amniocyte or chorionic villus samples in the ninth week of pregnancy. Affected male heterozygotes can be identified by HGPRT assay on red cell lysates. Carrier females can be identified by $HGRPT^+$ and $HGRPT^-$ mosaicism in hair roots; mosaicism can also be identified in cultured fibroblasts [7].

Treatment. Allopurinol, in appropriate dosage, can reduce plasma urate and urinary uric acid to reduce occurence of gouty arthritis, urate nephropathy and renal calculi. There is no effective treatment of the neurological features. However, padded wheelchairs and physical restraints may reduce spinal injury and self-mutilation. Dental extraction may also assist in preventing the latter [5,7].

Nutrition and the skin

[K. Weismann, pp. 57.87–57.106]

Lack of essential nutrients is most commonly due to insufficient intake of food, malabsorption (see below), vomiting or decreased passage time of food due to diarrhoea or fistulae. Some medications may interfere with utilization of nutrients. An increased metabolic requirement of nutrients may occur during periods of sudden weight gain, such as growth and convalescence. This may lead to relative deficiencies, as seen in patients receiving long-term parenteral nutrition who may become deficient in zinc or selenium.

In most cases, the cutaneous changes of inadequate nutrition are varied, reflecting combined deficiencies. Hence, when there is an apparently isolated deficiency, an underlying genetic or enzymatic defect should be suspected.

Table 57.12 Various causes of malabsorption.

Chelating substances in the gut
Phytates
Insufficient digestive enzyme activity
Pancreatic diseases (pancreatitis, mucoviscidosis)
Defective micelle formation
Obstructive jaundice, liver cirrhosis
Contaminated small bowel syndrome (i.e. presence of an abnormal bacterial flora in the small bowel)
Gastric resection (lack of hydrochloric acid production)
Stagnant loop syndrome (strictures, surgical blind loops, scleroderma, diabetic enteropathy)
Colonic reflux (intestinal fistula, extensive small bowel resection)
Agammaglobulinaemia
Defective enzyme activity or carrier function in the intestinal mucosa
Disaccharidase deficiency
Coeliac disease
Acrodermatitis enteropathica (zinc deficiency)
Hartnup disease (pellagra)
Loss of absorption capacity
Intestinal resection and bypass operation
Crohn's disease
Pernicious anaemia
Interference with intestinal lymphatics
Lymphangiectasis
Tuberculous mesenteric adenitis
Hodgkin's disease
Inadequate transport mechanisms in the blood
Abetalipoproteinaemia
Miscellaneous
Polyarteritis nodosa
Lupus erythematosus
Amyloidosis
Mastocytosis
Diabetes mellitus
Zollinger–Ellison syndrome
Protein-losing enteropathy
Hyperthyroidism
Hypothyroidism
Cronkhite–Canada syndrome
Dermatogenic enteropathy

Malabsorption

Malabsorption is a condition characterized by a decreased intestinal uptake of nutrients associated with an increased faecal excretion of fat (steatorrhoea). This may lead to various degrees of lack of proteins, minerals, trace elements, fat-soluble vitamins, carbohydrates and water. Some causes of malabsorption are listed in Table 57.12.

Non-specific cutaneous symptoms [1,2]. Non-specific symptoms may be observed in patients who have lost weight due to malabsorption or malignant disease. The skin changes reflect general illness rather than specific disease.

Itching and acquired ichthyosis. Itch is mostly caused by dry skin. Elderly patients are especially prone to developing dry skin, which easily becomes eczematized. Patients with cancer, chronic liver and kidney diseases and

lymphoma may develop an itchy atrophic ichthyosis [3]. Hypoferraemia may cause itch, which disappears after initiation of iron therapy. Serum ferritin is a sensitive indicator of the state [4].

Melanosis. Malnutrition due to malabsorption may cause symmetrical melanin hyperpigmentation of the skin, although melanocyte-stimulating hormone (MSH) levels are seldom increased. Other skin colour changes associated with malnutrition are those due to wasting and atrophy, and pallor due to anaemia.

Skin appendages. Brittle nails and hair loss are frequent findings in poorly nourished patients. In some cases, lack of zinc, iron and vitamins is the main cause. In the majority of patients the aetiology is probably multifactorial.

Specific cutaneous effects [1]. Vitamin deficiencies occur due to malabsorption. Lack of fat-soluble vitamins, in particular, may cause skin changes including follicular hyperkeratosis (lack of vitamin A), ecchymoses and haematuria (lack of vitamin K), and cheilitis, glossitis, neuritis and dermatitis (lack of vitamin B complex). Zinc deficiency-related skin changes may be seen.

Investigations. Patients presenting with skin changes suggestive of malabsorption should have a thorough medical examination and laboratory tests to determine both the causes and the consequences of malabsorption. Relevant tests include serum calcium, zinc, folate and albumin levels, faecal fat excretion and X-ray examination of the small intestine.

Treatment. The cause of malabsorption should be treated where possible, and dietary measures instituted to ensure adequate supply of all essential nutrients from a wide variety of foods [2].

Specific syndromes with malabsorption

Cronkhite–Canada syndrome [1]

See Chapter 59.

Whipple's disease

This is a rare disease of uncertain aetiology involving the gastrointestinal tract, skin, joints, heart and lymph nodes (Chapter 59). There is diffuse hyperpigmentation of the skin, and leg nodules or erythema nodosum may occur. The involvement of the heart includes inflammatory changes of the pericardium, myocardium and endocardium and may lead to valvular insufficiency [2].

Dermatitis herpetiformis (Chapter 41)

Enteropathy is present in at least two-thirds of all patients and may respond to a gluten-free diet. Patients may be managed on a gluten-free diet alone, and it at least enables most patients to reduce their requirement for dapsone [3].

Mucoviscidosis

SYN. FIBROCYSTIC DISEASE; CYSTIC FIBROSIS OF THE PANCREAS

Mucoviscidosis is an inherited disorder characterized by three major components: chronic lung disease, exocrine pancreatic insufficiency and an abnormally high sodium concentration of the sweat.

Aetiology. The mode of genetic transmission is autosomal recessive. The basic metabolic defect is unknown. The mucous secretion has an increased viscosity resulting in obstruction of the small bronchial branches, the excretory ducts of the pancreas and the bile ducts of the liver. This eventually leads to respiratory disease, pancreatic insufficiency and hepatic failure. The high sodium concentration in sweat is due to a lowered reabsorption of sodium in the sweat glands [1] (Chapter 45).

Histopathology. The exocrine sweat glands and pancreas show electron-dense bodies, and there are fewer than normal secretory vacuoles in the 'dark cells' of the sweat coils [2].

Clinical features. The main presenting features are chronic pulmonary disease, exocrine pancreatic insufficiency with malabsorption, retarded growth and hepatic disease. Skin changes in the form of acrodermatitis enteropathica-like lesions due to essential fatty acid and zinc deficiency have been seen [3,4]. Several studies have indicated that atopy is more common in patients with cystic fibrosis than in the general population [5], although the

prevalence of urticaria is not increased [6]. A purpuric rash may occur in patients with cystic fibrosis (Chapter 49).

Diagnosis. The diagnosis is established by finding of high sodium concentration in the sweat, absence of pancreatic enzymes in the duodenum, chronic respiratory disease, retarded growth and a family history of the disease.

Treatment. Respiratory infection is controlled by prolonged antibiotic therapy according to bacterial cultures. Pancreatic insufficiency is treated by pancreatic enzyme preparations orally and a diet low in fat. The liver disease and the sweat abnormality are not amenable to treatment at present.

Vitamins [1]

Vitamins are biologically active organic compounds, which are indispensable for the normal functions of the body. They have no direct function as an energy source or as structural tissue components, but in most cases act as coenzymes in various enzyme systems.

REFERENCE

1 Miller S. Nutritional deficiency and the skin. *J Am Acad Dermatol* 1989; **21**: 1–30.

Vitamin A

Vitamin A (retinol) is a cyclic polyene alcohol present in yellow and green vegetables, egg yolk, butter, liver and fish oils [1]. β-Carotene occurs in fruits, carrots and green vegetables, and is absorbed and converted to vitamin A in the body. The recommended daily allowance is 5000 i.u. (equivalent to 6000–12 000 i.u. β-carotene). The plasma level in normal adults is about 600 ng/mL [2]. Vitamin A is mobilized from liver stores and transported in plasma, in which it is bound to retinol-binding protein [3].

Vitamin A is essential for the reproductive system, bone formation, vision and epithelial tissues [4]. *In vitro* studies on human keratinocytes have shown that vitamin A affects their growth and differentiation [5]. In human volunteers, 150 000 i.u. daily of vitamin A produced demonstrable retardation of keratinocyte maturation [6]. Skin disorders with abnormal keratinization, such as ichthyosis, pityriasis rubra pilaris and Darier's disease, have been treated with high doses of oral vitamin A. There is a risk of intoxication by such treatment and stereoisomers of retinoic acid are now used instead [1,7].

Vitamin A deficiency

Vitamin A deficiency is seldom seen in the Western world today. It is observed mainly in diseases causing malabsorption and is often associated with deficiency of other fat-soluble vitamins.

Clinical features. Classical manifestations of vitamin A deficiency include xerophthalmia, follicular hyperkeratosis and generalized xerosis [8]. Follicular papules are seen especially on the dorsal and lateral areas of the extremities, so-called phrynoderma. Histologically, there is lamellated hyperkeratosis around the hair follicles with keratinous plugs and atrophy of the sebaceous glands [9]. Diagnosis is confirmed by the finding of a low vitamin A level in blood and a positive response to vitamin A supplementation.

Zinc deficiency may lead to vitamin A deficiency as zinc acts on the retinol-binding protein, which is the transport protein for vitamin A and which is indispensable for mobilization of the vitamin from the liver. Furthermore, zinc acts on the oxidation–reduction interconversion of vitamin A (alcohol dehydrogenase is a zinc metalloenzyme). Lack of zinc may provoke symptoms of vitamin A deficiency [10], for example night blindness in alcoholics may be due to a combined lack of vitamin A and zinc [11].

Vitamin A intoxication

Aetiology. Chronic hypervitaminosis A may be observed in young children if they are persistently overdosed with strong vitamin preparations. Most reported adult cases have ingested more than 100 000 i.u. daily for several months. There is probably a risk of toxic effects if more than 50 000 i.u. daily are ingested for long periods [1].

Clinical features. There is lethargy, anorexia, weight loss and diffuse alopecia. The skin becomes pruritic, rough and dry with desquamation. The lips are dry and cracked. Follicular keratosis, patchy erythema and purpura may occur in hypervitaminosis A or due to administration of synthetic retinoids [2]. In young children, painful swellings of the limbs due to bone changes are conspicuous.

Diagnosis. Vitamin A intoxication is diagnosed by consistent clinical findings associated with an increased vitamin

A level in the blood. Radiology may demonstrate bone changes in young children and in some adults.

Treatment. No treatment is needed except immediate discontinuation of the vitamin A.

Carotenoderma

β-Carotene is the natural provitamin of vitamin A (retinol). A high intake of food containing carotene, especially carrots, causes carotenaemia (increased carotene in plasma) and may induce carotenoderma due to excess carotenes in the sweat. The condition is characterized by orange discoloration of the stratum corneum, especially on palms, soles and in areas where sebaceous glands predominate. The condition is quite harmless and subsides gradually when the dietary habits are regulated. It may occur in pregnancy as a 'pica'.

Carotenaemia is also seen in patients with hyperlipidaemia (diabetes mellitus, myxoedema) and occurs in subjects unable to convert ingested β-carotene into vitamin A [12].

β-Carotene traps free radicals and has been studied together with vitamin E and selenium as a possible dietary factor that may inhibit cancers [13], although this hypothesis remains unproven [14].

Vitamin D [1,2]

Vitamin D is a group of antirachitic steroid derivatives with similar biochemical activity. It is synthesized in the body as vitamin D_3 (cholecalciferol), and is present in the diet from some animal sources (as vitamin D_3) or from plant sources as vitamin D_2 (ergocalciferol). There is little vitamin D_3 in the diet although it is present in cod-liver oil, butter, eggs and liver. Vitamin D is synthesized in the skin from 7-dehydrocholesterol, which is present in abundance, by the action of 290–320-nm UV irradiation (to previtamin D) followed by a temperature-dependent conversion stage. Vitamin D_2 is synthesized from its inactive provitamin, ergosterol, in plants, also by the action of UV irradiation. With adequate exposure to sunlight, dietary vitamin D is unnecessary [1]. Cholecalciferol is hydroxylated in the liver to form hydroxycholecalciferol, and further hydroxylation takes place in the kidney to form the biologically active 1,25-dihydroxycholecalciferol [1,2]. Vitamin D_2 follows the same hydroxylation pathway, and is equipotent to vitamin D_3. 1α-Hydroxyvitamin D_3 is a synthetic, highly potent vitamin D analogue used in the management of hypoparathyroidism, vitamin-D-resistant rickets and osteomalacia.

Vitamin D regulates calcium and phosphorus absorption and deposition, and influences the level of serum alkaline phosphatase. The skin is of unique importance in the synthesis, storage and release of vitamin D into the circulation [2]. Lack of vitamin D in children results in tetany and rickets (rachitis), and osteomalacia in adults. Elderly people produce less vitamin D_3. In children, limited exposure to sunshine may play an aetiological role; the same applies to some Asian women in the UK in whom there may be a combination of dietary deficiency and little sunlight exposure. Regular use of sunscreens may also lead to inadequate synthesis of vitamin D_3 [3]. It is remarkable how exposure to sunlight a few times a week can reduce the risk of osteoporosis, osteomalacia, muscle weakness and fractures [1]. The daily need for calciferol is about 400 i.u.

Vitamin D intoxication (long-continued administration of more than 100 000 i.u. daily) causes anorexia, vomiting, headache, diarrhoea, hypercalcaemia and hypercalciuria with osteoporosis, resembling the action of parathyroid hormone. Treatment consists of withdrawal of vitamin D, a low-calcium diet and systemic corticosteroids.

Vitamin E [1,2]

SYN. α-TOCOPHEROL

Tocopherols are present in oils of vegetables, seeds, corn,

whole wheat flour, nuts and some meats; D-α-tocopherol is the most biologically active form. The main physiological activity of tocopherol is antioxidation. Whether the vitamin is essential to humans is still a matter of debate. In rats, guinea pigs and rabbits, a true vitamin effect has been demonstrated. Various dermatological diseases and conditions have been claimed to respond to vitamin E [1–3]. So far, no true benefit has been definitely documented. Fat-soluble vitamin E is located in the stratum corneum and seems to play a role in protecting this layer from damage [2]. An inhibitory effect on hyaluronidase and a protective effect on cellular membranes and on vitamin A oxidation have been suggested, but the clinical relevance is doubtful. Neurological function in children with chronic cholestasis was improved following large doses of vitamin E [4]. Large doses of vitamin E in a controlled trial have been shown to reduce the risk of myocardial infarction [5]. Vitamin E has also been used in dermatology to reduce dapsone-induced haemolysis [6] and headache [7].

Vitamin B complex

The vitamins of the B complex are of great clinical significance. Isolated deficiencies of certain B vitamins are uncommon. Mostly combined deficiencies of the vitamins belonging to the group are involved, often occurring as a result of insufficient supply of protein and other essential nutrients (zinc, essential fatty acids).

The group includes:

1 aneurin (thiamine) (vitamin B_1);
2 riboflavine (vitamin B_2);
3 niacin (nicotinic acid) (B_3);
4 pyridoxine (vitamin B_6);
5 cyanocobalamin (vitamin B_{12});
6 folic acid;
7 pantothenic acid;
8 biotin (vitamin H).

Aneurin

SYN. VITAMIN B_1; THIAMINE

Aneurin is present in yeast, cereals, liver, meat, eggs and vegetables. It functions as cocarboxylase in carbohydrate metabolism and numerous other enzyme systems. It is involved in growth processes and in the function of the nervous system. Deficiency results in accumulation of pyruvic and lactic acids. Dietary deficiency may be a consequence of consuming polished rice as the staple food or, more commonly, of insufficient nutrition associated with chronic alcoholism (although beer drinkers have a reduced risk of developing B vitamin deficiency due to the presence of the vitamins in beer). Additionally, hypovitaminosis B_1 may be associated with pregnancy, lactation, diabetes mellitus, ulcerative colitis, coeliac disease, achlorhydria or myxoedema [1].

Clinical features [1]. The classical form of vitamin B_1 deficiency is beriberi, characterized by anorexia, weakness, constipation, symmetrical progressive polyneuritis, cardiac insufficiency with oedema and wasting of musculature. The diagnosis is based on the history and a low urinary aneurin excretion following an injection of 1.0 mg of aneurin. Excretion of less than 50 µg indicates a deficiency state.

Treatment. Aneurin 2–3 mg is given three times daily in mild cases. With severe cardiac and gastrointestinal involvement, or severe polyneuritis and muscular paresis, 20 mg twice a day given parenterally is indicated.

Riboflavine

SYN. VITAMIN B_2, LACTOFLAVINE

Riboflavine is a D-ribitol isoalloxazine derivative which is widely distributed in plant and animal tissues. It plays a part in intracellular redox reactions. Nutritional sources are milk and the same sources as those of vitamin B_1 [1]. The human requirement is 1–2 mg daily.

Clinical features. Deficiency becomes clinically manifest after several months of deprivation due to chronic illness and malnutrition, especially in elderly women who suffer from achlorhydria, or in malnourished children with malabsorption.

Ariboflavinosis may occur in alcoholic liver cirrhosis, and an association with other deficiencies, such as pellagra, is frequent. Clinically, there is photophobia due to conjunctivitis, sometimes with corneal vascularization, angular stomatitis (perlèche) and sore lips, tongue and mouth [1]. The tongue is purplish red and smooth. A scaly seborrhoeic dermatitis-like eruption may be seen around the nose, eyes, ears and genital area (oro–oculo–genital syndrome). An association with zinc deficiency is to be

expected, as the content of the two nutrients in foodstuffs is correlated [2].

Treatment. Treatment consists of 5–15 mg riboflavine two to three times daily for 2 weeks and correction of dietary errors.

Pyridoxine

SYN. VITAMIN B_6, PYRIDOXAL

Pyridoxine is a pyridine derivative, participating as a coenzyme in transaminase and decarboxylase reactions and in the metabolism of cystein, tryptophan and essential fatty acids. It is present in many foods including yeast, eggs and various grains. The recommended daily allowance is about 2 mg.

Although much is known about experimental deficiency in many species, the manifestations in humans are not well defined. Convulsions, anaemia and acrodynia may develop in infants [3]. Dermatitis has occurred and is attributed to disturbed metabolism of unsaturated fatty acids. Pyridoxine deficiency may follow therapy with isoniazid, hydralazine and penicillamine [4].

Vitamin B_{12}

SYN. CYANOCOBALAMIN; CYCOBEMINE

Vitamin B_{12} is involved in nucleic acid synthesis and erythrocyte production. Deficiency may occur in vegetarians, as plants do not contain the vitamin. More frequently it is due to lack of 'intrinsic factor' in pernicious anaemia. Hyperpigmentation, especially in dark-skinned races, may occur (Chapter 39). It is most pronounced in skin flexures, such as finger and palm creases, and on the knuckles. Pigmented streaks of the nails may be seen. An enlarged, red tongue is a characteristic finding [5].

Folic acid

Folic acid is a compound consisting of pteridine, *p*-aminobenzoic acid and glutamic acid. It is present in liver, meat, green leaves and milk. In the organism, folic acid is converted to folinic acid, which is the biologically active form. The conversion requires the presence of vitamin C. Folinic acid is needed for the transport of one-carbon units and therefore plays a role in growth and erythrocyte production. The daily requirement is estimated to be about 0.4 mg.

Although no consistent or specific cutaneous changes are related to folate deficiency, greyish brown pigmentation on light-exposed parts has been described [5,6]. Cheilitis, glossitis and mucosal erosions are common. Pigmentation similar to that of vitamin B_{12} deficiency has been associated with folate deficiency in pregnancy and lactation. Spotty pigmentation of palms and soles and pigmented palmar creases have been described. Folate deficiency is estimated by serum and erythrocyte folate levels. Subclinical deficiency may be present in patients with extensive skin disease.

Niacin

SYN. NICOTINIC ACID; VITAMIN B_3

Niacin is an essential component of two coenzymes, coenzyme I (nicotinamide adenine dinucleotide, NAD) and coenzyme II (NAD phosphate, NADP), which either donate or accept hydrogen in a wide range of biochemical reactions. Tryptophan, an essential amino acid, can be transformed to niacin, which is converted to the amide in the body. Niacin is involved in the biosynthesis of ceramides as well as of other stratum corneum lipids which improve the epidermal permeability layer [7].

Pellagra [8]. Cellular deficiency of niacin, resulting from an inadequate dietary supply of niacin and tryptophan, is termed pellagra. In Western Europe and North America pellagra is only rarely encountered now, mostly in subjects living on an unbalanced diet, such as chronic alcoholics, and in patients with gastrointestinal diseases or severe psychiatric disturbances. Rare causes are functioning carcinoid tumours (Chapter 44) and Hartnup disease (p. 57.84). Therapy with isoniazid (which competes biochemically with niacin owing to a close structural resemblance), 6-mercaptopurine or 5-fluorouracil may provoke pellagra [8,9].

The classical triad of clinical features (Fig. 57.45) is *dermatitis*, *diarrhoea* and *dementia*, not invariably appearing in this order. Redness and superficial scaling appear on areas exposed to sunlight, heat, friction or pressure (Fig. 57.46). The changes resemble sunburn and subside leaving a dusky, brown-red coloration, but this occurs more slowly than typical in sunburn [2] and exacerbation follows re-exposure to sunlight. On the face, a symmetrical 'butterfly' eruption is frequently observed and there is often a characteristic well-marginated eruption on the front of the neck ('Casal's necklace'). Asymmetrical lesions may appear at sites of old injury or stasis [10]. Gastrointestinal symptoms include pain, diarrhoea and achlorhydria in 50% of cases. In mild instances, the mental disturbance may pass unnoticed, patients perhaps being slightly depressed or apathetic. Sometimes, there may be frank disorientation, restlessness or other severe central nervous system symptoms [11]. Peripheral neuritis and myelitis are occasionally encountered.

Histological examination shows hyper- and parakeratosis, acanthosis and multiple melanin granules throughout the epidermis. Such changes are suggestive, but not diagnostic, of pellagra.

Drug eruptions, various forms of porphyria, photodermatitis, lupus erythematosus and actinic reticuloid may

Fig. 57.45 Pellagra. Erythema, scaling and hypermelanosis of the neck (Casal's necklace). (Courtesy of Dr J. Jörgensen, Copenhagen, Denmark.)

Fig. 57.46 Pellagra on the lower legs. (Courtesy of the Department of Dermatology, Gentofte Hospital, Hellerup, Denmark.)

cause diagnostic difficulty. The so-called pellagrous vulvitis, vaginitis and scrotal dermatitis may be attributed to accompanying ariboflavinosis and other deficiencies of the vitamin B group and of zinc.

In severe cases, intravenous niacin is required in doses of 50–100 mg once or twice a day. Otherwise, divided doses of oral niacin amide in a total dose of 0.5 g/day should be given. The amide is to be preferred, as it does not precipitate flushing, itching and burning as is seen following ingestion of niacin in large doses. Improvement can be expected within a day or two.

Kava dermopathy. Kava, a psychoactive intoxicating beverage used ceremonially and socially by Pacific Islanders [12], may produce a pellagra-like ichthyosiform dermopathy with widespread acquired ichthyosis [13]. Kava is produced by infusing dried roots of *Piper methysticum* with water or coconut milk. The cause of the skin disease has not been established; interference with tryptophan or niacin as previously suggested [13] is not likely. Interference with cholesterol metabolism akin to changes associated with lipid-lowering agents is a possibility. Kava dermopathy is curable with abstinence.

Biotin

SYN. VITAMIN H

Biotin is a water-soluble, sulphur-containing, heterocyclic carboxylic acid involved in bacterial metabolism and possibly functioning as a coenzyme in decarboxylation and other enzymatic processes. Deficiency can be induced by feeding raw egg-white containing avidin; this binds biotin and makes it poorly absorbable [14]. Short bowel syndrome in association with parenteral nutrition may cause biotin deficiency [15]. Symptoms include alopecia, conjunctivitis, eczema around the nose and mouth, hyperaesthesia, paraesthesia, depression and muscle pain. A multivitamin preparation supplying 60 µg of biotin daily cured an adult patient within 3 weeks [16]. Biotin seems to possess some antiseborrhoeic actions and has been used in high doses for therapy of Leiner's disease in infants (Chapter 14) [17].

Inborn errors of biotin metabolism [18]. The genetically determined disorders of biotin metabolism consist of two separate diseases: holocarboxylase synthetase deficiency and biotinidase deficiency. Both are transmitted as an autosomal recessive trait. Patients with holocarboxylase

deficiency present in the neonatal period with severe symptoms of organic acidaemia. The patients may have shown recurrent episodes of vomiting from birth and rapid respiration as a sign of severe metabolic acidosis. There are seizures, hypo- as well as hypertonia, electroencephalogram abnormalities, and the disease progresses to death unless diagnosis and effective therapy supervene. An erythematous, scaly rash is prominent over most of the body in the patients who survive the first days of life. The skin lesions may resemble ichthyosis and seborrhoeic dermatitis. The pattern of excretion of organic acids is characteristic, especially 3-hydroxyisovaleric acid and 3-methylcrotonylglycine in urine being increased. Lactic acidaemia is striking. The molecular defect is in the enzyme holocarboxylase synthetase.

Biotinidase deficiency. Biotinidase deficiency usually presents after 3 months of age. The cutaneous lesions may resemble those of acrodermatitis enteropathica, i.e. severe zinc deficiency. The hair is sparse, and there may be total alopecia. Neurological symptoms are prominent with myoclonic seizures and ataxia as common features. There are low levels of biotin in blood and urine. The fundamental defect is in biotinidase, which normally acts on biocytin, a biotin–lysine complex, thereby separating biotin from lysine [18].

Biotin treatment. Both of the biotin-related disorders discussed above are treated with an oral dose of biotin, usually 10 mg/day but some patients need less and some have required as much as 40 mg/day.

It has been reported that *uncombable hair syndrome* (Chapter 63) responded to oral biotin 0.3 mg three times a day [19].

Vitamin C [1,2]

SYN. ASCORBIC ACID

Vitamin C is a relatively strong organic acid, chemically related to the carbohydrates. Only the laevo form is biologically active. Ascorbic acid is a strong reducing agent, easily oxidized to dehydroascorbic acid, with which it constitutes a reversible redox system. Vitamin C plays a central role in collagen and ground-substance formation [3], metabolism of aromatic amino acids (phenylalanine, tyrosine), reduction of folic acid to folinic acid and a broad range of biochemical redox reactions, including the preservation of sulphur-containing enzymes in a reduced form. It occurs naturally in cabbage, potatoes, green vegetables and fruits. The recommended daily dose is 30–80 mg; a daily intake of 10 mg prevents scurvy.

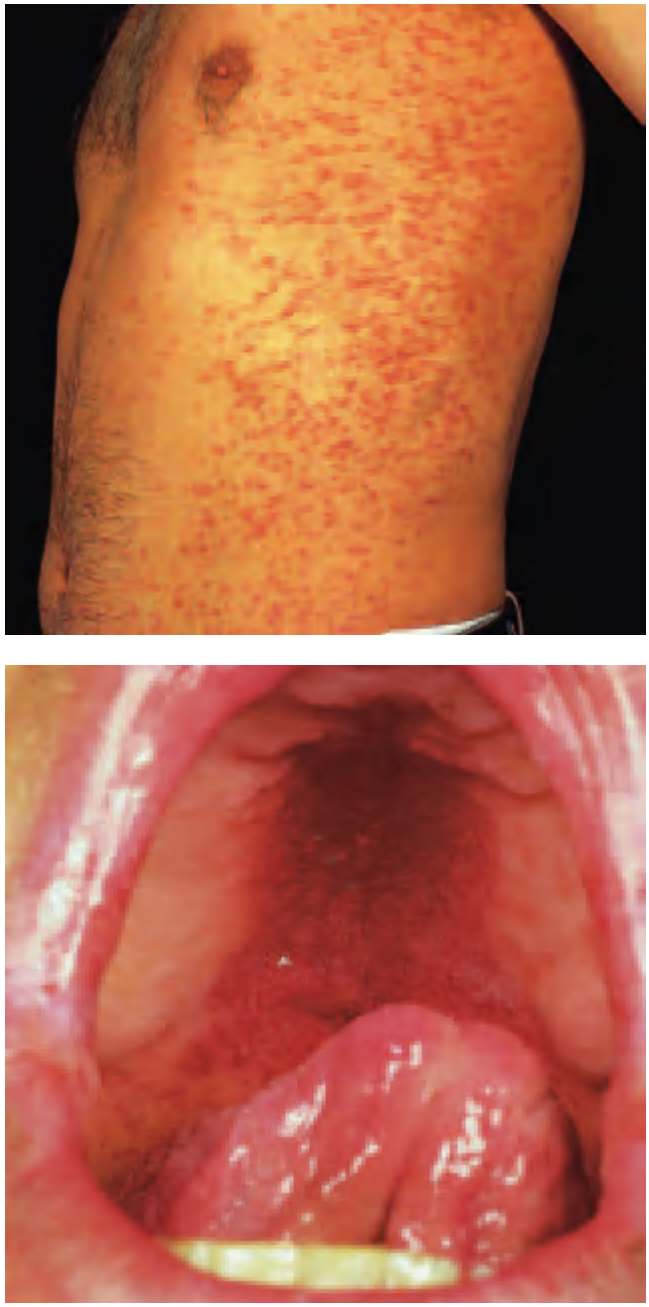
Vitamin C deficiency

SYN. SCURVY; SCORBUTUS; HYPOVITAMINOSIS C

Unlike most other animals, humans and guinea pigs are unable to synthesize ascorbic acid due to lack of the enzymatic pathways for synthesis of L-ascorbic acid from D-glucuronic acid.

In the deficiency state, collagen and ground-substance synthesis are depressed, which leads to a multiplicity of symptoms involving bones, mucous membranes and skin.

Aetiology. Lack of vitamin C is still a serious problem in many parts of the world where access to fruit and vegetables is limited and where general malnutrition prevails. By contrast, most cases in developed countries are a consequence of food faddism, ignorance or alcoholism [4,5]. Danish beer no longer contains vitamin C as an antioxidant, and can therefore no longer prevent scurvy in alcoholics [6]. Malnourished children with scurvy (Barlow's disease) may still be a paediatric problem as reported from Australia [7] and vitamin C deficiency has been observed in teenagers living on processed food devoid of fresh fruit and vegetables [8]. In patients with chronic gas-



(a)

(b)

Fig. 57.47 Scurvy. (a) Purpuric rash on the trunk and lower extremities; (b) purpura on the hard palate.

trointestinal disturbances, subclinical scurvy may be present [9]. Elderly men living alone, who rarely get fresh fruit or vegetables and who may abuse alcohol, are particularly at risk [10].

Clinical feature [4]. (Fig. 57.47). The initial skin change is follicular keratosis with coiled hairs on the upper arms, back, buttocks and lower extremities. Later, perifollicular haemorrhage with blood pigment discoloration especially on the legs, swollen bleeding gums, stomatitis and epistaxis occur. Large skin haemorrhages may be seen. Anaemia is usually present, and the patient appears resentful and mentally depressed. In the infant, dental development is impaired and oral changes may be severe. Tender subperiostal haematomas may develop and dominate the picture. Chronic hypovitaminosis C with 'woody' oedema and discoloration of the legs as the presenting feature has been described [11]. Subnormal serum levels of vitamin C are present (normal range about 17–94 μmol/L). The significance of low values without clinical symptoms is doubtful [7].

Treatment. The scorbutic patient should be treated with oral vitamin C 100 mg three times daily in addition to protein-rich food [4]. The response is dramatic. It is advisable to continue the therapy for several weeks to ensure repletion of the emptied body stores.

Kwashiorkor and marasmus [1,2]

Kwashiorkor is a nutritional syndrome with characteristic cutaneous changes due to severe protein malnutrition with relative carbohydrate excess. In children, there is retardation of skeletal and mental development, muscular wasting, fatty infiltration of the liver and oedema. Marasmus is the result of prolonged starvation, a wasting syndrome, resulting in 40–50% reduction in body weight but with no peripheral oedema.

Kwashiorkor

Aetiology [2]. Protein–energy deficiency is one of the commonest and most widespread nutritional disorders in developing countries. The majority of kwashiorkor cases are found in countries where the diet consists of corn, rice or beans. Kwashiorkor is more common in children than in adults and is a major paediatric problem in certain parts of the world. The onset in infancy is during the weaning and postweaning period. In Europe and North America,

Table 57.13 Some features distinguishing kwashiorkor from pellagra.

Kwashiorkor	Pellagra
Children more than adults	Adults more than children
Dermatitis with systemic signs of apathy and oedema	Dermatitis precedes gastrointestinal and neuropsychiatric symptoms in most cases
Eruption generalized; pale, ill-defined; 'crackled skin'	Exposed areas only; red, thickened, well-defined; later, dry, branny scales
Hair light, 'pepper and salt' appearance, thin	Normal
Nails sometimes soft and thin	Normal
High mortality if untreated	Low mortality

occasional cases are seen in patients suffering from malabsorption or eating a diet that includes an inadequate amount of protein. Milder forms are probably not uncommon, particularly in the elderly.

Kwashiorkor refers to the 'deposed child' who is no longer suckled. It is a multiple deficiency syndrome. The cause is related to lack of essential amino acids, vitamins and trace elements, particularly zinc. The skin manifestations, hair changes and failure to thrive may mimic those seen in acrodermatitis enteropathica. Serum zinc is low, but this may be attributable partly to hypoalbuminaemia. Hospitalized children may show persistent hypozincaemia after clinical cure has occurred, indicating a need for zinc supplementation together with vitamins and protein-rich nutrition [3,4].

Clinical features [1,2,5]. The symptoms of kwashiorkor usually first develop between the age of 6 months and 5 years. The most important feature in the child is a failure to thrive, with inhibition of growth and mental development; oedema and muscle wasting are also found.

The skin lesions are initially erythematous and later purple or reddish brown in colour with marked exfoliation. In milder cases a lacquered 'flaky paint' ('enamel paint') or 'cracked skin' appearance is present. The hair is dry and lustreless and may become light red-brown in colour. In more severe cases it may be prematurely grey or show a 'pepper and salt' appearance, and become sparse, fine and brittle.

The skin often shows dyschromia with hypopigmentation, perhaps the result of phenylalanine deficiency, and patchy post-inflammatory hyperpigmentation. In severe cases pigmentary changes are particularly striking. Mucosal lesions, such as cheilosis, xerophthalmia and vulvovaginitis, are found.

Mental disturbances are variable and may appear either as apathy or irritability. The child does not smile; when it does, it is a sign of recovery.

Oedema is the result of hypoalbuminaemia (less than 2.5 g/100 mL). The α- and β-globulins are low, while an increase in gammaglobulin is usual.

Hypoglycaemia with hypothermia, coma and severe bacterial or parasitic disease are rare, but often fatal, complications [6].

Mild cases of kwashiorkor appearing in the elderly show as a 'cracked skin' appearance on the front of the legs and lower abdomen. They have been reported under the title of geriatric nutritional eczema.

Prognosis. The short-term prognosis of mild cases which are given full dietary treatment is good, but mortality is high in severe and relapsing cases.

Diagnosis. Diagnostic difficulties occur in mild cases. The dietary history, 'cracked skin' and oedema, particularly when associated with pigmentary changes, should lead to the suspicion of protein deficiency. Acrodermatitis enteropathica may be mistaken for kwashiorkor.

The features distinguishing kwashiorkor from pellagra are shown in Table 57.13.

Prevention and treatment. Prevention of kwashiorkor depends on increasing the supply of animal proteins, and on education and social welfare in poor areas.

In an established case, a complete and balanced diet should be given as soon as possible. Skimmed milk is the most useful treatment, presumably through its amino-acid content. Appropriate measures should be taken to correct any electrolyte disturbance.

Marasmus [1]

Aetiology. Marasmus is derived from the Greek *marasmos*, which means wasting. It is a result of severe protein and calorie deprivation for a prolonged period. Worldwide, marasmus is more frequent than kwashiorkor and is especially seen in developing countries where food is absent or scarce. Severely ill, hospitalized patients may show signs of marasmus. Low zinc levels are a predominant feature.

Clinical features. Patients have a wrinkled, loose, dry skin. There is a substantial loss of subcutaneous fat tissue, and the facial expression is described as 'monkey facies' due to loss of the buccal adipose tissue. Follicular hyperkeratosis may be prominent in adults. The hair is thin and sparse and readily lost and the nails are fissured. Skin ulceration occurs.

Diagnosis. The combined finding of a severely reduced body weight, loss of subcutaneous fat, poor hair and nail growth and a loose, wrinkled, dry skin that appears too large is diagnostic. There is no peripheral oedema.

Prevention and treatment. This is as for kwashiorkor. Skin ulceration may respond to topical zinc paste or oral zinc supplementation in addition to a protein-rich nutritional supply.

Calcification and ossification of the skin [1–3]

Calcification or calcinosis cutis is the result of deposition of calcium and phosphate in organic matrices of the tissues. The process occurs in a wide range of different conditions. The mineral phase may be arranged in the manner seen in normal bone formation, *ossification*. If the deposition is not organized, the condition is termed *calcification*. The organic matrix consists largely of collagen or elastic tissue. All organic matrices of calcified or ossified tissues contain protein-bound phosphorus. In pathological ectopic calcification, the matrix is altered and contains acid proteins. In pseudoxanthoma elasticum, γ-carboxyglutamic acid, an amino acid present in calcium-binding proteins, has been found in high concentrations in the dermis. The solid phase of calcified tissue is made up of hydroxyapatite and amorphous calcium phosphate. Once formed, the focus increases in size by growth and may result in disorganized masses of pasta-like material.

Aberrant calcium deposition in the skin may be divided into three main groups:

- associated with localized or widespread tissue changes or damage (dystrophic calcification);
- unassociated with tissue damage or demonstrable metabolic disorder (idiopathic calcification);
- associated with an abnormal calcium and phosphorus metabolism (metastatic calcification) (Table 57.14).

Table 57.14 Various forms of calcinosis cutis.

Dystrophic calcification
Calcification usually associated with localized injury
Congenital
Fibrodysplasia ossificans
Traumatic
Foreign-body, haematoma, fat cell necrosis
Inflammatory
Acne, varicose veins, tuberculous granuloma, postoperative inflammation in scars
Degenerative infarcts (arterial, venous), venous stasis, parasitic cysts (e.g. echinococcal cysts)
Neoplastic
Benign: sebaceous cysts, lipomas, angiomas, calcifying epithelioma of Malherbe
Malignant: some liposarcomas
Calcification associated with widespread tissue injury
Dermatomyositis
Generalized scleroderma (Thibierge–Weissenbach or CREST syndrome)
Systemic lupus erythematosus
Acrodermatitis atrophicans
Pseudoxanthoma elasticum
Ehlers–Danlos syndrome
Idiopathic calcification
Calcinosis universalis; calcinosis circumscripta
Solitary nodular calcification of the skin ('cutaneous calculus')
Pinnal calcification
Tumoral calcinosis
Metastatic calcification
Hypercalcaemic
Hyperparathyroidism
Sarcoidosis
Vitamin D excess
Milk–alkali syndrome
Destructive bone disease
Metastatic carcinoma, lymphoma, multiple myeloma, leukaemia
Paget's disease
Normocalcaemic
Chronic renal failure
Pseudohypoparathyroidism

Dystrophic calcification [4]

The calcinosis is confined to the dermis or subcutaneous tissue and related to local connective tissue or fatty tissue damage, in the absence of any detectable abnormality of calcium metabolism. The calcification appears a variable time after the injury; for example, in dermatomyositis it occurs after a few years and in generalized scleroderma usually after 10 or more years. Dystrophic calcification may also occur in systemic lupus erythematosus [5,6].

Electrical injuries may be particularly likely to result in dystrophic calcification. An accumulation of calcium salts on dermal collagen fibres of pig skin was observed in scars following electrical injury [7]. Deposition of calcium salts in high concentration on a damaged skin surface may induce dermal calcification, as observed following electroencephalography in children [8]. In these cases, the skin was abraded prior to application of an electrode paste containing calcium chloride; lesions developed shortly after electroencephalography and disappeared in 2–6

months without therapy. An intact stratum corneum is protective.

Idiopathic calcification

Calcinosis universalis

The deposition of calcium in the dermis, subcutis and muscles is unrelated to any recognizable tissue injury or metabolic disorder. Many cases reported in the literature under the diagnosis were probably suffering from undetected dermatomyositis, systemic lupus erythematosus or scleroderma, but there remain a number of instances in which no underlying disease is demonstrable [2].

Histopathology. Initially, calcium particles gather around fat cells. Electron microscopy of early lesions has shown apatite crystals lying parallel to the collagen fibres [9].

Clinical features. Nodules or plaques 0.5–5.0 cm in size are symmetrically distributed over the extremities and, less commonly, the trunk. The lesions may become tender and ulcerate, discharging chalk-like creamy material consisting mainly of calcium phosphate with a small amount of calcium carbonate. After ulceration, a slowly healing sinus remains. Fingertip lesions are often painful, while in other sites there may be limitation of movement due to stiffening of the skin. The disease is eventually fatal.

X-ray examination is valuable for localizing the deeper deposits. Biochemical investigations are normal.

Treatment. Surgical removal of painful deposits may give temporary relief. In some instances, corticosteroids may be considered, although the response is variable. Cellulose phosphate combined with a low-calcium diet should be considered as therapy [10].

Calcinosis circumscripta

There may be only a few calcium deposits in the skin. Most cases of calcinosis circumscripta are found in generalized scleroderma or dermatomyositis but rarely it may occur as an idiopathic disorder [3]. Keloid formation with calcification has been described [11].

Idiopathic calcinosis of the scrotum [11,12]

Calcinosis scrotalis (Fig. 57.48) is a rare benign disorder consisting of multiple asymtomatic firm nodules 0.2–1.0 cm in diameter. It is often misdiagnosed as scrotal cysts. Dystrophic calcification in the penis has been reported following trauma, Peyronie's disease and cytostatic therapy.

(a)

(b)

Fig. 57.48 (a) Calcinosis scrotalis. (b) Shows solitary nodules after removal.

Calcifying epithelioma of Malberbe

This is described in Chapter 37.

Tumoral calcinosis [2,13,14]

Tumoral calcinosis occurs most commonly in the native population of Africa, particularly among younger age groups. Clinically, the lesions present as swellings around the large joints (hip, elbow, ankle and scapula), but there is no actual involvement of the joint. Extrusion of calcified material, which has been likened to a suspension of procaine–penicillin, may take place. Histologically, there is initially collagen necrobiosis, which results in cyst formation and a foreign-body response. The calcification is first granular; later, dense deposits are seen [13]. The aetiology is unknown, but it is probably a form of dystrophic calcification caused by mechanical injury.

Pinnal calcification [2]

Calcified ear cartilage has been observed in several conditions such as Addison's disease, ochronosis, acromegaly,

diabetes mellitus, hyperthyroidism, systemic chondromalacia (von Meyenburg's disease), familial cold hypersensitivity and frostbite.

Metastatic calcification [3,15]

In metastatic calcification, calcinosis occurs as a precipitation of calcium salts in normal skin, subcutaneous tissue, muscles and internal organs.

Aetiology. In all cases, there is an increase in the serum levels of calcium or phosphate. Hypercalcaemia may be due to hyperparathyroidism, vitamin D intoxication, milk–alkali syndrome or destructive bone disease with excessive osteoclastic activity. Metastatic carcinoma, multiple myeloma, leukaemia and Paget's disease of bone may all be associated with metastatic calcification. Calciphylaxis (Chapters 49 and 59) is a potentially fatal syndrome due to a raised serum calcium phosphate product, which is the result of chronic renal insufficiency in patients undergoing long-term renal dialysis, in whom there has been development of secondary or tertiary hyperparathyroidism [16].

Clinical features. The cutaneous manifestations are similar to those of calcinosis universalis. Additional clinical features reflect the primary disease.

Treatment. Only in hypervitaminosis D and the milk–alkali syndrome can improvement be expected by regulation of dietary habits and withdrawal of vitamin D and milk intake. In cases of renal insufficiency, restriction of dietary phosphate and oral administration of an aluminium hydroxide gel may be useful.

Ossification of the skin

SYN. OSTEOMATOSIS; OSTEOMA CUTIS

Osteomatosis represents cutaneous calcification with *de novo* bone formation in the skin [17]. It has been noted in suprapubic prostatectomy scars and in otherwise normal postoperative scars [18]. It may also occur in collagen vascular disease (lupus erythematosus, scleroderma and dermatomyositis) [19]. Cutaneous ossification without any known causative factor (also known as osteomatosis cutis, primary osteoma cutis or osteosis cutis) has been reported [17].

Post-acne osteoma cutis

This is a rare complication of long-standing acne vulgaris. It has been reported to occur as pigmented osteomas during tetracycline or minocycline therapy. The osteomas that represent metaplastic bone formation are located in mid or reticular dermis and consist of concentric lamellae with lacunae, Haversian canals and marrow cavities. With the use of tetracycline, more patients develop bluish, 1–2-mm, moveable papules on the face. Treatment consists of surgery or local 0.5% tretinoin cream with resultant transepidermal elimination of the lesions [20].

Iron metabolism [1]

The total iron content of an adult man is 4–5 g, 60–70% of which is blood haemoglobin iron. Small amounts of ferritin iron are present in erythrocytes, plasma and leukocytes [1]. Iron is stored in the liver, spleen and bone marrow as ferritin and haemosiderin. It is released readily from these sites according to the body's needs. Serum ferritin levels vary with the iron status of the individual and with certain diseases. The body has a limited ability

to excrete iron, and homeostasis is therefore regulated mainly by adjusting iron absorption. Iron compounds need to be reduced to the ferrous form (Fe^{2+}) to be absorbed. Ascorbic acid, which can reduce and chelate iron, enhances iron absorption.

The mechanism of iron absorption is not completely understood. Recent evidence points to an iron-transport system involving the binding of iron to the plasma membrane of mucosal cells and the interaction of transferrin in plasma with these sites.

Total iron in faeces varies between 6 and 16 mg/day depending on the amount ingested. Most of it is unabsorbed food iron.

Iron deficiency

General symptoms include fatigue, palpitations on exertion, sore tongue with atrophic filiform papillae, angular cheilitis (perlèche), dysphagia and koilonychia (Chapter 62). Generalized itch may be present [2] and hair loss with or without morphological changes of the hair shaft [3,4]. In infants and children, anorexia, retarded growth and decreased resistance to infections are the outstanding features. The recommended daily allowance is 10 mg in infants, 10–15 mg in children, 18 mg in young males and females, and 10 mg in both sexes above 20 years of age [5]. Pregnant women should receive supplemental iron, as the increased need for iron can barely be met by ordinary diets [6].

The diagnosis of iron deficiency is based on low serum iron levels, clinical symptoms and improvement following iron therapy. Serum ferritin is significantly correlated to bone marrow haemosiderin iron and provides a convenient method for assessing marrow iron stores in normal subjects [7].

Iron intoxication

Daily ingestion of 50–75 mg iron has been reported as safe [1], and even higher intakes in some individuals turn out to be harmless. Chronic iron intoxication has been reported among Bantus consuming beer that is brewed in iron utensils. The iron is in a soluble form and may supply a substantial net supply of iron. Iron-contaminated cereals do not induce siderosis because iron is present in a less available form.

Haemochromatosis [1,8]

Haemochromatosis is a syndrome characterized by the triad of hyperpigmentation, diabetes mellitus and cirrhosis of the liver, associated with increased iron deposition in the internal organs. Hypogonadism is frequently present. The female/male ratio is 1 : 10. Onset of symptoms is gradual, usually between 40 and 60 years.

Aetiology. Haemochromatosis can be found in the following conditions: idiopathic or primary haemochromatosis; chronic iron intoxication (e.g. Bantu haemochromatosis); chronic liver disease and iron overload (alcoholic haemochromatosis); hepatic haemosiderosis in anaemic patients with an ineffective erythropoiesis; and congenital transferrin deficiency. The cause of primary haemochromatosis is basically unknown, but a defective control of iron absorption is involved. The abnormality is inherited as an autosomal recessive trait (Chapter 59). Erythrocyte ferritin is increased 60-fold in idiopathic haemochromatosis, which allows a distinction between this disorder and alcoholic liver disease with iron overload [9]. In alcoholic haemochromatosis, alcohol consumption, particularly red wine and iron-containing beverages, plays an aetiological role. Whether the acquired form is seen in patients heterozygous for the trait is not known.

Histopathology. Liver biopsy in primary haemochromatosis shows marked iron deposits in the parenchymal cells and to a lesser degree in the Kupffer's cells. The hyperpigmentation of the skin is due to increased epidermal melanin and upper dermal melanophages, but iron deposits can be identified in the deeper dermis.

Clinical features. The skin shows a distinctive grey-brown pigmentation, especially on the face, flexural creases and exposed parts. This may precede other signs by many years but can appear late in the course. Sometimes, the buccal mucosa is involved as in Addison's disease but adrenal insufficiency is not present. The various skin changes were studied in 100 patients [10]. There was almost 100% frequency of hyperpigmentation, 75% had hair loss (including axillary and pubic hair), about 50% had koilonychia and 45% had ichthyosis-like, atrophic dry skin. Less frequent signs included palmar erythema, striate onychia, leukonychia and spider angiomas (findings that may be seen in cirrhosis of any cause). Hepatomegaly, diabetes, testicular atrophy, heart disease and weight loss are additional findings. Arthropathy, present in 25–50% of the patients, resembles rheumatoid arthritis, but serology is negative.

Diagnosis. The diagnosis should be suspected in a patient with diabetes mellitus, liver cirrhosis and hyperpigmentation. Liver biopsy is usually diagnostic.

Routine laboratory tests may reveal evidence of chronic hepatic disease or of diabetes mellitus. Total serum iron is increased to the range 180–300 mg/100 mL [1], serum transferrin saturation is above 80% [10] and the transferrin level and the total iron binding capacity (TIBC) may be reduced [8]. Serum and erythrocyte ferritin is high, reflecting the increased iron stores [9]. HLA-typing has revealed an increased frequency of HLA-A3, and -B14 [11] but has largely been superseded by genotyping for the commoner haemochromatosis genes (Chapter 59).

Treatment. An iron liver concentration above 100 μmol/g weight is an indication for therapy [6]. Organ damage may be reversed by reducing the excessive iron stores by repeated venesection for 1–2 years. Serum iron and serum transferrin and transferrin saturation remain unchanged until excess iron has been removed. Serum or erythrocyte ferritin should be monitored as a guide to the efficacy of treatment. Family members should have their serum iron estimated and, if found to have iron overload, should be treated with prophylactic venesection.

Sulphur metabolism [1]

Sulphur is a vital element for the normal function of the human body. It is an essential component of the amino acids methionine and cysteine and of chondroitin sulphate, which are involved in keratinization and formation of dermal collagen, respectively. Dietary thionine and cysteine are the main precursors for the synthesis of sulphur-containing components in the body. In homocystinuria there is a metabolic block in the pathway; clinical features include tissue-paper scars on the hands and sparse, fair hair due to impaired keratin formation. When the supply of sulphur-containing amino acids is inadequate, less sulphur is available to nail and hair growth, but the keratin produced seems to be normal [2]. The liver plays a central role in degradation of sulphur-containing amino acids. In chronic liver disease, low urinary levels of inorganic sulphate are present [1].

In exfoliative psoriasis with increased epidermopoiesis, relative sulphur depletion is found and the urinary excretion of inorganic sulphate is decreased. Hair loss in chronic exfoliative dermatoses may be related to diversion of sulphur-containing amino acids to synthesis of skin protein instead of hair keratin formation [2]. Mucopolysaccharide synthesis in the dermis is influenced by certain hormonal factors. Thyrotrophin (thyroid-stimulating hormone, TSH) has a stimulant action on connective tissue and the pituitary somatrophic hormone (growth hormone, GH) stimulates chondroitin sulphate formation.

Trichothiodystrophy [3,4]

Trichothiodystrophy is a sulphur-deficient brittle hair syndrome associated with ectodermal dysplasias. The hair is short and brittle with a characteristic microscopy in polarized light showing alternating light and dark bands (Chapter 63) [4]. There is a 50% decrease or more in the cysteine and sulphur of hair. The disease is inherited as an autosomal recessive trait.

Zinc metabolism [1,2]

Zinc belongs to the group of essential trace elements that comprises zinc, iron, copper, manganese, nickel, cobalt, molybdenum, selenium, chromium, iodine, fluorine, tin, silicon, vanadium and arsenic [3]. High concentrations of zinc are present in shellfish, legumes, nuts, whole grain and green leafy vegetables, whereas fruits usually contain insignificant levels [4]. Wine, beer and spirits contain very low concentrations of zinc. The zinc supply depends largely on the protein content of the food, and protein undernourishment will lead to an insufficient zinc supply.

Recommended dietary allowance of zinc [5]. The daily oral intake of zinc should average 3 mg in infants less than 6 months, 5 mg in infants 0.5–1.0 years old, 10 mg in children 1–7 years old and 16 mg from 11 years old onwards. Pregnant and lactating women should receive 20–25 mg zinc daily.

Biological functions. Zinc is indispensable to the normal function of all cells, cellular systems, tissues and organs in the human body. The essentiality is related mainly to its function as the metal moiety of important enzymes, such as alkaline phosphatase, alcohol dehydrogenase and several different dehydrogenases, and digestive enzymes [6]. Zinc also regulates DNA and RNA polymerases,

thymidine kinase and ribonuclease, and plays an important role in immunological functions.

Zinc deficiency

Zinc deficiency may be caused by a specific absorptive defect, as occurs in acrodermatitis enteropathica, by insufficient dietary intake, or due to diseases of the gastrointestinal tract causing diarrhoea and malabsorption (conditioned or acquired zinc deficiency).

Acrodermatitis enteropathica

Acrodermatitis enteropathica was first recognized in 1936 by Thore Brandt [7] and further investigated by Danbolt and Closs [8]. It is a rare disease believed to be transmitted as an autosomal recessive trait. In Denmark, the prevalence is about 1/500 000 inhabitants. *Adema disease* in black-pied cattle of Dutch descent represents a true parallel of the human disease.

Aetiology. Zinc absorption in young patients with acrodermatitis enteropathica is low, about 2–3% compared with 27–65% in normal adults. The cause of the specific zinc malabsorption is not known but can be overcome by an oral zinc load. Without zinc therapy, serum zinc levels are consistently low [9].

Clinical features. The disease typically starts after weaning or earlier if the infant is not given breast milk. The child turns peevish, withdrawn and photophobic, and develops a vesicobullous dermatitis on hands, feet and periorificial areas. The scalp hair is lost. Diarrhoea is often present. Growth is stunted and there is a decreased resistance to infections. Wound healing is poor and skin lesions do not heal [10].

Prognosis. Without proper management, the prognosis is poor and in the past a lethal outcome within 4–5 years was the rule.

Treatment. Halogenated 8-hydroxyquinolines (e.g. diodoquin) were formerly used for therapy on an empirical basis. Experimental animal studies have shown that iodochlorohydroxyquinoline, a commonly used antibacterial agent, increases ^{65}Zn absorption [9,10]. Zinc sulphate for acrodermatitis enteropathica was introduced in 1973–74 [11–13]. Oral zinc in a dose of about 2 mg/kg/day was found to cure all clinical manifestations. Prolonged therapy at least up to adult age is necessary.

Endemic nutritional zinc deficiency

Endemic zinc deficiency presenting with dwarfism and hypogonadism as the main symptoms has been reported from rural districts in Iran, Egypt and Turkey. The chronic zinc deficiency is attributed to the diet, which consists mainly of unleavened whole grain bread with a high fibre and phytate content. Zinc deficiency has been described in severely malnourished children in Jamaica [4], Egypt and various parts of Africa.

Acquired zinc deficiency

Zinc depletion syndrome. Where there is disturbed bowel function, the zinc loss is increased; if combined with decreased absorption and low dietary zinc intake, zinc depletion will develop. Zinc depletion syndrome was originally identified in patients who received prolonged total parenteral nutrition [13,14], most of whom had undergone extensive intestinal resections. The serum zinc level is decreased, often below 20 µg/100 mL (normal range 70–125 µg/100 mg, equivalent to 10–19 µmol/L).

Zinc deficiency in breastfed infants. Premature infants receiving mother's milk are at risk of developing zinc deficiency due to an insufficient zinc content in the milk to ensure rapid growth [15]. Premature infants have an extra need for zinc and zinc absorption is less than in mature infants.

Diseases of liver and pancreas. Chronic zinc deficiency may develop in patients suffering from malabsorption–malnutrition associated with alcoholic liver cirrhosis and alcoholic pancreatitis [13]. A defective exocrine pancreatic function and elevated urinary zinc excretion associated with liver cirrhosis [16] add to a negative zinc balance (Chapter 59).

Cancer chemotherapy. Cancer chemotherapy for leukaemia in children may provoke zinc deficiency [17].

Zinc deficiency and skin changes [18]

Acute zinc deficiency. General symptoms include septicaemia, photophobia and mental depression. Skin changes consist of eczematous eruptions on hands, feet, in the anogenital regions and around the body orifices. The finger flexural creases and the palms show characteristic flat, greyish, bullous lesions surrounded by red-brown erythema (Fig. 57.49). Oozing lesions may be seen on the heels of bedridden patients. Some lesions are black and necrotic, and burn-like skin changes may be seen. There is angular stomatitis with perioral lesions sparing the vermilion border.

Chronic zinc deficiency. The patient is often listless and mentally depressed. Skin lesions are typically seen on areas subject to repeated pressure and trauma, such as elbows, knees, knuckles and malleolar regions of the

Fig. 57.49 Zinc depletion syndrome with flat bullae on flexural finger creases.

Fig. 57.50 Acrodermatitis enteropathica with chronic zinc deficiency symptoms. Typical periorificial chronic skin lesions with necrotic areas around the nose. The vermilion area is always spared. The hair growth is poor.

Fig. 57.51 Beau's lines on thumbnails in a case of zinc depletion syndrome treated with zinc sulphate.

ankles. The lesions are brownish (Fig. 57.50). Seborrhoeic dermatitis-like changes may be seen on the face and acne vulgaris may flare.

A non-itchy, scaly dermatitis on the trunk has been described in chronic zinc deficiency of alcoholics.

Hair and nail changes. In zinc deficiency, hair growth ceases, and diffuse thinning of the scalp hair becomes progressive and eventually leads to total alopecia after weeks. Structural changes of the hair may be observed, such as broken spearhead-like endings, transverse striation of the shaft, pseudomonilethrix, longitudinal splits and bayonet hairs. Severe zinc deficiency usually causes temporary arrest of nail growth, which is manifest as transverse depressions (Beau's lines) on the fingernails which become visible 3–4 weeks after the start of zinc supplementation as the normal nail growth recommences from the nail matrix (Fig. 57.51) [19].

Pathology. In the acute stage, light microscopy reveals spongiosis, sometimes with formation of suprabasal cysts and clefts (Fig. 57.52). The horny layer is often separated or lost, and necrosis of the outer epidermal cells may be seen. In chronic zinc deficiency, there are more or less psoriasis-like changes of the epidermis (Fig. 57.53).

Electron microscopy of acute lesions shows degenerate basal cells with slender cytoplasmic protrusions and an intact basal lamina with multiple invaginations.

Diagnosis. Severe zinc deficiency is usually suspected from the clinical findings. The serum zinc and alkaline phosphatase levels are low and rise during zinc therapy

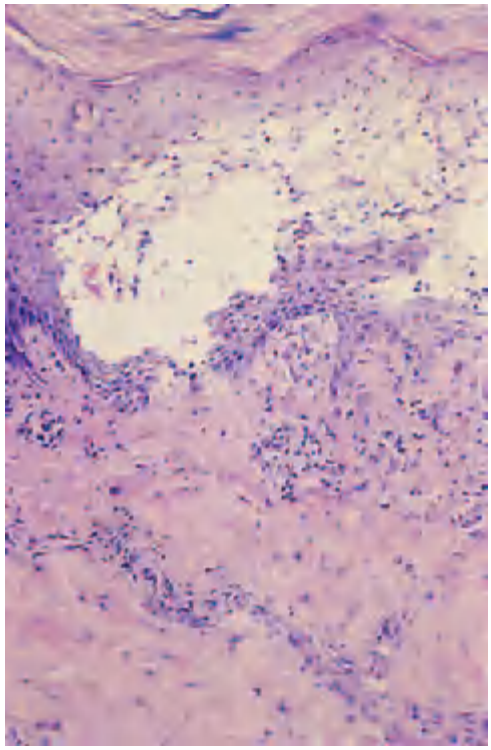

Fig. 57.52 Acute zinc deficiency with bullous dermatitis (same patient as in Fig. 57.49). Spongiosis, bulla and cleft formation is prominent. The basal cell layer is degenerate.

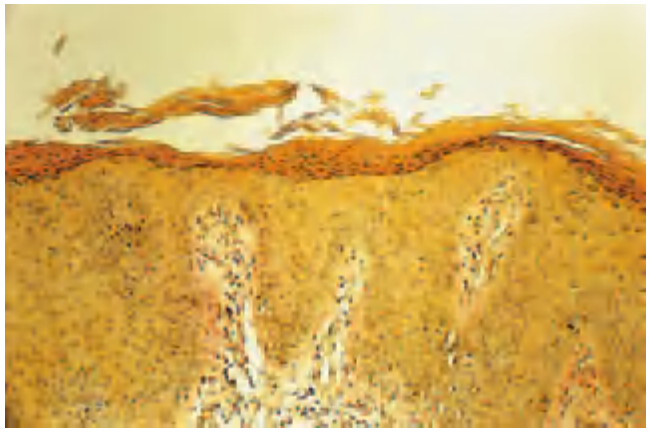

Fig. 57.53 Chronic zinc deficiency with parakeratosis, acanthosis and slight spongiosis.

[18]. It is important to consider the level of plasma albumin that binds 60–70% of circulating zinc. Hypoalbuminaemia is associated with lowered serum zinc values, which do not necessarily reflect a zinc deficiency.

In suspect cases, a therapeutic trial with oral or parenteral zinc should be undertaken. If no clinical improvement occurs within 4–5 days and the serum alkaline phosphatase remains unaltered, the patient is probably not zinc deficient.

Treatment with zinc. In adult patients, oral zinc sulphate ($Zn_2SO_4 \cdot 7H_2O$) tablets of 0.2 g are given two to three times a day (about 2 mg zinc/kg). Similar doses on a kilogram basis are given to children. Parenterally, 0.2–0.3 mg zinc/kg/day (about 10–20 mg/day in adult patients) is sufficient. For prophylactic purposes, total parenteral nutrition should supply no less than 70–80 µg zinc/kg/day. Infants and premature babies on parenteral nutrition should receive a prophylactic dose of 0.1–0.3 mg/kg/day [20].

There is no evidence of benefit from the general use of zinc sulphate in patients with chronic leg ulcers [21] or for the use of zinc to treat the common cold [22].

Copper metabolism

The normal adult body has been estimated to contain about 80 mg of total copper.

Copper in plasma occurs in two forms: about 90% is firmly bound as the blue copper protein coeruloplasmin, the remainder is loosely bound to plasma proteins, primarily albumin. Copper competes with the albumin-binding sites for zinc, so fluctuations in concentration of one of these metals are reflected by a change in concentration of the other. Coeruloplasmin is an oxidase involved in iron utilization. It does not play a role in copper transport to the tissue; this is done by albumin, which is the true transport protein. Copper is part of superoxide dismutase, catalysing superoxide anion radicals into hydrogen peroxide and oxygen.

Copper-induced green hair

Green hair is usually caused by deposition of copper from exogenous sources. Usually, the patient has blond or reddish hair that has been exposed to physical or chemical damage (sun damage or bleaching) whereby high-sulphur matrix proteins (mainly cysteine) are exposed, and are therefore available to bind copper ions. A high copper concentration may occur in swimming-pool water due to copper-containing algicides and in household tapwater due to copper piping [1,2]. A hair shampoo with an added copper chelating agent such as dimethylcystein (penicillamine) can remove the discoloration.

Copper deficiency

Copper deficiency has been reported to occur in infants receiving milk low in copper and in malnourished children given high-calorie nutrition with an insufficient copper supply. The symptoms include anaemia, neutropenia and failure to thrive.

Menkes' kinky hair syndrome. This is an X-linked defect in copper absorption, resulting in low copper levels in blood, liver and hair. There is progressive mental deterioration, metaphyseal lesions, degenerative aortic elastin and defective keratinization of hair (Chapter 63). There is no effective treatment [3].

Wilson's disease (hepatolenticular degeneration syndrome). This is a rare inborn error of copper metabolism, inherited as an autosomal recessive trait [4]. It is characterized by cirrhosis of the liver and degenerative changes in the brain, particularly the basal ganglia. Deposition of copper takes place primarily in the liver, brain, kidneys and cornea (Kayser–Fleischer ring). The patients have low coeruloplasmin and plasma copper levels.

Treatment consists of cupriuretic agents such as penicillamine or by inhibiting intestinal copper absorption by oral zinc sulphate [4].

Selenium metabolism [1]

Selenium is an essential element of the enzyme glutathione peroxidase. It plays a role against oxidative damage by endogenous peroxides. Selenium deficiency has long been known in several animal species. Selenium-deficient rats grow slowly, develop cataracts, lose their hair and show aspermogenesis. In humans, selenium deficiency has been reported in children, causing hypopigmented skin lesions and various other symptoms. Treatment consists of supplementation of selenium in low doses of 2 mg/kg/day [2]. Patients with psoriasis, atopic dermatitis, dermatitis herpetiformis and acne vulgaris have a lower glutathione peroxidase activity than normal controls [3]. The significance of this remains to be further studied. In a study on malignant melanoma, significantly lower serum selenium levels were demonstrated as compared with controls [4]. Serum selenium levels have been shown to be of a prognostic value in the follow-up of malignant melanoma and cutaneous T-cell lymphoma [5]. However, there is no apparent protective effect of selenium supplementation against the development of non-melanoma skin cancer [6,7].

Selenium is incorporated as the sulphide into shampoos for the treatment of seborrhoeic dermatitis. Selenium sulphide is water insoluble and possesses a very low toxicity. A possible protective role of selenium on cancer, cardiovascular diseases and rheumatic diseases has attracted much attention. There is no proven reason to recommend selenium supplementation.

Skin disorders in diabetes mellitus

[K. Weismann, pp. 57.106–57.109]

Diabetes mellitus [1,2]. Diabetes mellitus is a metabolic disorder characterized by elevated fasting and postprandial blood glucose levels and a variety of multisystem complications, mainly in the blood vessels, eye, kidney, nervous system and integument. Three main types can be distinguished. Type 1, also known as insulin-dependent diabetes mellitus or juvenile-onset diabetes, is characterized by abrupt onset of symptoms, insulinopenia, dependence on insulin injections, proneness to ketoacidosis and lack of ability to produce C peptide. Type 2, non-insulin-dependent diabetes mellitus or adult-onset diabetes, is characterized by lack of ketoacidosis except under stressful circumstances, ability to produce C peptide, a tendency to obesity and improvement following loss of weight. Type 3, secondary diabetes, is an additional type of diabetes, which occurs as a complication of pancreatic, hormonal or genetic disease or following ingestion of certain drugs or chemical compounds.

There are several reviews of skin disorders associated with diabetes mellitus [2–7].

Skin symptoms due to diabetic vascular abnormalities [3–5]

Diabetic microangiopathy. Both small and large blood vessels are affected in diabetes mellitus. In diabetic microangiopathy, there is proliferation of endothelial cells and deposits of PAS-positive material in the basement membrane of arterioles, capillaries and venules with resulting decreased luminal area [8]. Basement-membrane thickening is a characteristic finding in diabetic and prediabetic patients, but it is neither absolute nor pathognomonic for the disease [9]. The diabetic microangiopathy precedes manifest abnormalities of the disease, and it is possible that vascular changes are the primary expression of the disease. Microangiopathy is responsible for the retinopathy, nephropathy and possibly also neuropathy and dermopathy associated with diabetes.

Erysipelas-like erythema [9]. Well-demarcated, red areas occur on the legs or feet of elderly diabetics. Some of the patients have an underlying destructive bone disease caused by a small vessel insufficiency. It is seen mostly in elderly patients with an average duration of diabetes mellitus of 5 years. Cardiac decompensation may be involved.

Fig. 57.54 Diabetic dermopathy.

Wet gangrene of the foot. This is a late manifestation of diabetic microangiopathy. Non-diabetic atherosclerotics tend to develop a dry form as a result of large vessel insufficiency.

Diabetic rubeosis [10]. A peculiar rosy reddening of the face, and sometimes of the hands and feet, may be seen in long-standing diabetes. The changes have been attributed to decreased vascular tone or diabetic microangiopathy. Rubeosis may have some practical diagnostic significance, especially in fair-skinned patients.

Diabetic dermopathy (diabetic shin spots) (Fig. 57.54). This is the most common dermatosis associated with diabetes mellitus. Microangiopathy and possibly neuropathy are involved [11]. Lesions are predominantly situated on the shins, forearms, thighs and over bony prominences. About half of patients show such lesions, more frequently men than women. The initial lesion is an oval, dull-red papule 0.5–1 cm in diameter. It evolves slowly, producing a superficial scale, leaving an atrophic brownish scar. The colour is due to haemosiderin in histiocytes near the vessels [12]. Microscopically, a combination of vascular disease with PAS-positive thickening of the vessel wall and minor collagen changes is found. Although not confirmed in all studies, recent research suggests that there is a significant correlation between the presence of these lesions and other complications of diabetes, such as retinopathy, nephropathy and neuropathy [13].

Fig. 57.55 Diabetic foot with neurotrophic ulceration.

Large vessel disease [4]. Atherosclerosis is the second form of vascular disease frequently associated with diabetes mellitus. The patient shows intermittent claudication with pallid and cool skin distally on the extremities. The postural test discloses delayed filling of the veins. Common clinical sequelae are myocardial infarction, cerebral thrombosis, nephrosclerosis and ischaemic gangrenous lesions of the legs and feet. Microangiopathy is usually present together with large vessel involvement.

Diabetic neuropathy

Elderly patients with an insidious onset of the disease are especially at risk. Commonly, there is a distal symmetrical polyneuropathy with mixed motor and sensory nerve involvement. The motor neuropathy of the foot is characterized by dorsally subluxed digits, distally displaced plantar fat pads, depressed metatarsal heads, hammer toes and pes cavus [3]. Proper foot care is essential to prevent formation of indolent perforating ulcers ('mal perforans'). A painless and slowly penetrating ulcer of the sole and of other pressure sites is suggestive of diabetic neuropathy. The ulcer is circular and punched out in shape, occurring in the middle of a callosity (Fig. 57.55). An initial subepidermal haemorrhagic bulla may give rise to discoloration of the surrounding skin [4]. Loss of temperature and pain sensation and absence of the ankle reflex (an early sign of diabetic neuropathy) indicate a neuropathic origin. Sensory abnormalities of the lower extremities include numbness, tingling, aching and burning. Burning feet and restless legs are common complaints, which intensify at night while lying down. Autonomic neuropathy may cause decreased or absent sweating of the lower extremities with compensatory sweating in other skin areas. Damage to autonomic nerves of the skin in chronic advanced cases is manifested by oedema, erythema and atrophy [3].

The *diabetic foot* requires special attention. There is a multifactorial aetiology [6]. Peripheral neuropathy causes ulcers, loss of ankle jerks and vibration sensation. The foot has accentuated plantar arches and hammer toes, there is interdigital maceration leading to bacterial and fungal infection. Diabetic angiopathy leads to ulceration, which may be complicated by necrosis, gangrene and osteomyelitis [14].

Cutaneous infections in diabetes mellitus

Skin infections due to *Staphylococcus aureus* and group A *Streptococcus haemolyticus* are common in diabetic patients [15]. Before insulin and antibiotics were available, infections causing severe furuncles, carbuncles and styes were frequent among diabetic individuals. In malignant external otitis, invasive *Pseudomonas* infection can progress through cellulitis and osteitis to cranial nerve damage and meningitis with a high mortality rate, so-called malignant otitis externa (Chapter 65) [16].

Non-clostridial gas gangrene. This complication develops in the soft tissues near a gangrenous focus. It was diagnosed in 17% of diabetics who were admitted to hospital because of gangrene or ulceration [17]. The commonest pathogens are *Escherichia coli*, *Klebsiella*, *Pseudomonas* and *Bacteroides* spp. in various combinations. The outcome is generally good.

Candida albicans. Candida albicans infections of mouth, nail folds, genitals and intertriginous skin areas are frequent in diabetics. Candidiasis may be the presenting feature of diabetes, and is frequently seen in diabetic patients whose disease is not well controlled [3]. A high glucose level of the saliva seems to account for the oral infection [18]. Phimosis is a common complaint of diabetic men, and recurring candidal infection is usually the cause. Dermatophyte infections are not more frequent in diabetic than in non-diabetic individuals [19].

Insulin resistance and acanthosis nigricans [20–22]

Tissue resistance to insulin is a major feature underlying the development of acanthosis nigricans in many diseases (e.g. Cushing's syndrome, acromegaly, Laurence–Moon–Bardet–Biedel syndrome, Prader–Willi syndrome and congenital lipodystrophy). There are two syndromes of insulin resistance. The type A syndrome has been reported in hyperandrogenetic women with clinical signs of virilization or accelerated growth (the acronym HAIRAN has been proposed: HA, hyperandrogenism; IR, insulin resistance; AN, acanthosis nigricans). A genetic defect at the insulin receptor or in a post-receptor pathway has been postulated. The type B syndrome has been reported in older women with signs of immunological

dysfunction. High plasma levels of insulin are thought to contribute to the development of acanthosis nigricans.

Various skin disorders associated with diabetes mellitus [23]

Necrobiosis lipoidica (pp. 57.119–57.124) [2–7]. Necrobiosis lipoidica is frequently associated with diabetes mellitus. Frequencies of diabetes between 42% and 62% have been reported in patients with necrobiosis lipoidica, although necrobiosis lipoidica is uncommon (0.3%) among diabetic patients [3].

Disseminated granuloma annulare (pp. 57.109–57.119). This is rarely seen in diabetic patients; the evidence that granuloma annulare is associated with diabetes mellitus is inconclusive [24].

Diabetic bullae. Various forms of diabetic bullae have been described. They occur as spontaneous atraumatic lesions mostly on feet and hands. A typical blister arises on a non-inflamed base, measures from a few millimetres to 3–5 cm in size, and heals without scarring in 2–5 weeks. Histological examination shows intra- or subepidermal separation without acantholysis [5,25,26].

Pruritus. Pruritus was once considered a typical symptom of diabetes mellitus. The frequency of generalized pruritus in diabetic patients is unknown. Anogenital pruritus may be caused by candidiasis or haemolytic streptococci.

Stiff joints and waxy skin. Waxy tight skin on the backs of the hands and limited joint mobility may be seen in patients with insulin-dependent diabetes [5,6,27].

Scleredema of diabetes mellitus. Whether post-infectious scleredema and diabetic scleredema are identical diseases, with a more severe course in the diabetes-associated form due to altered host response, is still a matter of debate [23]. The condition is seen mainly in overweight adults with non-insulin-dependent diabetes, is essentially permanent, causes little morbidity, and there is no specific treatment although penicillin, methotrexate, ciclosporin, low-density lipoprotein apheresis and PUVA have all been used with benefit in scleredema adultorum.

Vitiligo (Chapter 39). Vitiligo occurs more frequently in diabetic individuals. In late-onset diabetes, a 4.5% frequency has been reported [28].

Lichen planus (Chapter 42). An increased incidence of abnormal glucose tolerance tests in patients with lichen planus, especially oral lichen planus, has been reported [29]. However, the overall support for a true association is limited [6].

Haemochromatosis (Chapter 59). The main symptoms are liver disease, hyperpigmentation, joint disease, hypogonadism and, eventually, diabetes.

Eruptive xanthomas of the skin. Eruptive xanthomas of the skin may develop in diabetic patients with hyperlipidaemia. The lesions slowly resolve when the diabetes is properly managed.

Finger pebbles. Among 60 patients with diabetes mellitus, 45 (75%) had a pebbly appearance of the knuckle and distal finger skin. Similar changes were observed in 21% of control subjects [30]. The changes may be of external origin (trauma) or internal (acanthosis nigricans).

Skin tags. Skin tags are small, soft, pedunculated lesions occurring on eyelids, neck and axillae. They are often associated with obesity. Among 216 patients with skin tags, 57 (26%) had diabetes of the non-insulin-dependent type, of whom only about one-quarter were classified as obese [31].

Local insulin reactions [6,32]. Insulin may cause immediate local reactions, starting as erythema, which turn urticarial within 30 min and subside within an hour; these are probably IgE mediated. Serious generalized immediate reactions are rare.

The most common reactions are delayed, starting about 2 weeks after onset of insulin therapy. An itchy nodule develops at the site of injection. It lasts for days and heals with hyperpigmentation and perhaps a scar. Delayed hypersensitivity is involved.

Insulin lipodystrophy. Insulin lipodystrophy is rare. Patients present with atrophic plaques at the sites of insulin injection. There is atrophy of the subcutaneous fat. The lesions seldom show complete spontaneous resolution. The mechanism is not known.

Reactive perforating collagenosis (folliculitis). There have been reports of perforating collagenosis in patients with diabetes with and without renal insufficiency. The cause is attributed to diabetic microangiopathy and injury by scratching [33].

Granuloma annulare

[D.A. Burns, pp. 57.109–57.119]

Introduction. Granuloma annulare was first described by Colcott Fox in 1895 [1], and established as a specific entity by Radcliffe Crocker in 1902 [2]. It is a disease in which, in typical cases, the skin and/or subcutis are involved in a process characterized by foci of alteration of collagen (necrobiosis) surrounded by histiocytes and lymphocytes. Clinical variants include localized, generalized, perforating and subcutaneous patterns [3,4].

Aetiology [1–3]. Although the aetiology and pathogenesis of granuloma annulare are unclear, it appears likely that it represents a reaction pattern to a variety of triggering factors. Reported triggering factors have included insect bites [4], a cat bite [5], waxing-induced pseudofolliculitis [6], tuberculin tests [7], bacille Calmette-Guérin (BCG) vaccination [8,9], hepatitis B vaccination [10], a possible relation to antitetanus vaccination [11], and occupational pressure on the fingers in a milkman [12]. In the past, its occurrence with tuberculosis was noted in a number of reports, and cases may still be encountered in which there appears to be an association between these two disorders [13]. Other infectious agents that have been implicated in the causation of lesions of granuloma annulare include human papilloma virus [14], varicella/zoster virus [15–20] (although persistence of viral DNA does not appear to be related to granuloma formation [18,21]), Epstein–Barr virus [22,23] (but Epstein–Barr virus could not be demonstrated in lesions occurring in HIV-positive patients [24]), parvovirus B19 [25], hepatitis C virus [26] and HIV [24,27–35]. Although there has been evidence implicating *Borrelia burgdorferi* in some cases [36,37], it was absent in others [38]. Examination of several biopsy specimens using polymerase chain reaction amplification did not reveal any evidence of *Bartonella* infection [39].

Seasonally recurrent granuloma annulare has been described [40,41], and sun exposure may have acted as a precipitating factor in one of these cases [41]. Sun exposure is thought to have provoked or contributed to localization of lesions in a number of cases [42–45]. Disseminated granuloma annulare has occurred in a patient undergoing PUVA therapy [46]. Whether actinic granuloma is a distinct entity, or represents granuloma annulare on sun-exposed skin has been discussed recently [47–49], and has been the subject of debate in the past [50–55].

A report of granuloma annulare occurring in the red areas of tattoos [56] prompted description of a similar case and the suggestion that both were examples of a perforating collagenosis [57].

There is a report of disseminated granuloma annulare occurring in the same sites as lesions of erythema multiforme minor [58].

Some cases of granuloma annulare-like lesions attributed to drugs may have been examples of drug-induced interstitial granulomatous reactions [59].

It has been suggested that an immunoglobulin-mediated vasculitis is the cause of the necrobiotic granulomas [2,60], but evidence from immunofluorescence studies is conflicting—some authors have demonstrated immunoreactants in vessel walls [60], whereas others have not [61,62]. An alternative view is that the pathogenetic mechanism is a delayed-type hypersensitivity response [2,62–66].

An increased prevalence of HLA-Bw35, compared with controls and those with localized lesions, has been demonstrated in individuals with generalized granuloma annulare [67].

The relationship between diabetes mellitus and granuloma annulare is discussed below, as are apparent associations with several other disorders.

Histopathology [1–5] (Figs 57.56 & 57.57). The most characteristic histological lesion in granuloma annulare is the necrobiotic granuloma, but there are three histological patterns that may occur: necrobiotic palisading granulomas, an interstitial form, and granulomas of sarcoidal or tuberculoid type [1]. Umbert and Winkelmann [3] found that the commonest histological pattern was the interstitial type, as did Friedmann-Birnbaum *et al*. [4]. The latter authors compared the histopathological features of localized and generalized granuloma annulare, and noted that the interstitial pattern was more frequent in localized than in generalized disease; the prevalence of the palisading granuloma pattern was almost equal in both clinical types. Dabski and Winkelmann [5] also found that the interstitial pattern was common in both these types of granuloma annulare, and in many cases it occurred alone, without palisading granulomas. However, they noted a prominent palisading pattern more frequently in localized disease than in the generalized variety. Observer variation and the existence of more than one pattern in the same section may have contributed to differences in the findings in these series.

Necrobiotic granulomas are characterized by foci of necrobiosis surrounded by histiocytes and lymphocytes,

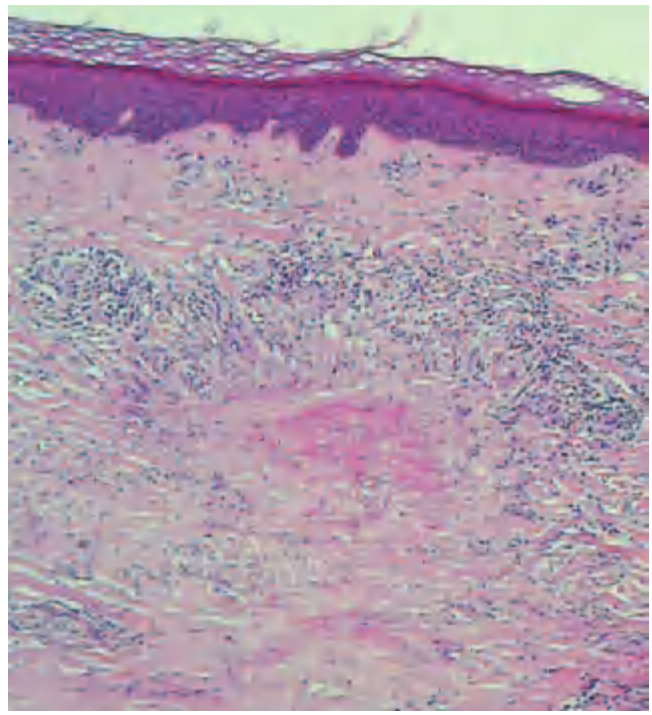

Fig. 57.56 Granuloma annulare. Nodule in upper dermis. H&E stain. (Courtesy of Dr M. Bamford, Department of Pathology, Leicester Royal Infirmary, Leicester, UK.)

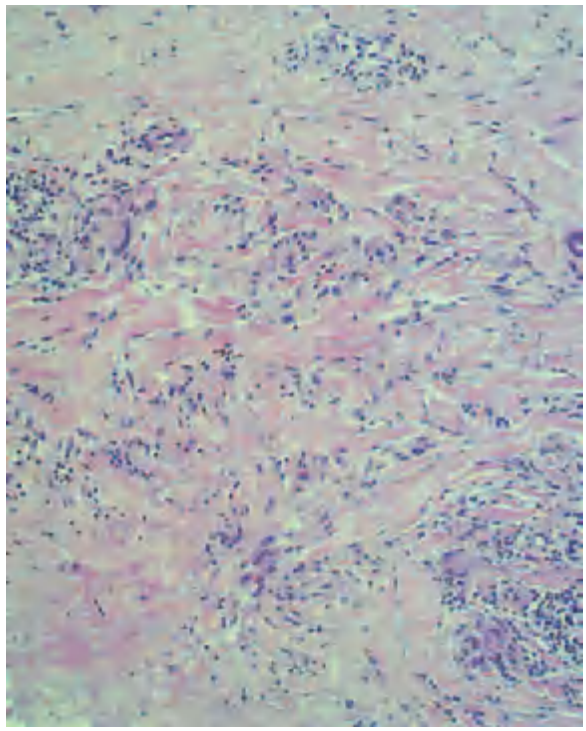

Fig. 57.57 Granuloma annulare. Nodule—well circumscribed with good palisade of histiocytes and central necrobiosis. H&E stain. (Courtesy of Dr M. Bamford, Department of Pathology, Leicester Royal Infirmary, Leicester, UK.)

with the histiocytes commonly forming a palisaded pattern. There are varying numbers of multinucleate giant cells in this peripheral zone. T cells in the lymphocytic infiltrate are of the helper/inducer phenotype ($CD4^+$) [6–8], but in two cases associated with HIV infection a predominantly T-suppressor ($CD8^+$) infiltrate was demonstrated [9,10]. Analysis of the T-cell repertoire and cytokine pattern has shown a T-cell response characterized by a combination of a few skin-specific clones together with many non-specific T cells, and abundant production of interleukin-2 (IL-2) [8]. The high local production of IL-2 could be responsible for the non-specific attraction of T cells to the granulomas.

Mucin is present within the foci of necrobiosis, and can be seen more readily by staining with alcian blue or colloidal iron. Small deposits of lipid material may also be present in these areas. Some form of collagen alteration, most commonly fragmentation of collagen bundles, was observed in 79% of cases of localized and 53% of cases of generalized granuloma annulare by Dabski and Winkelmann [5]. There is a marked reduction in, or absence of, elastic fibres [11,12]. Metalloproteinases are probably involved in the damage to collagen and elastic fibres [13,14].

The granulomas are situated in the superficial and middermis and, in contrast with necrobiosis lipoidica, areas between them are relatively normal.

In the interstitial pattern there are no formed areas of necrobiosis, histiocytes and lymphocytes are present around blood vessels and between collagen bundles, and collagen fibres are separated by mucin.

The sarcoidal or tuberculoid pattern is uncommon, and may cause problems in diagnosis. The presence of mucin and eosinophils can help to distinguish granuloma annulare from sarcoidosis.

There is a perivascular infiltrate of lymphocytes and histiocytes. Eosinophils are variably present [15]. In one study [16], the presence of eosinophils was strongly associated with a palisaded architectural pattern and the presence of necrobiosis. Plasma cells are rare. A vasculitis has been described in or near foci of necrobiosis [17].

Histiocytes express the marker PG-M1 [18]. They may show an increased mitotic rate, recognition of which is important, in particular in differentiating granuloma annulare from epithelioid sarcoma [19–22].

Epidermal changes are inconspicuous except in perforating granuloma annulare. In this variant there is a superficial area of necrobiosis surrounded by palisading histiocytes, situated beneath a perforation in the epidermis [1,2,23]. The necrobiotic material is extruded via the perforation. At the margins of the perforation there are varying degrees of epidermal hyperplasia.

The lesions of subcutaneous granuloma annulare often contain large areas of necrobiosis, and they are similar to rheumatoid nodules both clinically and histologically. Patterson [24] found that alcian blue staining of mucin in lesions of granuloma annulare was the most helpful distinguishing feature.

Other disorders with similar histological features include granulomatous mycosis fungoides [25–27], interstitial granulomatous dermatitis (interstitial granulomatous dermatitis with arthritis; interstitial granulomatous dermatitis with plaques; palisaded neutrophilic granulomatous dermatitis) [28–34] and the interstitial granulomatous drug reaction [35,36].

Clinical features [1,2]. Granuloma annulare can occur at almost any age—in one series the youngest patient was 1 year old and the oldest was 76 years old [3]—but the majority of affected individuals are under 30 years of age [3]. It is twice as common in women as in men. There are a few reports of familial cases [3–8]. Clinical variants include localized, generalized, perforating and subcutaneous.

Localized granuloma annulare is the commonest form, and typically presents as a ring of small, smooth, flesh-coloured or erythematous papules (Fig. 57.58). Stretching the skin enables the papules to be seen more readily. The surface of the skin over the papules is intact and there is usually no scaling. Annular lesions tend to enlarge centrifugally. They may be solitary or multiple, and may occur anywhere on the skin, although the dorsa of the hands (Figs 57.59 & 57.60) and feet, and the fingers (Fig. 57.61) are the commonest sites. Lesions are usually symptomless, although some may be tender to touch.

The other patterns of granuloma annulare may occur alone or in association with the annular lesions. In the generalized or disseminated pattern, there are numerous skin-coloured or erythematous papules, which may have an annular configuration or consist of myriad symmetrically distributed, often coalescing lesions, on the trunk and limbs [9–11] (Fig. 57.62). The area enclosed by annular papules is often violaceous in colour. Pruritus may be a prominent complaint in generalized lesions [11]. Although generalized granuloma annulare may occur in children, the mean age at onset is later than in the localized variety, and in the series of Dabski and Winkelmann [11] it was 51.7 years. The exact incidence of the generalized pattern is unknown, but 8.9% of all patients with

granuloma annulare seen at the Mayo clinic had a generalized or disseminated pattern [11]. As in the localized form, twice as many females are affected as males. Although in immunocompetent individuals localized disease is more

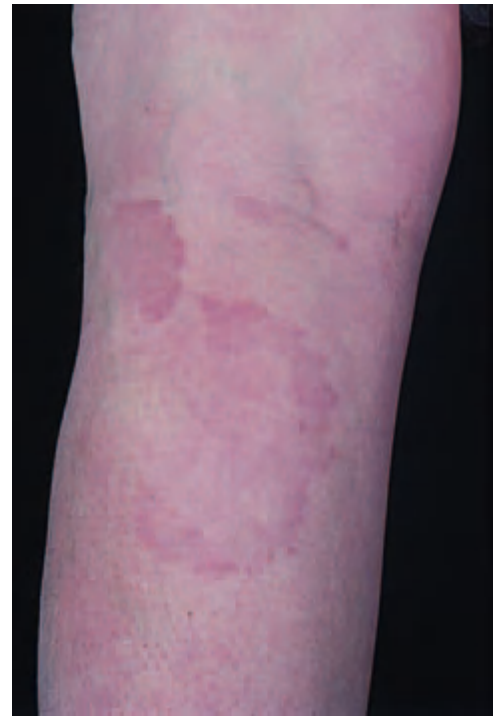

Fig. 57.62 These annular lesions were part of an extensive eruption on the limbs in a patient with generalized granuloma annulare.

common than generalized granuloma annulare, in HIV-infected patients the generalized pattern predominates [12–16]. The sparing of vaccination sites in a case of generalized granuloma annulare is an interesting phenomenon [17].

Perforating granuloma annulare was named by Owens and Freeman in 1971 [18]. In this uncommon variety, some of the papules develop yellowish centres and discharge a little clear, viscous fluid. This dries to form a crust, which eventually separates, and may leave a hypo- or hyperpigmented scar. Lesions may be localized or generalized [19–22]. A high incidence of perforating granuloma annulare has been reported in the Hawaiian Islands [20,21]. Perforating lesions have been present in some of the reported HIV-positive individuals with granuloma annulare.

Subcutaneous granuloma annulare is also uncommon. It occurs predominantly in children, and has been given a variety of names, including benign rheumatoid nodules [23], pseudo-rheumatoid nodules [24], deep granuloma annulare [25,26], subcutaneous palisading granuloma [27], isolated subcutaneous granuloma and subcutaneous necrobiotic granuloma [28]. Lesions are nodular and occur predominantly on the scalp and legs, particularly in a pretibial location [4,28–30]. Magnetic resonance imaging features are diagnostically helpful [31,32].

Other reported variants of granuloma annulare include a papular umbilicated form on the dorsa of the hands in children [33], a case of 'follicular pustulous' granuloma

Fig. 57.63 Granuloma annulare on the ear.

annulare, in which palisading necrobiotic granulomas occurred in a perifollicular distribution [34], linear granuloma annulare [35,36] and 'patch' granuloma annulare, in which erythematous patches occur on the trunk and limbs [37]. It must be remembered that in interstitial granulomatous dermatitis there are linear lesions on the chest wall, producing the so-called 'rope sign', and erythematous patches occur in the interstitial granulomatous drug reaction.

Uncommon sites for lesions are the ears (Fig. 57.63), where the perforating variety is particularly unusual [38], penis [39–44], palms [45] and periocular regions [46–51].

Mucous membranes are spared, although there is a report of involvement of the oral mucosa in a patient with HIV infection [52].

A destructive form has been described [53,54].

The postal questionnaire survey carried out by Wells and Smith [3] revealed that in about 50% of patients the lesions resolved within 2 years. However, about 40% of those whose lesions cleared had a recurrence, in the majority of cases at the same sites as the original lesions. In this study, there did not appear to be any difference in prognosis between individuals with single lesions and those with multiple lesions, and although there is an impression that spontaneous resolution is less likely to occur with generalized granuloma annulare there does not appear to be any documented confirmation of this.

There are reports of anetoderma secondary to generalized lesions [55], and of mid-dermal elastolysis occurring with granuloma annulare [56] or subsequent to lesions resembling granuloma annulare [57].

Levin *et al.* [58] have discussed resolution of lesions following biopsy, and noted the paucity of information relating to this phenomenon in the literature. There appears to be anecdotal evidence of its occurrence, but little documentation. However, it is of interest, in this context, that scarification is one form of physical treatment which has been advocated in the past [59–61].

Differential diagnosis. When the typical annular arrangement of papules is present, the diagnosis is usually straightforward. However, granuloma annulare may be mistaken for tinea corporis, although the latter is more inflammatory, and the annular margin is scaly. Other annular lesions and granulomatous conditions may cause diagnostic confusion, including annular lichen planus, erythema annulare centrifugum, erythema multiforme, erythema migrans of Lyme disease and tertiary syphilis [1].

With regard to subcutaneous granuloma annulare, the differential diagnosis of subcutaneous nodules of the scalp and legs in children is extensive, and includes trauma, infection and tumours; a diagnostic biopsy will usually be necessary. In adults, nodular lesions have to be distinguished from sarcoidosis and rheumatoid nodules.

The differential diagnosis of perforating granuloma annulare includes molluscum contagiosum, transepithelial elimination disorders such as perforating collagenosis and acquired perforating dermatosis, sarcoidosis and papulonecrotic tuberculide [2,3]. As mentioned above, epithelioid sarcoma may masquerade as perforating granuloma annulare.

Mycobacterium marinum infection has histologically simulated interstitial granuloma annulare [4]; other histological differential diagnoses include granulomatous mycosis fungoides, interstitial granulomatous dermatitis and interstitial granulomatous drug reaction, as mentioned above.

Associations. There has been much discussion of whether there is an association between granuloma annulare and diabetes mellitus. A number of studies have not demonstrated any relationship, whereas several others have found a significant association [1–3]. In those whose results suggest a possible relationship, some have favoured an association with generalized granuloma annulare [4–6] whilst others have shown an association with localized disease [3,7], and possibly with localized nodular granuloma annulare [8]. It is of interest to note that in three reports [3,7,8] the majority of diabetics were insulin-dependent (type 1). A recent study, employing a case–control design, did not show any association between granuloma annulare and type 2 diabetes [9]. The patient population studied did not include anyone with type 1

diabetes. In order to clarify the situation further, large-scale studies are required, in which the pattern of granuloma annulare and the type of diabetes are recorded.

Thomas *et al.* [10] reported a man with granuloma annulare of the skin and intra-abdominal lesions, insulin-dependent diabetes and polyendocrine disease, in whom there appeared to be a relation between diabetic control and the granuloma annulare.

Granuloma annulare has been described in a child with Mauriac's syndrome (juvenile diabetes, stunted growth and hepatomegaly) [11].

There are a number of reports of the coexistence of both localized and generalized granuloma annulare and autoimmune thyroiditis in women [12–17], and results of a recent case–control study indicated an association between localized granuloma annulare and autoimmune thyroiditis [18]. In one case with generalized granuloma annulare, the skin lesions improved in concert with disappearance of antithyroid antibodies and restoration of the euthyroid state [13]. Generalized granuloma annulare has also been reported in a patient with a toxic adenoma of the thyroid (Plummer's disease) [19].

Recent reports suggest the possibility of an association between uveitis and granuloma annulare [20,21].

Li *et al.* [22] have summarized and analysed reports addressing a possible relationship between granuloma annulare and malignant neoplasms. In the cases reviewed, skin lesions which had histological features of granuloma annulare, but were often atypical clinically (for example, painful lesions on the palms and soles), occurred in patients with a neoplasm (in 56% of cases this was a lymphoma). They concluded that there was no definite relationship between granuloma annulare and malignant neoplasms.

There are isolated reports of the occurrence of temporal arteritis in a patient with generalized granuloma annulare [23] and of the coexistence of granuloma annulare and morphoea [24].

There are a number of reports of the occurrence of granuloma annulare and necrobiosis lipoidica in the same patient [25–28], and of the association of granuloma annulare and sarcoidosis [29–32].

Treatment. The tendency of granuloma annulare to remit spontaneously complicates accurate assessment of the efficacy of any treatment. In some patients explanation that this is the natural course of the disease is all that is required, and certainly in children it is preferable to await spontaneous resolution rather than subjecting them to the

discomfort of some of the treatment methods. Potent topical steroids, with or without occlusion, are used by many dermatologists, but often with little benefit. Intralesional steroids, given either by needle injection or jet injector [1], appear to be more effective in the management of localized lesions. Cryosurgery also appears to be an effective treatment for localized disease. In a study of 31 patients, in which nitrous oxide and liquid nitrogen were employed, resolution was achieved in all following a single freeze–thaw cycle in the majority [2]. The cosmetic result obtained by cryosurgery with nitrous oxide was independent of the size of the lesion, whereas in individuals treated with liquid nitrogen a better cosmetic result was obtained with smaller lesions. Because of this, the authors of the report proposed that use of nitrous oxide as refrigerant was preferable to liquid nitrogen.

Localized granuloma annulare has also been treated with local injections of low-dose recombinant interferon-γ [3]. Complete resolution of lesions occurred in the three treated patients, with no recurrence during 12 months of follow-up.

Although some reports have indicated a beneficial effect of oral potassium iodide in the treatment of disseminated granuloma annulare [4,5], a double-blind, placebo-controlled, crossover study showed that it had no advantage over placebo [6].

PUVA therapy appears to be an effective treatment for generalized granuloma annulare, and good results have been reported using both oral and topical psoralens [7–13]. In many cases, however, maintenance therapy is required to sustain the benefit. Cream PUVA therapy has also been shown to clear localized lesions [14]. Ultraviolet A-1 phototherapy has also been reported as effective in the treatment of generalized granuloma annulare [15].

Etretinate [16,17] and isotretinoin [18–20] have both been of benefit in disseminated disease. Isotretinoin has also improved localized [21] and perforating granuloma annulare [22].

There are a few reports of the use of ciclosporin in generalized granuloma annulare [23–25], with good results in most cases. Other treatments which have been used with apparent benefit in isolated cases or in small numbers of patients with disseminated granuloma annulare include low-dose chlorambucil [26–30], dapsone [31], antimalarials [32–34], niacinamide [35], pentoxifylline [36], tranilast [37], fumaric acid ester [38], clofazimine [39], topical vitamin E [40], and a combination of vitamin E and a 5-lipoxygenase inhibitor [41].

Recent reports suggest that imiquimod [42] and topical tacrolimus [43] may be helpful.

Most of the treatments mentioned above have been employed in patients with perforating lesions, with varying degrees of success [44].

Lesions of subcutaneous granuloma annulare should be left to resolve spontaneously once the diagnosis has been confirmed [45].

Necrobiosis lipoidica

[D.A. Burns, pp. 57.119–57.124]

Introduction. Necrobiosis lipoidica was first described by Oppenheim in 1930 [1], and was subsequently named necrobiosis lipoidica diabeticorum by Urbach in 1932 [2]. Because it is not peculiar to diabetes, it is now usually called necrobiosis lipoidica. It is similar in histological appearance to granuloma annulare, but has a distinctive clinical appearance characterized by sharply demarcated plaques of atrophic yellowish skin, which may ulcerate.

Aetiology [3]. This condition was originally regarded as a complication of diabetes mellitus, but it was soon realized that some patients with necrobiosis lipoidica did not have overt diabetes. The precise relationship of the diabetic state to necrobiosis lipoidica is still not clear, although they are undoubtedly associated. The association is discussed below.

Some authors have considered vascular changes to be important in the pathogenesis of necrobiosis lipoidica, but in Muller and Winkelmann's histopathological study vascular involvement was very mild in about a third of the cases [4]. An altered plasma protein profile [5], elevated factor VIII-related antigen [6] and fibronectin [7] may contribute to the vascular changes.

The possible role of an antibody-mediated vasculitis as an initiating event in necrobiosis lipoidica has provoked debate, as results of immunofluorescence studies differ. Laukkanen *et al*. [8] did not demonstrate immunoreactants in lesional skin, but others have shown immunoreactants, principally IgM, C3 and fibrin, in vessel walls in the involved skin, and IgM, C3 and fibrinogen at the dermal–epidermal junction [9,10]. Dahl [11] has discussed immunofluorescence findings in necrobiosis lipoidica.

Whatever the mechanism, there is evidence of impaired microcirculation in non-diabetic individuals with necrobiosis lipoidica compared with controls, as measured by laser-Doppler flowmetry [12].

Although vascular factors may play a role, the precise pathogenesis of necrobiosis lipoidica remains unknown.

Histopathology [1–3] (Figs 57.64 & 57.65). The histological appearances are similar to those of granuloma annulare, but some features differ. The epidermis is normal or atrophic, and absent if there is ulceration. The dermal changes involve its full thickness, and often extend into the subcutaneous fat. Early lesions show a perivascular and interstitial mixed inflammatory cell infiltrate. Areas of necrobiosis are usually more extensive and less well defined than in granuloma annulare. There is degeneration of collagen and elastin within lesions [4]. Histiocytes border the areas of necrobiosis. There are variable numbers of Langhans' or foreign-body giant cells.

A perivascular inflammatory infiltrate includes occasional eosinophils and, in contrast with granuloma annulare, plasma cells.

Lymphoid nodules, containing germinal centres, may be present in the deep dermis or subcutaneous fat [5].

Lipid can be demonstrated in the necrobiotic areas, and cholesterol clefts may be present [6]. Mucin may be present in the dermis, but it is not as prominent as in granuloma annulare.

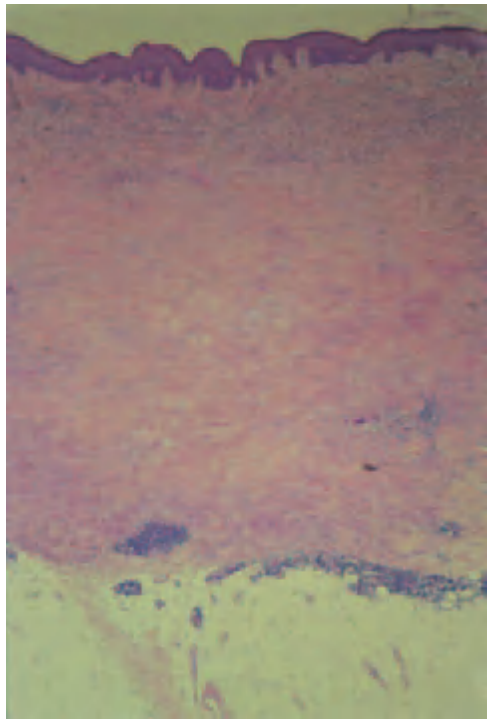

Fig. 57.64 Necrobiosis lipoidica. Extensive necrobiosis in the dermis. H&E stain. (Courtesy of Dr M. Bamford, Department of Pathology, Leicester Royal Infirmary, Leicester, UK.)

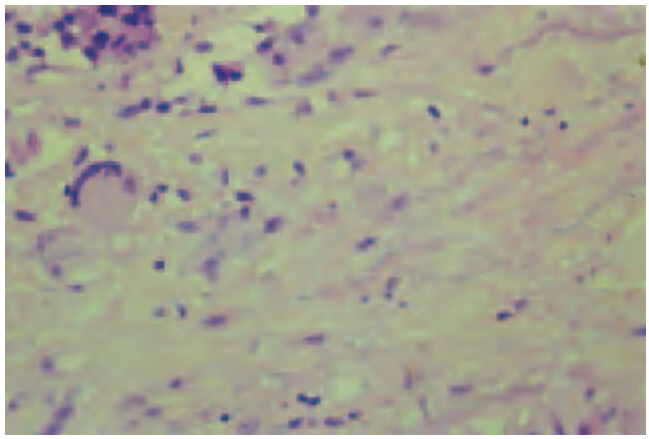

Fig. 57.65 Necrobiosis lipoidica. Giant cell adjacent to area of necrobiosis. H&E stain. (Courtesy of Dr M. Bamford, Department of Pathology, Leicester Royal Infirmary, Leicester, UK.)

Small, superficial blood vessels are increased in number and telangiectatic. Deeper dermal blood vessels often show thickening of their walls and proliferation of endothelial cells. The walls are often infiltrated with PAS-positive, diastase-negative material.

Histologically, comedo-like plugs at the periphery of lesions represent elimination of necrotic material through hair follicles [7].

Anaesthesia in the lesions appears to be related to a decreased number of nerves within them [8].

In old, atrophic lesions there is considerable fibrosis in the dermis and subcutis.

8 Boulton AJM, Cutfield RG, Abouganem D *et al*. Necrobiosis lipoidica daibeticorum: a clinicopathologic study. *J Am Acad Dermatol* 1988; **18**: 530–7.

Clinical features [1–3]. Necrobiosis lipoidica may occur at any age, but usually develops in young adults and in early middle age. In those with insulin-dependent diabetes, the age of onset is earlier than in non-insulin-dependent and non-diabetic individuals [4]. It is rare in childhood [5,6]. The female : male ratio is 3 : 1. Familial occurrence is rare [7,8].

Typical lesions occur on the pretibial skin, and begin as a firm, dull-red papule or plaque, which enlarges radially to become a yellowish, atrophic plaque with an erythematous edge (Figs 57.66 & 57.67). The surface is often glazed in appearance, and telangiectatic vessels may be prominent (Fig. 57.68). Lesions are usually symptomless. Anaesthesia and hypohidrosis are features of the affected skin [2,9,10]. Comedo-like plugs may occur at the periphery of lesions [11] (see above). In most cases, lesions are bilateral, and they are similar in appearance whether occurring in diabetic or non-diabetic individuals [1].

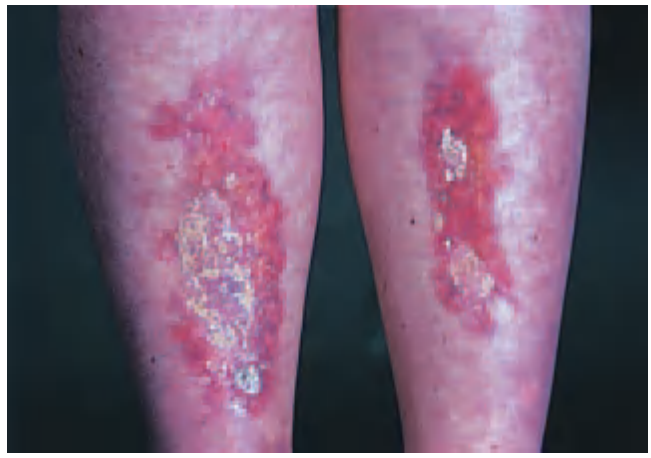

Fig. 57.66 Necrobiosis lipoidica. Lesions on both shins.

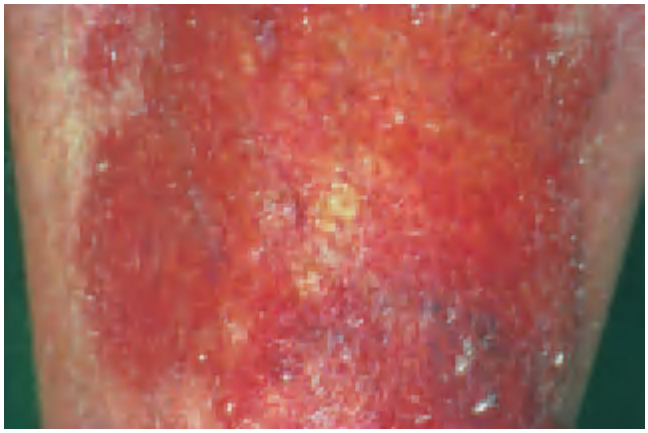

Fig. 57.67 Area of necrobiosis lipoidica showing yellowish colour, atrophy and prominent vessels.

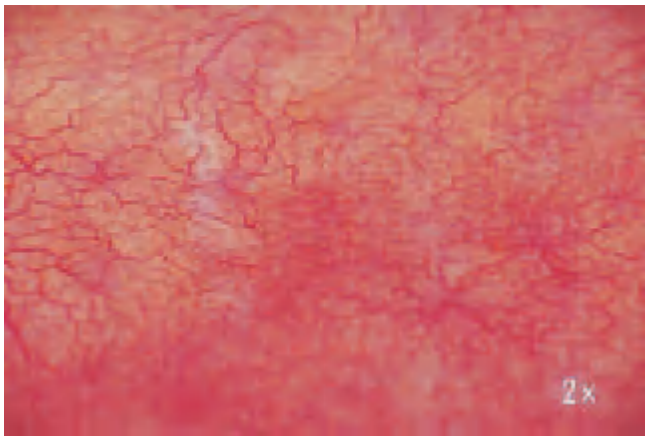

Fig. 57.68 Prominent telangiectasia in an area of necrobiosis lipoidica.

They tend to be persistent, and some may ulcerate [12] (Fig. 57.69). In one study [4], ulceration correlated with sensory impairment. Squamous cell carcinoma may develop in long-standing lesions [13–16].

Lesions can also occur on other parts of the body, including the trunk [17] and penis [18,19], and rarely may be diffuse [20]. They may also occur in surgical scars [21–23].

The number of lesions and their rate of progress are very variable. Slow extension over many years is usual, but long periods of quiescence, or resolution with variable atrophy and scarring (Fig. 57.70), may occur.

Wilson Jones [24] described an 'atypical annular form' of necrobiosis lipoidica affecting the upper face and scalp margins. The majority of affected individuals were female, and some developed lesions of necrobiosis lipoidica elsewhere. Since then, other authors have described similar annular lesions occurring predominantly on the exposed skin of the head, neck and arms, and these have been named Miescher's granuloma [25] and actinic

Fig. 57.69 Ulcerated necrobiosis lipoidica.

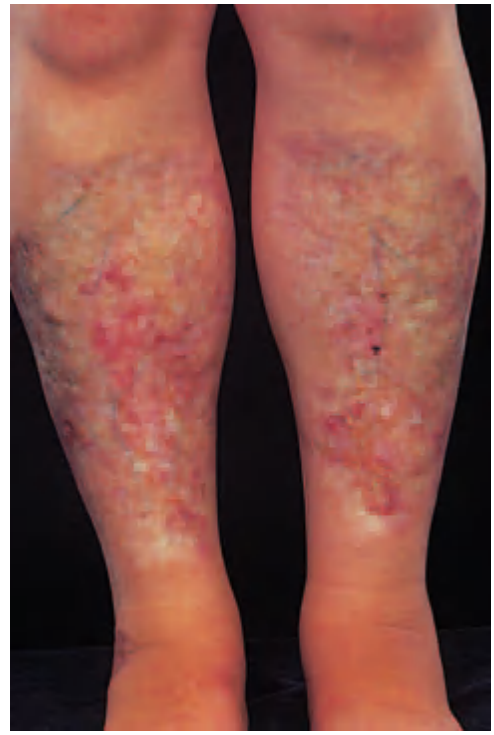

Fig. 57.70 'Burnt out' necrobiosis lipoidica—marked atrophy is evident.

granuloma [26]. Hanke *et al.* [27] proposed the term 'annular elastolytic giant cell granuloma' for these lesions. A similarity to granuloma multiforme (p. 57.124) is also apparent. The relationship of these disorders to each other

and to the necrobiotic granulomas has provoked debate [3,28].

Differential diagnosis. Lesions with marked fatty infiltration, particularly when not on the legs, may be mistaken for xanthomas. Necrobiotic xanthogranuloma is a rare destructive xanthogranuloma, in which red-orange or yellowish indurated plaques most frequently involve the periorbital regions and trunk [29,30]. It is associated with systemic lesions and a monoclonal gammopathy (Chapter 52).

Associations. Although it is accepted that there is a relationship between necrobiosis lipoidica and diabetes mellitus, there is some disagreement about the closeness of this association. In Muller and Winkelmann's large series of cases, 111 of 171 patients with necrobiosis lipoidica (65%) had diabetes, and several of the non-diabetic patients subsequently had abnormal glucose tolerance tests [1]. Whereas, in a study from Ireland [2], of 65 individuals with necrobiosis lipoidica only seven (11%) were known to have diabetes at the time of presentation. Necrobiosis lipoidica is relatively uncommon in diabetic patients, with reported prevalences of 0.3% [1] and 1.2% [3], and appears to be rare (0.06%) in childhood diabetes [4].

It is most commonly seen in patients with type 1 diabetes [3,5], but also occurs in type 2 diabetes, and in recent years has been reported in children and adolescents with type 2 diabetes [6,7], including Prader–Willi-associated diabetes [8]. A recent survey of the records of 178 patients fitting the clinical criteria for maturity-onset diabetes of the young (MODY), which is a subtype of non-insulin-dependent diabetes, showed a prevalence of necrobiosis lipoidica of 2.8% [9].

There is some evidence that diabetic patients who have necrobiosis lipoidica are at higher risk of retinopathy and nephropathy than diabetics who do not [5,10,11].

In the past, it was noted that good control of diabetes did not appear to have a significant effect on the course of necrobiosis lipoidica [1], but it would be of interest to reassess this aspect of the disease in the context of advances in diabetes care in recent years.

Necrobiosis lipoidica has also been reported as occurring in association with ulcerative colitis [12] and Crohn's disease [13], ataxia-telangiectasia [14] and after jejunal bypass surgery [15]. Reports of its occurrence with granuloma annulare have been mentioned previously (p. 57.117). It has also been reported in association with sarcoidosis [16,17].

Magro *et al.* [18] have demonstrated histopathological evidence of an 'active vasculopathy' in the majority of a series of cases of necrobiosis lipoidica associated with systemic disease.

Treatment. Potent topical corticosteroids, particularly if applied beneath an occlusive dressing and changed weekly, may help [1]. Locally injected triamcinolone, delivered by needle or jet injector [2], can improve the appearance, but atrophy usually remains. As there is evidence of extension of the inflammatory infiltrate into apparently normal skin surrounding active lesions, injection of steroids into perilesional areas might help to limit progression [3]. The use of oral steroids may be of benefit [4,5]. Petzelbauer *et al*. [5] employed short-course steroid therapy which resulted in cessation of disease activity in six patients, and no recurrence in a mean follow-up period of 7 months.

There are several reports of benefit from topical PUVA therapy [6–10].

Other treatments which have been employed in the past, with varying degrees of success, include fibrinolytic agents [11], high-dose nicotinamide [12], clofazimine [13], pentoxifylline [14–16], tretinoin (0.05%) [17], prostaglandin E_1 [18,19] and aspirin or an aspirin/dipyridamole combination [20–22]. Aspirin alone was subsequently shown to be ineffective [23,24], and in a randomized, double-blind comparison with placebo, patients treated with an aspirin/dipyridamole combination did not show any significant improvement [25].

Pulsed dye laser has been employed, and may improve the telangiectatic and erythematous components [26] but skin breakdown can occur [27].

Ulcerated necrobiosis lipoidica has been treated by excision and grafting [28–30], although recurrence tends to occur unless the excision is deep [30]. Other treatments that have been used for ulcerated necrobiosis lipoidica include oral steroid [31], ciclosporin [32,33], mycophenolate mofetil [34], topical granulocyte–macrophage colony-stimulating factor [35,36], infliximab [37], hyperbaric oxygen [38,39], topically applied bovine collagen [40] and grafting with bioengineered dermal tissue [41,42].

Granuloma multiforme

[D.A. Burns]

Definition. A chronic granulomatous skin condition, which is characterized clinically by firm papules aggregated into plaques or forming the edges of annular lesions and histologically by focal necrobiosis and histiocytic granulomas. It has been reported from Africa, Indonesia and India [1–7]. Leiker and coworkers [1–3] first described granuloma multiforme and distinguished it from tuberculoid leprosy. Leiker called it Mkar disease, after the town where it was first studied. The condition is endemic in certain villages in eastern Nigeria, where the local inhabitants refer to it in the Ibo tongue as 'Ununo Enyi' (elephant ringworm) [4,7].

The disease appears to occur predominantly in females over the age of 40 years [4,7,8].

Aetiology. The morphology and histological features of lesions, and their distribution predominantly on exposed parts of the body indicate that this disorder may be granuloma annulare on light-exposed areas. It has been suggested that the primary event may be sun-induced damage to dermal connective tissue [8].

Pathology [4,9]. There are focal areas of necrobiosis, with loss of elastic tissue, surrounded by histiocytes. Multinucleated giant cells are usually a prominent feature. There is a perivascular lymphocytic infiltrate with variable numbers of plasma cells and eosinophils.

Clinical features. The upper, uncovered parts of the body are predominantly affected. The initial lesions are small, flesh-coloured papules which become aggregated into plaques or form the elevated rims of annular lesions. In larger annular lesions the central area is often hypopigmented. Pruritus may be prominent. The condition lasts for many months or years, and may persist indefinitely.

Differential diagnosis. Leprosy is endemic in the same regions where granuloma multiforme is found, and can look very similar. However, there is no loss of sensation or sweating, or other evidence of neural involvement in granuloma multiforme. In addition, the histological changes are different.

Treatment. None is known to be effective.

Chapter 58

Sarcoidosis

D.J. Gawkrodger

Definition

There is no universally accepted definition of sarcoidosis. Many attempts have been made, but as long as its cause is unknown, definitions must be empirical and may also be inaccurate. Current definitions still have to avoid aetiological implications and the illogicalities that may result from them.

Scadding and Mitchell [1], after a full discussion of the difficulties, suggested the following: 'Sarcoidosis is a disease characterized by the formation in all or several affected organs or tissues of epithelioid cell tubercles, without caseation, although fibrinoid necrosis may be present at the centre of a few, proceeding either to resolution or to conversion of the epithelioid cell tubercles into hyaline fibrous tissue.'

The characteristic histology should be present in all affected tissue and similar in all parts of it. This excludes the sarcoid-like histology found in tuberculosis, brucellosis or leprosy. It is characterized by non-caseating epithelioid granulomas.

Main features

The most important features of sarcoidosis are as follows.

1 The disease process is usually generalized. The term is seldom applicable to a localized granulomatous reaction even though it may have similar histological findings.

2 The clinical manifestations are protean; the disease process is usually widespread; the course is protracted and usually benign, though sometimes with dangerous and disabling sequelae and complications.

3 The disease may affect any organ of the body (the adrenal gland possibly excluded). The lymph nodes, lungs, liver, spleen, skin, eyes, small bones of hands and feet, and salivary glands are most frequently affected.

4 All affected organs conform to a similar histological pattern.

5 Other changes present to a varying and inconstant degree include suppression or weakening of tuberculin and other intradermal responses, an increase in the serum gammaglobulins and a raised serum calcium level.

6 The Kveim reaction is positive in most active cases. This test is no longer available.

History [2–4]

The earliest description of a case which would now be categorized as sarcoidosis was probably Besnier's report in 1889 [5] of an association between reddish-blue lesions of the face and nose with swellings of the fingers [4]; the name 'lupus pernio' reflected his view that this might be a variant of lupus vulgaris. Tenneson in 1892 added the histological description [6]. In 1898 Hutchinson described two more cases of a skin eruption, probably sarcoidosis, to which he gave the name of 'Mortimer's malady' after one of his patients [7]. Boeck in 1899 [8] recorded his 'multiple benign sarkoid of the skin', and the current term 'sarcoidosis' stems from his misinterpretation of the histological changes. However, it was Boeck who first developed

the concept of a disease involving both the skin and internal organs—a concept taken further by Schaumann [9], who again emphasized the generalized nature of the disease and showed that skin changes were not a necessary feature of it. The disease was further expanded by the inclusion of 'osteitis tuberculosa multiplex cystica' [10], uveoparotid fever [11], pulmonary and other manifestations [12,13]. The introduction of mass radiography led to the recognition of hilar lymphadenopathy, with or without erythema nodosum, as an early benign form [14,15] and this has altered the whole concept of the disease, which is now seen more often by chest and general physicians than by dermatologists.

Epidemiology [1]

The apparent increase in sarcoidosis over the last 40 years has been due partly to better detection, especially by mass radiography. However, even in countries with compulsory notification of the disease, there are bound to be many cases in an early, asymptomatic stage that remain undetected. For this reason, prevalence and incidence figures have to be interpreted with caution, though it is now clear that the disease has a worldwide distribution.

Sarcoidosis seems to be most prevalent (more than 10 per 100 000 population) in developed countries, but 'each succeeding world congress brings to the fore yet another country which has achieved manhood by joining in the world recognition of sarcoidosis' [2].

The danger of drawing inferences from unrepresentative collections of patients is well known [3], but certain groups do seem to be especially prone to sarcoidosis. It is, for example, more common in Afro-Caribbeans than in white inhabitants of the same area [4,5]. Other especially vulnerable groups include Puerto Ricans in New York and Irish immigrants to England. A useful study of 401 consecutive patients presenting to a district general hospital in the UK [6] gives a view of ethnic representation: Irish and Afro-Caribbean patients were disproportionately common in the material, but no attempt was made to assess incidence or prevalence in the population covered. Erythema nodosum was particularly common in the British and Irish; other skin manifestations occurred in 30 patients, 80% of whom were under 45 years of age.

Overall, sarcoidosis may be slightly more common in women than in men, and usually presents between the ages of 20 and 40 years. It is rare in young children [7]. The fact remains, however, that despite the voluminous data available, the factors influencing the prevalence and incidence of sarcoidosis remain obscure. Occupational, socioeconomic and climatic factors may be more important than have been recognized so far.

Aetiology

Despite intensive investigation, the cause of sarcoidosis remains unknown; it is not even clear whether the condition has only one or many causes. Most of the earlier theories have been discarded; others remain unproven. Evidence from genetic and environmental sources has been inconclusive, and immunological studies have, perhaps, raised more questions than they have solved. Speculations now lie in two main areas: infectious causes and genetic factors. Both may be interlinked.

Infectious agents

Many infectious agents have been put forward as the cause of sarcoidosis, but cultures are always negative and responses to treatment have not supported these beliefs. However, it remains possible that the disease represents an unusual host reaction to one or more infective agents—

as yet unknown. Diagnostic confusion with tuberculosis led to speculation that *Mycobacterium tuberculosis*, perhaps in some transmuted form, might be responsible for the symptom complex of sarcoidosis. Recent evidence has lent some support for this. Serological studies have shown that patients with sarcoidosis have raised levels of antibodies to *M. paratuberculosis*, similar to those seen with Crohn's disease [1]. A polymerase chain reaction study revealed the presence of various subtypes of mycobacterial DNA (including *M. avium–intracellulare*) in 16 of 20 cases of cutaneous sarcoidosis [2]. In addition, it was recently reported that acid-fast cell-wall-deficient forms of *M. tuberculosis* have been grown from the blood of patients with active sarcoidosis [3]. The significance of these findings is unclear at present, and the contribution of any mycobacteria to the pathogenesis of sarcoidosis is unknown. The onset of cutaneous sarcoidosis has been described following *M. marinum* infection [4].

Histoplasmosis and other fungi, which can produce granulomas exactly mimicking sarcoidosis, also have been suspected as possible causes, but their geographical limitations rule them out. Finally, it is always tempting to consider a viral cause for an obscure disease, but there is still no evidence to take this beyond mere speculation.

Genetic and familial factors

Familial sarcoidosis is well recognized and occurs more commonly than chance would predict. In ethnic groups known to have a high prevalence of sarcoidosis, the probability that an index case will have a sibling with sarcoidosis is about 10% [5]. In one study of 645 cases of sarcoidosis, 26 came from 12 families [6]. A literature search [7] found 182 affected sibling pairs; the excess of like-sex pairs was thought to reflect the effects of environmental exposure which they are more likely to share than unlike-sex pairs. Far fewer examples of husband/wife sarcoidosis have been recorded [8] and this suggests that family aggregates occur either on a mainly genetic basis, or require a common environmental exposure during childhood. No consistent mode of inheritance has been found, although a recessive pattern may be more common [9].

Studies of human leukocyte antigens (HLA) have not clarified the matter [10]. Differences between black and white subjects exist. Among black patients in the USA, sarcoidosis occurred significantly more frequently in individuals with BW15—but so did tuberculosis [11]. In London, white people with HLA-B8 were especially likely to have arthritis or erythema nodosum [12]. A recent Japanese study of 63 patients with sarcoidosis suggested that susceptibility for the disease may reside in the HLA-DRB1 locus, with resistance being conferred by the HLA-DRB1*1302 locus [13].

It seems likely that the HLA type can influence the pattern of the disease, rather than determine its occurrence.

Interferon-alpha (IFN-α) therapy

In more than 20 case reports [14–18], sarcoidosis has developed 15 days to 30 months after commencing IFN-α treatment. Some patients [14–16] had chronic myelogenous leukaemia and cutaneous lymphoma, conditions known to be associated with sarcoidosis on occasions. Others have had chronic hepatitis C [17,18]. Fifty per cent of cases have skin signs [18]. It is suggested that IFN-α might stimulate Th1 immune responses that are thought to be involved in sarcoidosis.

Histopathology

The histological changes are similar in all organs affected and are remarkably constant. The essential feature is a monotonous repetition of aggregates of epithelioid cells with pale-staining nuclei, which form the characteristic discrete sarcoidal granulomas (Fig. 58.1). Multinucleate giant cells are usually, but not invariably, present. An inconstant and variable rim of lymphoid cells surrounds the granuloma but this is never well developed—hence the

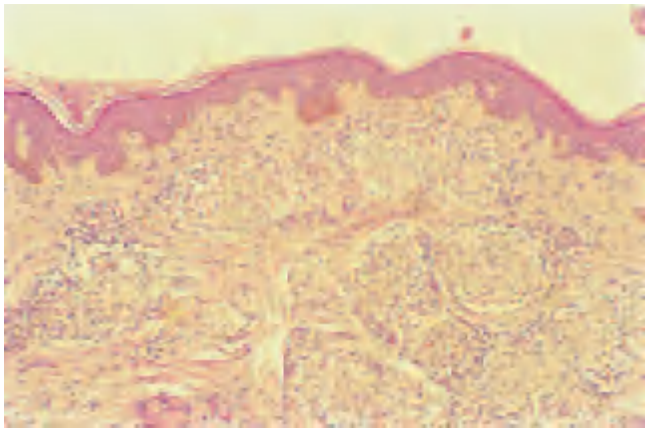

Fig. 58.1 Sarcoidosis. The epidermis is normal, while the superficial and mid-dermis contain numerous small granulomas without caseous necrosis. (Courtesy of Dr T.J. Stephenson, Royal Hallamshire Hospital, Sheffield, UK.)

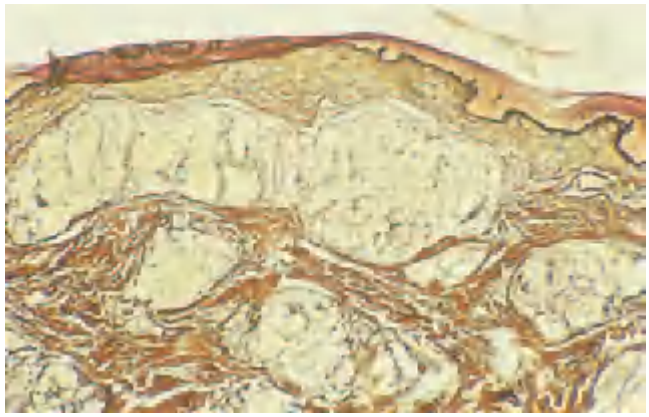

Fig. 58.2 Sarcoidosis. Reticulin stain of the section shown in Fig. 58.1, showing that the granulomas contain strands of staining reticulin, indicating that they lack caseous necrosis. (Courtesy of Dr T.J. Stephenson, Royal Hallamshire Hospital, Sheffield, UK.)

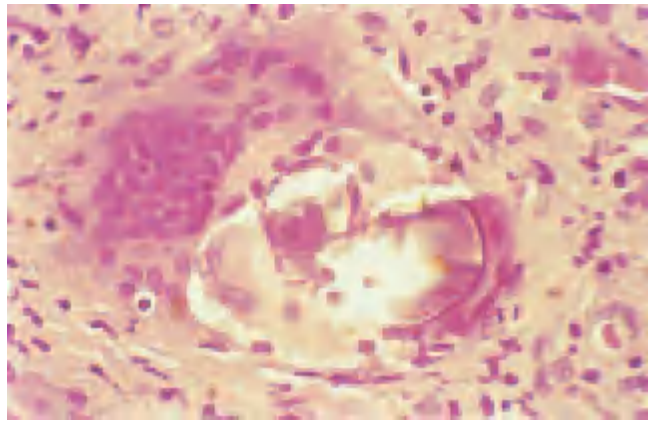
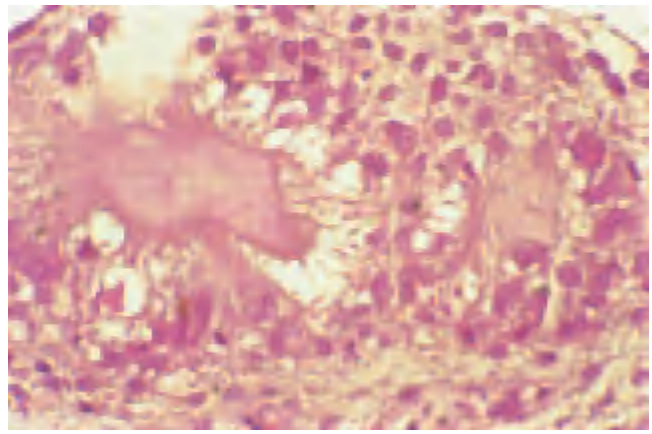


(a)



(b)

Fig. 58.3 (a) A Schaumann or conchoid body. These laminated calcospherites tend to fracture and to cause score marks. They stain basophilically. They are thought to arise from dystrophic calcification and it is suggested that they indicate chronicity. (b) High-power view of a granuloma in sarcoidosis showing an asteroid body within a giant cell. (Courtesy of Dr T.J. Stephenson, Royal Hallamshire Hospital, Sheffield, UK.)

term 'naked tubercle'. Caseation is absent, although an inconspicuous focus of fibrinoid necrosis or coagulation may occur within the granuloma. A fine reticulin network encircles the granuloma and may penetrate it (Fig. 58.2). The infiltrate tends to occur lower in the dermis than that of lupus vulgaris, and in erythrodermic sarcoidosis the granulomas are looser and less well defined. Epidermal changes can include hyperkeratosis, parakeratosis, acanthosis, atrophy and spongiosis: occasionally a lichenoid reaction is seen [1].

During the development of the granuloma, the loosely packed epithelioid cells of the early stage become more numerous and compact (their development is stimulated by IFN-γ produced by Th1 lymphocytes), and giant cells appear by their fusion. Reticulum appears and hyalinization becomes progressively more apparent as fibrosis gradually obliterates the characteristic features of the granulomas. This is the cause of the irreversible tissue scarring of the late stage of the disease. Polarizable foreign bodies were found in 12 of 50 cases of cutaneous sarcoidosis (all of whom also had systemic granulomatous disease), suggesting that in some patients, a foreign body may be an inciting stimulus for granuloma formation [2].

Inclusion bodies

These are often found in the giant cells in sarcoidosis and other sarcoidal granulomas, but are not specific. Their numbers increase as lesions age. The following types are recognized.

1 *Schaumann (conchoid) bodies* (Fig. 58.3a) are basophilic concentric lamellar structures, 100 μm in diameter, composed of lipomucoglycoproteins impregnated with calcium and iron, and they show central birefringent crystals.

2 *Asteroid (stellate) bodies* (Fig. 58.3b) are between 10 and

Table 58.1 Main histological features of sarcoidosis and tuberculosis.

Feature	Sarcoidosis	Tuberculosis
General structure	Monomorphic tubercles	Caseating tubercles
Form	Discrete, sharply defined 'naked tubercles'	Confluent, diffuse
Epithelioid cells	Large, grouped, predominant	Massed, irregular or at margin of caseation less than 50%
Giant cells	Large, usually sparse Langhans' and foreign body	More numerous, Langhans' predominate
Lymphocytes	Sparse cuffing	More numerous and scattered
Inclusion bodies	Frequent	Occasional
Blood vessels	Usually normal or dilated	May show fibrinoid changes
Reticulin	Fine and abundant around tubercles	Destroyed
Caseation	No	Yes (but not lupus vulgaris)
Fibrinoid	Sometimes at centre of tubercle	Vascular and perivascular (late)
Healing process	Progressive hyalinization from periphery; gradual dissolution	Dense collagen mesh. Retraction, fibrosis, calcification

15 μm in size; their central core is surrounded by radiating spicules (the 'open umbrella frame' [3]). They consist of collagen [4].

Development of the granuloma [5]

Several strands of research have combined to increase our understanding of the complex cascade of cellular and mediator interactions involved in granuloma formation:

1 The technique of bronchoalveolar lavage, allowing easy harvesting of cells involved in the inflammatory process within the lungs.

2 Studies of evolving Kveim antigen-induced granulomas.

3 The study of immune deposits in cutaneous sarcoidosis.

4 The use of monoclonal antibodies to characterize the cells found within the sarcoidal lesions.

The architecture of a cutaneous sarcoid granuloma follows a pattern in which the centre consists of activated macrophages and epithelioid cells, surrounded by dendritic cells. Many activated $CD4^+$ helper/inducer T lymphocytes are present at the centre of the granuloma with a smaller population of $CD8^+$ suppressor/cytotoxic T lymphocytes at the periphery [6]. The antigen in sarcoidosis remains unknown, but the arrangements within the granuloma suggest an active immunological process. In addition, most workers have been able to demonstrate immune deposits within cutaneous granulomas, presumably as a consequence of the presence of circulating immune complexes known to occur in some patients with sarcoidosis. The most usual finding has been of immunoglobulin M (IgM) in the walls of dermal blood vessels or at the dermo-epidermal junction.

In the lung, an alveolitis precedes granuloma formation. Circulating blood monocytes appear in the lung, presumably in response to local chemotactic factors, and these aggregate into epithelioid cell granulomas. Pulmonary macrophages are induced by an unknown trigger mechanism to secrete interleukin-1 (IL-1), which is responsible for the migration of T lymphocytes to the site of disease activity. IL-1 also activates T cells and stimulates T-cell release of IL-2, which further amplifies local inflammatory activity. Activated T cells secrete chemotactic factors for monocytes and migration inhibitory factors. Fibrosis is enhanced by fibronectin and growth factors derived from alveolar macrophages.

Differential diagnosis

Typical tuberculosis is usually distinguishable by the histological features listed in Table 58.1. Sarcoidosis may be particularly hard to separate from lupus vulgaris if lymphocytes are more abundant than usual. In tuberculoid leprosy, epithelioid cells surround and are associated with the nerves, and there is more central necrosis.

However, the histology of true sarcoidosis cannot always be distinguished from that of sarcoidal granulomas due to other causes—the key to the diagnosis of sarcoidosis lies in the uniformity of the histological changes in all affected organs.

Lupoid leishmaniasis, granulomatosis disciformis, rosacea and Crohn's disease may pose difficulties. Plasma cells and coagulation necrosis are features of syphilis. The granulomas of cat scratch fever are said to be larger than those of sarcoidosis. When sarcoid-like reactions occur in a scar, the possibility of a foreign-body reaction must be considered. Talc may be recognized by its refractile nature.

Immunological aspects [1,2]

Important advances have been made in our understanding of the immunology of sarcoidosis in recent years; yet the paradox of the disease remains. How is it that granulomas can evolve, presumably as a consequence of a local T-cell-mediated immune response to antigenic insult (e.g. a superantigen or a particulate antigen ingested by macrophages), in a condition apparently characterized by reduced cell-mediated immunity? Even if the cutaneous anergy of sarcoidosis is partly explained by a movement of activated helper T cells to sites of disease activity, leaving in the circulation an excess of anergic suppressor cells, then it still has to be accepted that Kveim-induced granulomas, at least, can develop during a state of depressed immune responsiveness.

Cell-mediated immunity

Depression of cell-mediated immunity is the hallmark of sarcoidosis; indeed, the first immunological defect to be demonstrated was lack of reactivity to tuberculin. Sensitivity to tuberculin is depressed to a variable degree and becomes negative in about two-thirds of patients [3]. However, there is no absolute correlation between reactivity and the state of the disease, and some failure of immunological response may persist despite apparent clinical resolution.

Later, this anergy was shown to extend to other intradermal allergens such as *Candida*, pertussis, trichophyton and mumps antigens. The combination of a depressed reaction to mumps antigen with normal circulating antibody responses is characteristic of, but not specific for, sarcoidosis. The response to dinitrochlorobenzene (DNCB) is also defective [4].

The levels of circulating T lymphocytes expressing the γ/δ T-cell marker are increased in sarcoidosis, and correlate with the defect in cellular immunity [5]. T-cell receptor gene studies from blood and sarcoid lesions are consistent with an oligoclonal expansion of T cells from an antigen-driven response [6]. The formation of sarcoid granulomas, like tuberculoid, is characterized by the expression of a Th1 cytokine profile, i.e. the T-lymphocytes secrete IL-2, IFN-γ, and tumour necrosis factor-α (TNF-α) [7]; there is inactivation of Th2 lymphocytes. Th2-type granulomas have a prevalence of eosinophils and are seen, for example, in schistosomiasis.

Humoral immunity

All classes of serum immunoglobulins are increased. Activated T lymphocytes release B-cell growth factor and a B-cell differentiation factor, which together increase immunoglobulin production at the sites of disease [8]. Significantly raised levels of circulating antibodies may be found to rubella, measles, herpes simplex, the Epstein–Barr virus and cytomegalovirus [9]. The prevalence of asthma, eczema and hay fever is unaltered in patients with sarcoidosis [10].

Immune complexes are present in more than 50% of patients with sarcoidosis [11] and are manifested clinically by erythema nodosum, polyarthritis and uveitis.

General manifestations of sarcoidosis [1–3]

There is no disease with more varied manifestations. Its course is unpredictable. Several years may separate one manifestation from another, and any organ of the body may be involved. Symptoms result from invasion and replacement, pressure, anaemia, hypercalcaemia and fibrosis.

A full history must include details of race, area of residence, previous tuberculin testing and bacille Calmette–Guérin (BCG) vaccination, industrial exposure to beryllium and any previous disease, such as erythema nodosum, that may be related, even distantly.

Staging of the disease

Pulmonary sarcoidosis is classically divided into four stages on the basis of the chest radiograph:
Stage 0: 5–10% of patients with sarcoidosis have a normal chest radiograph.
Stage I: bilateral hilar lymphadenopathy alone—seen on the presenting radiograph of 35–45% of patients (Fig. 58.4).
Stage II: bilateral hilar lymphadenopathy with parenchymal lung involvement of fine 'fluffy' or coarse type.

Fig. 58.4 Chest radiograph showing bilateral hilar lymphadenopathy typical of sarcoidosis.

Stage III: late stage of pulmonary infiltration with fibrosis and pulmonary insufficiency.

Extrapulmonary manifestations of sarcoidosis cannot be staged in this way, although some generalizations are possible. Erythema nodosum is, *par excellence*, an early feature, occurring with stage I pulmonary disease, and carrying a good prognosis. Iridocyclitis and anterior uveitis are usually associated with the later stages and more persistent forms of the disease. An attempt can be made to classify sarcoidosis on the basis of the degree of internal involvement, and on the type of skin lesions, as 'early' (e.g. erythema nodosum and bilateral hilar lymphadenopathy), 'intermediate' (e.g. papular and nodular forms) and 'late' (e.g. plaque, subcutaneous or lupus pernio). However, this may be unreliable, as the prognosis mostly depends upon the extent of internal disease, and this may not become apparent until treatment is too late to be effective. Of this disease, it has been aptly said: 'One of its most singular details . . . is the frequency of its clinical silence'.

Systemic features

General symptoms

The onset is often marked by lethargy, loss of weight and general malaise, but may be symptomless. A dry cough, dyspnoea and chest pain are present in half the patients.

Bone and joint changes

An acute polyarthralgia may accompany erythema nodosum. A more chronic polyarthritis may appear later in the disease, chiefly in Afro-Caribbeans. Bone changes, often asymptomatic, were found in 8% of 260 patients routinely examined radiologically [4]. Classically, they involve the small bones of the hands and feet in middle-aged females with lupus pernio. The most common change is lysis with bone cysts. The nasal bones, and occasionally the calvarium, may be involved in a way which mimics metastatic deposits [5].

Cardiac involvement [6,7]

Granulomatous infiltration of the conducting system may lead to heart block, papillary muscle dysfunction, congestive cardiac failure, pericarditis, chest pain, arrhythmias or even sudden death. The patients are often young, and the condition may be revealed only at post-mortem. Cardiac involvement is more common than was once believed, being found in 20–50% of autopsies on patients with sarcoid [6]. An abnormal electrocardiogram (ECG) was found in 14% of 401 patients examined routinely [4]. A careful cardiac examination should be routine procedure in all cases of established sarcoidosis.

Muscle involvement

Polymyositis and myopathy occur rarely, and even muscle weakness and tenderness are uncommon despite the fact that random muscle biopsies in patients with sarcoidosis are positive in 50–80%.

Nervous system involvement [8,9]

About 5% of patients with sarcoidosis have nervous system involvement and a wide variety of syndromes may result, including optic nerve lesions, cranial nerve palsies, meningoencephalitis, multiple sclerosis-like changes, peripheral neuropathy, mononeuritis multiplex and psychiatric changes. The facial nerve is frequently affected, with or without Heerfordt's syndrome (see below). Involvement of the hypothalamus or brainstem is rare but important. Sarcoidosis may also present as diabetes insipidus, hypopituitarism or endocrine abnormalities. The cerebrospinal fluid can show elevated protein and/or cells. Magnetic resonance imaging (MRI) may reveal abnormalities. Peripheral neuropathies often settle, but central nervous system manifestations seldom do so.

Ocular involvement [10]

The eyes are involved at some time in 25–50% of patients

with sarcoidosis; eye disease is the first feature of sarcoidosis in about 10% of patients. The main types of ocular involvement are as follows:

1 *Uveitis*. Anterior and posterior uveitis are the most important and serious manifestations. Acute and chronic forms occur. The onset is usually insidious and 'mutton-fat' precipitates are found on the corneal epithelium. Iridocyclitis may be severe and recurrent. Complications include glaucoma, cataract and iris synechiae.

2 *Iris nodules*. These represent granulomatous infiltration of the stroma of the iris.

3 *Retinochoroiditis*. This usually occurs with chronic uveitis.

4 *Conjunctivitis*. Conjunctival nodules are common and are opaque, grey, slightly elevated lesions. 'Millet-seed' nodules may involve the eyelid margins. Biopsy will help to confirm the diagnosis of sarcoidosis; even 'blind' biopsies may reveal the disease.

5 *Lacrimal gland involvement*. Decreased lacrimal gland secretion is not uncommon (keratoconjunctivitis sicca is a presenting feature in about 10% of cases). Sarcoidosis is one cause of Mikulicz's syndrome (bilateral swelling of the lacrimal and salivary glands). Sjögren's syndrome can coexist with sarcoidosis and poses particular diagnostic problems.

6 *Optic nerves*. These may be involved as part of a widespread involvement of the central nervous system or as unilateral retrobulbar disease. Papilloedema, retrobulbar neuritis and optic atrophy may result.

7 *Orbital involvement*. This may cause unilateral proptosis.

8 *Other ocular syndromes*.

(a) Lofgren's syndrome (erythema nodosum, bilateral hilar lymphadenopathy and acute iridocyclitis) is usually self-limiting.

(b) Heerfordt's syndrome includes uveitis, parotid gland enlargement, fever and cranial nerve palsies, usually of the facial nerve.

(c) Keratoconjunctivitis sicca with parotid and lacrimal gland enlargement.

(d) Lupus pernio, chronic iridocyclitis, bone cysts and pulmonary fibrosis.

Pulmonary and upper respiratory changes [11]

Pulmonary changes dominate the later stages of the disease, and progressive diminution of respiratory function is the most common cause of incapacity. All patients with clinical or radiographic evidence of pulmonary involvement should be referred to a chest physician, who will decide on the need for and timing of treatment.

Upper respiratory involvement is often associated with chronic pulmonary disease and may be asymptomatic. Nasal stuffiness or blockage, with crusting and a nasal discharge, are common [12]. Cartilage or bone may be destroyed.

Renal involvement [13]

Symptoms are rare, but scattered granulomas can be found at autopsy in up to 40% of patients. Renal failure may be secondary to granulomatous invasion or to hypercalcaemia.

Reticuloendothelial system involvement

Lymph nodes are enlarged in about 50% of patients and may provide a convenient site for biopsy. An enlarged spleen can be felt in about 15% of cases [14]; hypersplenism may cause thrombocytopenia [15].

Involvement of the liver and other organs

It is evident that no organ is exempt from the occasional deposit of sarcoidal granuloma, and the dermatologist, as much as the general physician, should attempt to delineate the full extent of the disease in all patients. In no disease is it more important to look repeatedly 'under the skin' for other signs. Liver granulomas are found in 63–87% of patients with sarcoidosis and mild elevation of the serum alkaline phosphatase or bilirubin is seen in up to 80% of cases [16] although the liver is only palpable in about 20% of patients.

Hypercalcaemia and hypercalciuria [17]

The frequency of hypercalcaemia varies greatly (from 2% to 40% in different series), but it is less common than hypercalciuria. In one series, 11% of 1760 sarcoid patients had hypercalcaemia, while 40% had hypercalciuria [18]. Persistent hypercalcaemia is manifest clinically as polyuria, nocturia or polydipsia in the absence of hypertension. It can cause nephrocalcinosis and renal failure. The details of the abnormal calcium metabolism in sarcoidosis are still debated: sarcoid granulomas can themselves produce 1,25-dihydroxyvitamin D [19], which may increase calcium absorption via the gut. Persistent hypercalcaemia is one indication for systemic steroid therapy.

Sarcoidosis and pregnancy

The condition may improve during pregnancy, only to relapse thereafter. Miscarriages and congenital abnormalities are not especially common [20].

Sarcoidosis of the skin

Between 20% and 35% of patients with systemic sarcoidosis have skin lesions [1], but cutaneous sarcoidosis can also occur without systemic disease. Significant pulmonary disease may be silent [2]. In six of 13 patients with cutaneous sarcoidosis, but without a past history of sarcoidosis, no other systemic signs of the disease were detected during prolonged follow-up [3]; in another series of 188 patients with cutaneous sarcoid, 50 had no systemic involvement [4]. Finally, the extent of any cutaneous lesions does not correlate with the extent of systemic disease.

Classification. This has been made more difficult by the use of eponyms which are no longer appropriate and which should now be discarded. A simple morphological classification is shown in Table 58.2, but more than one type of lesion may exist at the same time. The differences between the main patterns lie in the manner and extent of the involvement of the skin or subcutaneous tissues.

Table 58.2 Classification of sarcoidosis of the skin.

Type of cutaneous lesions	Stage of disease
Erythema nodosum	Acute ('benign')
Erythematous and erythematopapular	Acute and subacute
'Scar sarcoidosis'	Acute and subacute
Papular ('small nodular')	Acute and subacute
(Boeck) lichenoid variety	
Erythrodermic (Schaumann)	Subacute and chronic
Nodular	Subacute and chronic
Annular (or circinate)	
Angiolupoid (Brocq–Pautrier)	
Subcutaneous	
Plaque	Chronic
Lupus pernio	
Miscellaneous	Usually chronic
Ulcerative, psoriasiform, palmoplantar, ungual, mucosal	
Sarcoidosis of black Africans	

The specific lesions of sarcoidosis take the form of granulomatous infiltrates: erythema nodosum stands out from these as a non-specific accompaniment of early sarcoidosis without the characteristic sarcoidal granulomas.

Clinical features. The features of the specific cutaneous lesions arise from a dense accumulation of epithelioid cell granulomas in the dermis. In the deep nodular and infiltrative types, the subcutaneous tissue is involved by extension. The lesions of sarcoidosis are generally recognizable as nodules or plaques with a greater degree of infiltration than would be expected from their surface appearance. Their colour ranges from yellow ochre to the livid violaceous hue which is most marked in lupus pernio. On diascopy, a pale yellowish-grey colour remains; sometimes, individual nodules are apparent. There is a tendency to form annular lesions. The epidermis is rarely affected, except for a light scaling, but some degree of vascular dilatation is frequent, especially in angiolupoid sarcoid. Scarring is unusual except in the papular and annular forms.

There is no characteristic distribution, though the small nodular type tends to involve the extensor aspects of the limbs, and rarely the trunk, while the large nodular type affects predominantly the face, hands and trunk. The manifestations of the disease vary from country to country: mucosal involvement, for instance, is rare in France but common in Scandinavia.

Classical forms

Angiolupoid form

A rare but characteristic variety. It affects women predominantly, almost always occurring at the side of the bridge of the nose towards the corner of the eye, below the

Fig. 58.5 Annular sarcoidosis of the face.

inner edge of the eyebrow, or on the adjacent area of cheek. There are seldom more than two tumours. They are soft and hemispherical, with a well-marked orange-red or reddish-brown colour and of a more livid hue than other forms. This is due to the marked telangiectatic component, which alters the normal grey-yellow appearance on diascopy. There is little tendency to spontaneous resolution.

Annular forms (Fig. 58.5)

Annular lesions were seen in 32 of 188 white subjects with cutaneous sarcoid lesions [1] and occurred mainly in the chronic stage. They are formed by peripheral evolution and central clearing. They occur particularly on the forehead, face and neck. The central area may become depigmented and scarred. Ulceration is rare. The lesions may resemble annular necrobiosis of the scalp [2], but can be differentiated histologically. Diffuse papular forms may also show an annular configuration.

Erythema nodosum

Sarcoidosis is but one of the many causes of erythema nodosum—a subject dealt with in detail in Chapter 49. It occurs most often in the spring, in young women, and signals an early and usually 'benign' variety of sarcoidosis, with bilateral hilar lymphadenopathy and a tendency to involute spontaneously. Most cases resolve completely within 2 years.

The frequency with which erythema nodosum is reported in sarcoidosis varies from series to series, no doubt depending upon the selection of material. This was well shown in a worldwide survey of sarcoidosis [3] in which erythema nodosum pinpointed the onset of the disease in 600 (17%) of 3676 patients. The distribution was uneven between the countries studied, the condition affecting one-third of British patients and being less evident elsewhere. In a Danish series [1], 25 out of 188 patients with cutaneous sarcoidosis had erythema nodosum which tended to affect younger patients (mean age 30 years) than did infiltrative sarcoidal lesions (mean age 48 years).

Lupus pernio [4]

This is a relatively common skin manifestation of sarcoidosis. In a Danish series of 188 patients with cutaneous sarcoidosis, 22 had lupus pernio [1]; a British series of 147 patients with various skin lesions included 35 with lupus pernio [4]. It tended to affect older patients, was twice as common in women as in men, and was more common in Afro-Caribbeans than in their white counterparts.

Large bluish-red and dusky violaceous infiltrated nodules and plaques occur more or less symmetrically on the nose (Fig. 58.6), cheeks, ears, fingers, hands and toes (Fig. 58.7). The lesions may feel soft, doughy or

(Courtesy of Dr F.A. Ive, Dryburn Hospital, Durham, UK.) (c) Sarcoidosis of the terminal phalanx involving the nail. (d) Radiograph of the hand in a patient with finger involvement by sarcoidosis, showing lucent areas in the bones of the phalanges.

indurated. Discrete nodules with a typical appearance on diascopy may be found at the edge sometimes. The surface is often glistening, and the epidermis stretched, with large pilosebaceous follicles. Ulceration rarely occurs in the skin; gross mutilation, as in lupus vulgaris, never. Involved ear-lobes may become massive ('turkey ears'). Other chronic skin lesions, including plaques and subcutaneous nodules, may accompany lupus pernio. Scarring alopecia may occur on the scalp.

Nasal involvement is associated with swelling, ulceration or crusting of the nasal vestibule, and patients may present with difficulty in breathing. Submucous resection carries the risk of nasal septal perforation and collapse of the nose.

Lupus pernio tends to be associated particularly with other forms of chronic fibrotic sarcoidosis, including upper respiratory tract sarcoidosis, bone cysts, lacrimal gland and renal sarcoidosis, and with hyperglobulinaemia and hypercalcaemia.

Lupus pernio tends to persist: lesions of more than 2 years standing seldom resolve. The facial disfigurement it causes may lead to emotional scarring, which may justify aggressive lines of therapy including plastic surgery [5]. Topical camouflage is an important adjunct to this therapy.

Maculopapular and erythematous forms (Fig. 58.8)

This is separate from the papular form (see below). Transient 'prodromal' maculopapular eruptions were noted in the early stages of sarcoidosis in no less than eight of 33 patients who showed cutaneous signs of the disease [6] and are apparently seen most commonly by chest and general physicians. Diffuse forms of papular sarcoidosis do occur but are uncommon. Even less common are ill-defined patches of a lavender colour, sometimes slightly

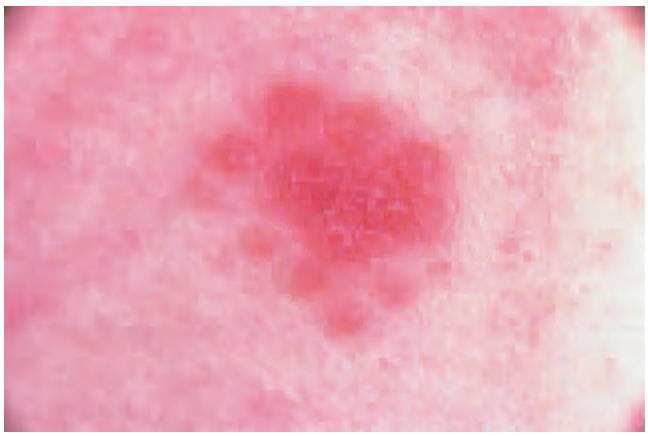

Fig. 58.8 Confluent scaly macules of the trunk due to sarcoidosis. (Courtesy of Dr R.H. Champion, Addenbrooke's Hospital, Cambridge, UK.)

scaly or lightly infiltrated. On the face, these simulate rosacea. Sand-like lupoid grains are sometimes seen on diascopy, but more frequently there is a yellow discoloration. Transient parotid swellings and hepatosplenomegaly may be seen [7]. Such cases pursue a long course, fluctuating in severity. Pruritic maculopapular lesions have been described [8].

Nodular forms (Fig. 58.9)

Here the lesions are larger than 5 mm, usually single or relatively few, and remain circumscribed. Red or yellowish-red at first, becoming violaceous or purplish-brown later, they are soft or firm, round and most often affect the proximal parts of the limbs, the trunk and the face. Dilated vessels may be seen on the surface of the lesions which are extremely indolent. As they involute, the centre may become depressed, and the lesions are eventually replaced by brownish telangiectatic marks, or yellowish-white atrophic and fibrotic patches.

Papular (small nodular type) (Figs 58.10 & 58.11)

The papules are hemispherical and vary in size from 1 to 5 mm. Orange or yellowish-brown at first, they later become brownish-red or violaceous, painless and torpid. Only a few lesions or several hundred may appear, arising in crops but eventually becoming stationary. They particularly affect the face (especially in Afro-Caribbeans) and extensor aspects of the limbs, but rarely the trunk or mucous membranes.

On diascopy, the lupoid grains are of a more opaque appearance and colour than those of lupus vulgaris, resembling grains of sand. If probed with a needle they feel firm. When lesions disappear they often leave a pale, yellowish-white or telangiectatic scar. Occasionally they become confluent, merging into an erythematous plaque

(Fig. 58.12). A ringed nummular configuration was present in the second of Schaumann's four cases [9].

Widely disseminated, hard, shotty, subcutaneous papules can appear with the granulomas lying in the deep subcutaneous tissues and fascial planes. A lichenoid variety is discussed separately on p. 58.15.

Fig. 58.12 Plaque-type sarcoidosis affecting the face in a black African. (Courtesy of Dr J.E. Bothwell, Barnsley District General Hospital, Barnsley, UK.)

In general, the papular type carries a more favourable prognosis than do other types of infiltration. Confirmatory biopsy of other organs should be carried out, although this form may occur without other manifestations of the disease.

Histopathology. The infiltrate is in the high and mid-dermis. It may be hard to distinguish from acne agminata in which, however, caseation can be seen.

Fig. 58.13 Sarcoidosis. Lesions of the plaque type are present on the upper back. (Reproduced with permission from Harcourt Publishers, Ltd.)

Differential diagnosis. Lupus erythematosus can be mimicked. Papular forms of secondary syphilis are distinguished by the course and associated features of this disease. Occasionally, acne agminata (Chapter 43) presents difficulties.

Plaque form (Fig. 58.13)

It is convenient to keep this form distinct. It involves chiefly the limbs, shoulders, buttocks and thighs. The lesions are characteristically diffuse, and extend further than is apparent on the surface. They may form placards of an irregular shape with more superficial nodules superimposed, sometimes having a crescentic or serpiginous outline resembling tertiary syphilis. On the legs, they may closely resemble necrobiosis lipoidica (Fig. 58.14). They are very persistent.

Scar sarcoidosis (Fig. 58.15)

Sarcoidosis appearing in a scar may be the only cutaneous sign of the disease, and is therefore of diagnostic importance. Scar involvement was seen in 26 of 188 white patients with sarcoidosis [1], and may represent a form of Koebner phenomenon. Long-standing scars, often on the knees, become inflamed and infiltrated, giving rise to typical purplish-red lesions which turn brown as they fade. There is some resemblance to a keloid, but the lesions do not itch. This form of sarcoidosis is as common in men as in women [10].

Scar sarcoidosis occurs in three situations:

1 In the acute eruptive phase, following erythema nodosum, or in the scars of biopsies taken at that time.

2 At any later stage of the disease, sometimes moving in parallel with pulmonary changes and slightly in advance of iritis [6]. Exacerbation of the systemic disease may be preceded by this warning sign.

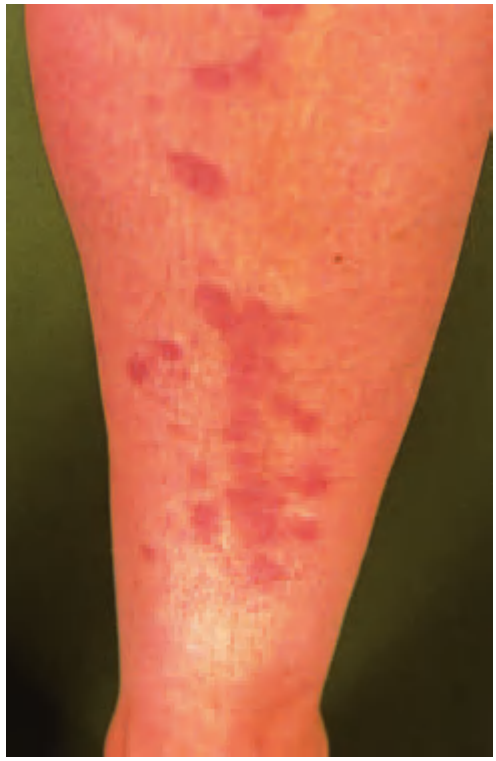

Fig. 58.14 Sarcoidosis of the plaque type on the shins, resembling necrobiosis lipoidica.

Fig. 58.15 Scar sarcoidosis on the presternal area. (Courtesy of Dr D.A. Burns, Leicester, UK.)

3 At inoculation sites—for example, after venepuncture [11], BCG or tuberculin tests. The involvement of tribal scarification marks is the commonest presentation of sarcoidosis in Nigeria [12,13].

The histology is typical. Confirmatory evidence of sarcoidosis should be sought (by chest radiography, and biopsy from other organs), as local sarcoidal reactions may occur in scars contaminated with silica. A silica granuloma in a scar may, rarely, progress into scar sarcoidosis [14]. Tattoos may also show sarcoidal reactions.

Subcutaneous sarcoidosis [15]

It seems likely that the first case report of subcutaneous sarcoidosis was indeed that of Darier and Roussy in 1904 [16], although they considered that their patient had tuberculosis. However, the term 'sarcoid of Darier–Roussy' has been used so often for granulomatous conditions other than sarcoidosis that it has become devalued and should be discarded.

Nevertheless, subcutaneous sarcoidosis does exist, although it is rare, especially in white people [17]. It takes the form of tender or painless persistent nodules, most often on the extremities of middle-aged patients. Systemic involvement is usually present, sometimes as hilar lymphadenopathy [18].

Histopathology. The infiltrate is naturally greater in nodular lesions but remains circumscribed. In the subcutaneous form, the sarcoid process may at first be located in the septa and at the periphery of the fat lobules, eventually replacing the lobules with granulomatous nodules. In the angio-lupoid form, vascular dilatation is prominent.

Differential diagnosis. Lymphocytoma cutis can be separated by its histology. Four other diseases cause particular difficulty, and serial sectioning and cultures of biopsy material may be necessary. They are as follows:

1 *Tuberculoid leprosy*. Distinguished by loss of thermal appreciation and of the histamine flare, a positive Mitsuda test and invasion of nerves.

2 *Lupus vulgaris*. In its exuberant form, this can scarcely be distinguished, although vitropression is said to reveal more translucent nodules of an 'apple jelly' rather than a greyish-yellow colour. Ulceration and scarring ultimately occur. Histology helps, but does not decide: a therapeutic test with antituberculous drugs does.

3 *Lupoid leishmaniasis*. The same difficulties exist clinically and histologically. Leishman–Donovan bodies are rarely found. The Kveim test is negative.

4 *Local sarcoid reaction*. By definition, this is confined to local areas or sites of trauma. There are no other signs of sarcoidosis, and the Kveim test is negative.

Unusual and atypical forms

In addition to the 'classical' forms of the disease described above, a wide variety of unusual forms have been recorded, particularly in Afro-Caribbeans.

Alopecia

Alopecia of the scalp due to sarcoidosis is well recognized [1,2]. Alopecia of the shin has been a presenting sign of the disease [3]. Sarcoidal granulomas were found on histology, and the Kveim test was positive.

Atrophic forms

The rare atrophic types of cutaneous sarcoidosis may be localized to the legs [4] or generalized [5–7]. It is usually accompanied by ulceration.

Erythrodermic sarcoidosis

This is extremely rare. Red scaling patches extend and merge into infiltrated brownish-red sheets. Lymphadenopathy is usually pronounced. During resolution, typical papules and nodules may separate from the plaque, which gradually loses its infiltration and disappears. A reticulate yellowish stippling may be seen as it resolves. One unique case was associated with periarteritis and ulceration [8]; in another patient, a 6-year-old boy, the eruption resembled pityriasis rubra pilaris [9].

Hypopigmentation

Macular hypopigmentation or hypopigmented areas around a central indurated lesion were first recorded in eight of 145 patients (mostly Afro-Caribbeans) with sarcoidosis [10]. There have been several subsequent reports [11–13]. Lesions vary from 0.2 to 1 cm in diameter and occur mainly on the limbs [13]. They may be tender, but are not anaesthetic, and may be the first sign of the disease [14].

Histologically, epithelioid cell granulomas are usually present in the dermis; occasionally the changes are non-specific [11,14]. The melanocytes show degenerative changes but electron-microscopy studies have not been helpful [11]. The differential diagnosis includes leprosy, post-inflammatory hypopigmentation, idiopathic guttate hypomelanosis and pityriasis lichenoides chronica [15]. The condition does not respond to corticosteroids [11], but may repigment after prolonged psoralen and UVA (PUVA) therapy [14].

Ichthyosiform sarcoidosis [16–18]

More than 19 cases of ichthyosiform sarcoidosis are reported [18]. It usually occurs on the lower legs as large, thick, polygonal adherent scales that may or may not overlie dark red papules and nodules. Biopsy reveals epidermal changes consistent with ichthyosis vulgaris, as well as non-caseating epithelioid granulomas in the dermis, even in the absence of clinically detectable dermal abnormality. Almost all patients with ichthyosiform sarcoidosis have systemic involvement. In patients with acquired ichthyosis, biopsy may be worthwhile to exclude occult sarcoidosis.

Lichenoid forms

The lichenoid variety of sarcoidosis consists of pinhead-sized papules, skin-coloured, erythematous or yellowish in hue, that can be follicular or closely grouped in round or oval clusters and show slight scaling [18]. It constitutes 1–2% of skin sarcoidosis and may pose difficulties in diagnosis [19]. Although the lichenoid form resembles lichen planus or lichen scrofulosorum, the tuberculin test is negative, the course is indolent and the histology characteristic. Arguments have, however, been adduced in favour in a mycobacterial cause, because of atypical features which are sometimes present [20].

Miscellaneous forms

Many have been described, including the following: pseudotumoral [21], psoriasiform [22,23] and pruriginous varieties [24]; lupus erythematosus-like and lupoid forms; a bizarre polymorphous light eruption type; perifollicular pustules and papules widely scattered over the body; keratotic lesions of the palms simulating psoriasis or syphilis [25], thrombophlebitis [26]; vulval disease [27]; and breast mass [28,29]. Hyperpigmentation may occur, particularly in Afro-Caribbeans [10]. Oedema of the lower leg, usually

unilateral, is an uncommon manifestation of sarcoidosis [30]. It may occur due to vascular or lymphatic compression from enlarged inguinal or parailiac lymph nodes, or from direct granulomatous infiltration of the skin. Calcinosis with subcutaneous plaques was present in one unusual patient [31]. Pain after alcohol or showering has also been described.

Mucosal involvement

Buccal lesions or tongue involvement are occasionally found when sought [1]. The nasal mucosa is often affected in lupus pernio [2,3] and is a convenient site for biopsy. Difficulty in breathing, or a purulent catarrh, may be the presenting symptom. Yellowish-brown nodules or a diffuse infiltration with crusting occur [4]. The nasal bones may be involved; or the nasal cartilage may collapse [5]. Nodules with a hyperpigmented halo, diffuse pale-yellow plaques, or ulceration may be found on the buccal mucosa, palate, larynx or tongue.

Nail involvement [6]

This is rare, affecting only one in 400 patients with sarcoidosis in one series [7]. Changes recorded have included the following: thickening, opacity, fragility, layering, convexity, longitudinal ridging, pitting, atrophy, nail loss, pterygium and red or brown discoloration of the nail beds. Surrounding skin changes may be minimal, but in almost every case the nail abnormalities will be accompanied by cysts in the bone of the underlying terminal phalanx and a chronic disease course, often with lupus pernio.

Sarcoidosis in black Africans and African Americans (Fig. 58.16)

The lesions are often exuberant and bizarre, and the skin is especially affected, although erythema nodosum is uncommon [8,9]. Psoriasiform or lupus erythematosus-like

Fig. 58.16 Sarcoidosis in a black African, showing typical verrucous changes. (Courtesy of Dr J.E. Bothwell, Barnsley District General Hospital, Barnsley, UK.)

Fig. 58.17 Extensive ulceration of the foot and ankle due to sarcoidosis. (Courtesy of Dr R.H. Champion, Addenbrooke's Hospital, Cambridge, UK.)

lesions [10], verrucous and keloid-like forms [11,12], 'atypical' plaques or nodules [13], ulcerative lesions resembling papulonecrotic tuberculides [11], giant nodular forms and other atypical lesions occur, with more typical manifestations elsewhere. Shiny, waxy papules are a particular presentation [8]. The histological features may be equivocal and tuberculosis is a common cause of death. When the lesions are annular, histoplasmosis must be excluded [14].

Small ulcerating nodules, sometimes associated with deep, softer non-ulcerative lesions, have been described [10]. The histology is that of sarcoidosis but the infiltrate is diffuse, fibroblasts are numerous and the vessel walls in the subcutis are thickened.

Skin lesions in children [15]

Sarcoidosis in children is uncommon; a presentation with erythema nodosum is especially so. In one series of 28 children [16], nine had skin lesions and three developed serious eye or joint symptoms. Though papular forms of skin sarcoidosis are seen in older children, younger ones may present with uveitis or keratitis, progressive joint disease and skin lesions consisting of maculopapules, reddish-brown confluent plaques or eczema-like lesions [17–19]. Other reported cases have shown unusual features: follicular [20], miliary [21] or erythrodermic lesions with keratotic pitting [22]. The chest radiograph is often normal [17]. The severity of eye or joint involvement may justify corticosteroid therapy, often for several years, despite the risks at this early stage.

Ulcerated sarcoidosis [23] (Fig. 58.17)

This is a rare presentation: more than 35 cases have now been described, most of which were reported individually [24,25]. It usually occurs in women and black people. Ulcers develop most often on the legs [26] and may be punched-out and apparently appearing *de novo*, or arising on existing nodules and plaques, or, rarely, on extensive atrophic areas [27]. The possibility of necrobiosis lipoidica should be kept in mind, particularly in patients with diabetes [25]. The distribution of the ulcers may be unusual: a flexural distribution in one patient resembled that of metastatic Crohn's disease [28]. The granuloma may be of necrotizing type, with caseation or minimal fibrinoid necrosis [29]. True primary vasculitic changes are usually absent.

Verrucose forms [30]

Papular lesions may progress to crusted verrucose and sometimes ulcerative lesions [31] which may mimic halogen eruptions, fungal infections or tuberculosis.

Associated diseases

Some associated diseases are understandable against the background of depressed immunological responses; some are due to a simple blocking of the activity of an organ by granulomatous infiltration, and others are uncommon and poorly understood associations. In a disease as common as sarcoidosis, coincidental associations can be expected from time to time.

Infections

A critical review of previous reports of invasive fungal infections such as cryptococcosis [1] has suggested that in many of these the entire cause of the granulomatous illness was infection, rather than sarcoidosis complicated by infection. In the series which accompanied the review, 122 patients with sarcoidosis were, in fact, found to be remarkably free of infections: three had *Aspergillus* mycetomas in cystic areas in the lung and another also had pulmonary tuberculosis, but the only extrathoracic manifestation was one case of disseminated zoster. Patients with sarcoidosis, however, are prone to extensive and stubborn wart virus infections, despite an unusually high prevalence of circulating antibodies to wart antigen [2].

Immunologically mediated conditions

In a series of 190 female patients with sarcoidosis, four had hyperthyroidism and four had Hashimoto's thyroiditis with antibodies [3]. Another patient in the same series had myxoedema and Addison's disease. Chronic urticaria may occur more frequently than would be expected by chance [4]. At least 14 cases of associated sarcoidosis and connective tissue disorders have been described [5].

Effects of infiltration

Granulomas, especially in the pituitary or thyroid, may cause endocrine disease. Invasion of the thyroid may be without effect or, if massive, can cause hypothyroidism [6]. Cushing's syndrome and diabetes insipidus, secondary to involvement of the pituitary, have been reported. The list of such cases may be extended to cover most endocrine diseases.

Vasculitis with sarcoidosis

There are occasional but well-authenticated reports of cutaneous vasculitis occurring in the course of sarcoidosis, usually early in the disease. In a series of six patients, five of them children, the vasculitis was associated with systemic illness including fever, lymphadenopathy, musculoskeletal and eye disease, and systemic steroids were given [7]. Three of these patients, all African Americans, had large-vessel disease on angiography. Erythema nodosum itself may be regarded as a form of vasculitis. Skin biopsy may show foci of epithelioid cell granulomas centred on damaged vessels [8]. An apparently unique case of leukocytoclastic vasculitis with epithelioid cell granulomas has been described [9] and annular forms documented [10]. The occurrence of vasculitis fits with the presence of circulating immune complexes in the early stages of sarcoidosis.

Malignancy

An analysis of 131 cases of coincident sarcoidosis and malignancy suggests an increased risk of developing lymphoproliferative disease [11]. The relationship between sarcoidosis and solid tumours was less clear-cut, but most marked with carcinoma of the lung. Sarcoidosis may precede the development of a lymphoma (the 'sarcoidosis–lymphoma syndrome') by 18 months to 28 years [12]. All types of lymphoma may develop [12]. Another study [13] found an increased incidence of thyroid cancer and leukaemia. Five patients with sarcoidosis developed multiple myeloma (four several years later and one at the time of diagnosis of the sarcoidosis) [14].

Necrobiosis lipoidica and granuloma annulare

There have been several reports of patients with sarcoidosis and necrobiosis lipoidica [15,16], and with sarcoidosis and granuloma annulare [17]. To complete the circle of association, patients with both necrobiosis lipoidica and granuloma annulare have also been described. In one African American woman with pulmonary sarcoid, fresh lesions of histologically typical granuloma annulare were adjacent to histologically classic sarcoid papules, suggesting that the former progressed to the later [18].

These associations may be fortuitous, but histological overlap between sarcoidosis and necrobiosis may occasionally be seen [19]. Granuloma annulare is important in the differential diagnosis of sarcoidosis, as is necrobiosis, particularly of the scalp and face. Granuloma annulare shares some aspects of collagen metabolism with sar-

coidosis [20], but in granuloma annulare the Kveim test is negative [21,22].

Other associations

Associations with psoriasis and gout [23], pyoderma gangrenosum [24,25] and secondary syphilis [26] have been reported, but seem likely to have been coincidental. Two Kveim-positive patients were found to have primary biliary cirrhosis [27], and a sarcoidal plaque on the face has been described in a woman with primary biliary cirrhosis [28]. Two cases of porphyria cutanea tarda have also been reported [29,30].

Course and prognosis [1]

The prognosis of sarcoidosis is difficult to assess because of its frequent 'clinical silence' and the uncertainty of its onset. Several attempts have been made to list favourable and unfavourable factors [2–4], most of which have been mentioned elsewhere in this chapter. Table 58.3 is an attempt to summarize the course of sarcoidosis. The prognosis is generally better in females, in those with less severe pulmonary disease at the onset and in patients with a positive tuberculin test and normal globulin levels [4]. HLA-B8 may be associated with a tendency to spontaneous resolution [5]. In the African American, the course may be fulminant.

Table 58.3 The course of sarcoidosis.

Prognosis	Stage	Cardinal features*	Unfavourable events
? Abortive cases, or may be absent	Prodromal	Malaise, fatigue, fever, depression, polyarthralgia	–
60% subside in 6–18 months	Acute	*Erythema nodosum*, *scar sarcoidosis*, *erythematopapular rashes*, polyarthralgia, iridocyclitis, lymphadenopathy	? Sudden cardiac death
	Subacute	*Papular*, *nodular* or *scar*, pulmonary changes, lymphadenopathy, recurrent iritis, parotitis, spleen, liver	May be cardiac death
Prolonged intermission or resolution	Intermittent Chronic		
Gradual, often slow	Progressive	*Lupus pernio*, *erythrodermic*, bone cysts, cataracts, hypersplenism	Blindness
Irreversible but often extremely slow and patient survives, though disabled	Fibrotic regression	Progressive pulmonary fibrosis, nephritis, nephrosis, cataracts, glaucoma	Blindness, death
	Functional failure	Emphysema, cor pulmonale, nephrolithiasis, renal failure, tuberculosis	Death

* Skin signs are in *italics*.

About 60% of patients with stage I pulmonary disease will have recovered within 2 years [6,7]. The presence of erythema nodosum does not alter the prognosis. In the classic forms of the disease, the prognosis is quite different: only a small proportion of those in pulmonary stage II and beyond resolve spontaneously [7]. Morbidity from blindness, pulmonary disease, renal failure and the cosmetic and social effects of a disfiguring skin lesion are the not inconsiderable burdens of a disease that follows a relentless course of smouldering activity [8]. Despite corticosteroid therapy, half the patients continue to have abnormal respiratory function.

Most types of cutaneous sarcoidosis occur in the subacute and chronic stages, and their course is usually prolonged. Many papules and nodules tend to resolve within months or years, but plaques are even more resistant. Lupus pernio is especially persistent and is often accompanied by the involvement of other organs, further modifying the prognosis.

Mortality in sarcoidosis [9] has been estimated at 3–6% [4,7]. However, this may ignore undiagnosed deaths from cardiac involvement. Renal involvement is also a potential cause of death as, rarely, is progressive pulmonary disease.

Investigations

The most important single criterion for the diagnosis of sarcoidosis is the finding of typical granulomas histologically [1], but the need for histological support varies with the pattern of clinical features. For example, in the UK, patients with erythema nodosum and bilateral hilar gland enlargement may not require biopsy, although this is necessary in other forms of the disease. Other investigations may add weight to the diagnosis, and may be useful in monitoring the activity of the disease.

Biopsy

The involvement of several organs will allow the clinician to select the biopsy site best suited to the individual patient. The dermatologist has the advantage of dealing with a site easily accessible for biopsy, but it may still be necessary to confirm the presence of sarcoidosis as opposed to a sarcoidal reaction, and biopsies from other organs are then needed. In one series [2] involving 292 biopsies from 10 sites, 87% were positive, but biopsies from the skin proved less reliable than those from lymph nodes, parotid gland or nasal mucosa. Scars that become infiltrated provide acceptable histological evidence of sarcoidosis. A mucosal biopsy is an alternative to skin biopsy in lupus pernio. A conjunctival biopsy should be considered, and may be positive even if no obvious lesions can be seen [3], as may a biopsy of the lower lip [4].

A range of techniques is now available to obtain biopsy material from other areas. These include the removal of epitrochlear or scalene lymph nodes, mediastinoscopy with mediastinal node biopsy, liver biopsy, gastrocnemius muscle biopsy (even when there are no muscle symptoms) [5], and transbronchial lung biopsy or mediastinal node biopsy through a flexible fibrescope [6]. The latter may be the most helpful and least disturbing for patients with suspected systemic sarcoidosis and intrathoracic manifestations, but carries some risk of pneumothorax. Bronchoalveolar lavage in patients with active pulmonary involvement shows an increase in the number of helper T lymphocytes present, but this is not specific for sarcoidosis.

Kveim test [7,8]

Fifty years after Kveim described it, the test which bears his name is still something of an immunological puzzle. Until recently, it was a simple and useful way of supporting a diagnosis of sarcoidosis. The Kveim test is no longer available due to the infective risk of injecting human tissue, but nevertheless details of the test are of interest and will be outlined.

The test depends upon the ability of sarcoidal tissue, usually from the spleen of an affected individual, to evoke epithelioid cell granulomas like those of sarcoidosis when injected intradermally into a patient with sarcoidosis. Positive results were found in a high proportion of patients with active early disease, but became less common in chronic disease.

The technique used is important. An easily relocated site, usually on the forearms, was injected intradermally with 0.1–0.2 mL of shaken antigen using a 1-mL tuberculin syringe and a narrow-gauge needle. In a positive reaction, a papule usually appeared within 2–3 weeks and slowly increased in size. It was best excised at 6 weeks for histology.

A positive result was the unequivocal presence of an epithelioid granuloma, exactly mimicking the natural disease, though usually less profuse. Histological interpretation was difficult in 10–20% of responses; epithelioid

cells may be diffusely scattered in the dermis or granulomatous aggregates of histiocytes may not be arranged in the usual circumscribed foci of an epithelioid granuloma. The occasional presence of birefringent particles can make interpretation more complicated. False-positive foreign body-type reactions had to be disregarded.

An adequate Kveim antigen had to be sensitive enough to detect at least 60% of cases of active sarcoidosis and specific enough to exclude all but 2–3% of non-sarcoid cases [9]. To achieve this, the antigen had to be validated by extensive tests on normal subjects and on patients with other conditions, such as Crohn's disease, in which false-positive reactions are known to occur [10]. The safety of the Kveim test with regard to it being free from infective agents, e.g. human immunodeficiency virus, cannot be guaranteed and hence it is not available at the present time. The active principle in Kveim material was heat-stable, and also stable on storage, though some loss of sensitivity was observed over a period of years [11]. The active material is particulate and probably lies within the membrane-containing elements of the sarcoidal tissue [12], although its exact constitution has not been established. It is not known whether the active ingredient is an antigen derived from the aetiological agent of sarcoidosis or whether a positive Kveim response is a manifestation of host predisposition to form granulomas on antigenic stimulation. These two hypotheses are not mutually exclusive.

Other investigations

A chest radiograph should be taken in all cases, no matter what the clinical presentation. Hand radiographs show cystic changes only in chronic disease, and usually only when there are clinical abnormalities in the fingers. Sputum should be examined and cultured for acid-fast bacilli, and a weak or negative tuberculin response may add weight to the diagnosis of sarcoidosis. An ECG is needed to exclude cardiac involvement. Pulmonary function tests may also be indicated. High-resolution computed tomography of the chest is helpful to define lung field involvement.

The erythrocyte sedimentation rate (ESR) is usually raised in active phases, and a rise in the ESR 6–8 weeks after the onset of erythema nodosum may indicate lung involvement [13]. Slight anaemia, neutropenia or lymphopenia are often noted, but these changes, and the hypergammaglobulinaemia which occurs in over half the chronic cases, are not of proven diagnostic or prognostic significance. Serum calcium should be checked, as an increase may lead to chronic renal failure.

Angiotensin-converting enzyme (ACE) [14] is produced by sarcoidal granulomas. Raised serum levels are found in some 60% of patients with sarcoidosis, but are also present in other conditions such as diabetes and alcoholic liver disease. This limits the value of the test as a diagnostic aid, although it remains a useful monitor of disease activity.

Other markers of disease activity [15] vary in their usefulness in sarcoidosis. They include lysozyme, β_2-microglobulin, neopterin, collagenase and fibronectin levels. The serum level of soluble intercellular adhesion molecule 1 (ICAM-1), which is shed from cell surfaces and is a measure of the inflammatory response, mirrors disease activity in active sarcoidosis [16]. Hydroxyprolinuria may indicate disease activity. Radioactive gallium-67 uptake occurs in some pulmonary infections and neoplasms as well as sarcoidosis, but if these can be excluded it provides a way of separating active from fibrotic pulmonary disease.

Treatment [1,2]

The chance of spontaneous remission favours a conservative approach to systemic therapy, which will usually carry the hazards of long-term immunosuppression, such as opportunistic mycobacterial infection [3] or a gross proliferation of viral warts [4]. At any time the pattern of the disease may change, but an expectant policy is often best if the course is not progressive and if vital structures are not involved.

Johns *et al*. [1] list the most frequent indications for systemic treatment:

1 Symptomatic pulmonary disease
2 Progressive or persistent parenchymal lung disease after 2 years
3 Posterior ocular disease or anterior disease not responding to local steroids
4 Persistent fever or weight loss
5 Liver disease with significant dysfunction or hepatosplenomegaly
6 Disfiguring skin disease or lymphadenopathy
7 Nervous system disease
8 Hypercalcaemia
9 Myocardial disease
10 Myopathy or myositis
11 Thrombocytopenia
12 Other significant organ involvement—for example, kidneys.

A major determinant is the degree to which a patient's normal life is disrupted by the disease, but objective measurements, such as pulmonary function tests, may be a more valuable way of monitoring therapy than symptoms alone.

A few patients with severe cardiac or pulmonary disease have come to transplantation; the sarcoidosis does not necessarily recur in the graft, perhaps due to the use of potent immunosuppressive agents [5].

In the skin clinic any decisions about the use of systemic therapy must take into account the seriousness of the accompanying internal involvement and the natural history of the particular type of skin lesion. Papular lesions, for example, are likely to fade without treatment, whereas lupus pernio is not.

Topical therapy

High-potency topical corticosteroids may sometimes prove helpful, as may intralesional triamcinolone injections. Tacrolimus, which inhibits hapten-induced production of Th1 cytokines and TNF-α by T cells, was recently reported to be beneficial when used topically in cutaneous sarcoidosis [6]. Cryotherapy and radiotherapy have occasionally been used [2]. PUVA therapy has been successful in hypopigmented sarcoidosis [7] and in erythrodermic sarcoidosis [2]. In certain types of cutaneous sarcoidosis, e.g. lupus pernio, cosmetic camouflage advice is helpful.

Systemic therapy

Corticosteroids are usually the most effective treatment, given at first in a relatively high dose, possibly 30 or 40 mg prednisolone daily, and then tapered over a period of several weeks to a lower maintenance dose of possibly 15 mg on alternate days. The length of the course of treatment will vary from case to case but is usually at least 6 months. Intravenous 'pulse' methylprednisolone, for example 1 g/week for 8 weeks, may be effective in those with the most severe neurological disease [5].

Cytostatic drugs may be tried if corticosteroids are contra-indicated or have been ineffective. Methotrexate has been used with some success [8] and has been recommended for use with corticosteroids for lupus pernio [9]. Chlorambucil [10] has its advocates, and azathioprine may be used for its steroid-sparing effect.

Other drugs which have been tried with some success include allopurinol [11,12] and antimalarials [13]. Minocycline, 200 mg daily for 12 months, produced complete resolution in eight and partial improvement in two out of 12 patients with cutaneous sarcoidosis [14]. Levamisole is not recommended [15]. The response to ciclosporin has been variable [5]. Isotretinoin and thalidomide have induced complete resolution in one case each of cutaneous sarcoidosis [16,17].

Laser and ultraviolet radiation

Lupus pernio has been improved using a flashlamp pulsed-dye laser [18], and UVA1 (340–440 nm) has been effective for forehead plaque sarcoid [19].

Other sarcoidal reactions

A number of infections and chemicals may cause sarcoid-like granulomas, although their features are seldom as clear-cut histologically [1,2]. Such reactions differ from sarcoidosis in several important respects:

1 They involve only those organs normally affected by the disease in question, or on the route of absorption or deposition of the chemical.

2 The Kveim test when performed has been negative.

3 The tuberculin reaction is usually not depressed.

The following text describes reactions which should be borne in mind in the differential diagnosis of sarcoidosis.

Infections

The problem of differentiating tuberculosis and leprosy from sarcoidosis has been dealt with on p. 58.5. Syphilis, brucellosis, fungus infections and some bacterial or viral diseases may produce a sarcoidal type of tissue response but any clinical resemblance is usually superficial.

Foreign materials

Silicates occur in many common materials—for example, in talc, kaolin, quartz and as a constituent of slate, brick, gravel and coal. Silicosis from the inhalation of silica dust is an important industrial hazard, but wounds containing crystals of silica normally remain unchanged indefinitely. Talc has been the cause of granulomas in surgical wounds when used as a glove powder. The long delay between the implantation of silica and the appearance of the granuloma suggests that the silica may not be the immediate cause of the reaction. In one case, a silica granuloma has progressed to scar sarcoidosis [3]. It is wise to examine all sarcoidal reactions under polarized light: silica particles are doubly refractile and differ from Schaumann bodies in that the crystalline material is spiculated but not laminated.

Beryllium reactions [2] are rarely seen now that beryllium is no longer used in the manufacture of fluorescent lights. The cutaneous lesions of systemic berylliosis are indistinguishable histologically from those of sarcoidosis, whilst the granulomas due to local beryllium implantation show marked central necrosis.

Zirconium granulomas may form in the axillae as a delayed hypersensitivity reaction to the zirconium content of deodorants [1,4].

Sea-urchin spines may induce foreign-body or sarcoidal granulomas [5]. The exact cause of the reaction is unknown. Intralesional triamcinolone may help speed resolution if excision is not practicable [6].

Foreign-body reactions to lipids (fat granulomas, epidermal cysts) and reactions to other lipid and non-lipid extraneous matter are variable and often show many giant cells.

(b)

Fig. 58.18 (a) Sarcoidal reaction to pigment in a tattoo. (Courtesy of Dr P. Collins, St Vincent's Hospital, Dublin, Eire.) (b) Histology of a sarcoidal reaction to two varieties of tattoo pigment, one opaque and one green. (Courtesy of Dr T.J. Stephenson, Royal Hallamshire Hospital, Sheffield, UK.)

Thesaurosis [7] is a pulmonary infiltration occurring in those heavily exposed to polyvinyl–pyrrolidine hair sprays in hairdressing procedures.

Sarcoidal reactions in tattoos (Fig. 58.18). A granulomatous dermal infiltrate may accompany sensitization reactions to any pigment of the tattoo, or may occur alone. Less commonly, a pure sarcoidal reaction is present as an indolent lump within a tattooed area. Regional lymph nodes may also show a sarcoidal reaction [8]. Such lesions may be accompanied by other signs of sarcoidosis or a

positive Kveim test [9,10] and are occasionally the only skin manifestation of the disease [11]. The pulmonary disease may be silent [12]. The association of a sarcoidal reaction in a cobalt tattoo with uveitis in three cases and with erythema nodosum in one [13] emphasizes the need for a thorough investigation of all cases showing a sarcoidal type of infiltrate.

Other reactions. A sarcoid-like reaction has been reported from exposure to acrylic or nylon fibres, either as dust or from walking on acrylic carpets [14]. The significance of a sarcoidal reaction to ear piercing [15] was not clear in the presence of a positive Kveim test.

Crohn's disease

The similarity between the histological and immunological features of Crohn's disease and sarcoidosis led to speculation about a common aetiology. However, the rarity of sarcoidosis of the intestine makes this unlikely, and earlier reports of positive Kveim tests in patients with Crohn's disease have not been fully substantiated [16].

Whipple's disease

Sarcoid-like changes have been recorded in the skin and lymphatic glands [17]. Diarrhoea is an important distinguishing clinical feature and jejunal biopsy will confirm the correct diagnosis (Chapter 59).

Farmer's lung [18]

This is caused by the inhalation of mouldy hay containing fungal spores: sarcoid-type granulomas sometimes develop slowly around the air passages and the condition then runs a course not unlike pulmonary sarcoidosis.

Other conditions

Sarcoid-like granulomas can occur in the skin and lymph nodes of patients with lymphoma: most commonly in Hodgkin's disease [19], but also in non-Hodgkin's lymphoma [20,21]. Sarcoid reaction is described with other malignancies, e.g. papillary thyroid carcinoma [22].

Epithelioid cell granulomas may also be a feature of rosacea [23]. In one unusual case [24], rosacea-like facial lesions, with a sarcoidal histology, were seen in a patient with a poorly differentiated lymphoma.

An epithelioid cell granuloma histology is found in granulomatous cheilitis and the Melkersson–Rosenthal syndrome, sometimes in necrobiosis lipoidica [25] and in granulomatosis disciformis, and has been reported in giant cell and other forms of arteritis [26].

Chapter 59

Systemic Disease and the Skin

R.M. Graham & N.H. Cox

Introduction

The systemic associations of skin diseases have been stressed throughout this book. In this chapter, many of these associations are listed again, along with some other important conditions. They are grouped so as to be helpful to the general physician or internist. It is hoped that such a presentation will also be useful to the dermatologist who is asked to help in the diagnosis of obscure internal disease. Many further references may be found by turning to the chapter in which the relevant dermatosis is considered in detail. The texts listed below [1–4] provide much more information than it is possible to give here, and are also a source of additional references.

Endocrine disorders

The physiological effects of hormones on pigmentation, hair growth, sebaceous glands and connective tissue have been described in other chapters. This section is limited to discussion of specific endocrine pathology with cutaneous features. Greater detail is provided in several general references [1–5].

Pituitary syndromes

Hyperpituitarism [1–3]

Excessive secretion of growth hormone (GH, somatotrophin) causes an increase in plasma insulin-like growth factor-1 (IGF-1). These hormones stimulate synthesis of collagen and glycosaminoglycan in the skin and skeleton, leading to insidious hypertrophy of skin, subcutaneous tissues and viscera, and to periosteal bone growth. This causes acromegaly in the adult (most cases), and gigantism in children whose bony epiphyses have not yet closed.

Acromegaly (MIM *102200) and gigantism

Aetiology. The usual cause (over 95%) is a benign adenoma or hyperplasia of the eosinophilic cells of the adenohypophysis, producing GH and often prolactin. Other tumours, such as bronchial carcinoma, may occasionally cause acromegaly, usually by ectopic secretion of GH-releasing hormone (GH-RH). Individual, viable epidermal cells are larger than normal, and epidermal cell turnover is increased [4].

Clinical features. Periosteal new bone formation of the facial bones and skin causes the characteristic facies. Features are prognathism, frontal bossing, widely spaced teeth and acral hypertrophy, which causes elongated, blunt and thickened fingers. Dermatological features include a protruding, thickened lower lip, oedematous thick eyelids, a large and furrowed tongue (Fig. 59.1), triangular large ears, numerous skin tags ('fibroma molluscum'), widened skin pores, wet and oily skin due to hyperhidrosis and increased sebum production, acne and cutis gyrata of the scalp (Chapters 12 and 63) in more extreme cases. Hyperpigmentation develops in about half of the affected individuals due to increased levels of melanocyte-stimulating hormone (MSH), and acanthosis nigricans may occur. The scalp hair is initially coarse and there may be hirsutism, but later in the disease there is a decrease in gonadotrophin production, which causes the hair to become finer, with loss of secondary sexual hair. The nails are flat and wide and grow fast. Pachydermoperiostosis (Chapter 12) is an important differential diagnosis. In this disease, there is no macroglossia or prognathism, and the fingers are characteristically clubbed.

Non-cutaneous features include macroglossia, heart failure and hypertension due to left ventricular hypertrophy, visual field defect and headache due to the neoplasm, arthropathy, carpal tunnel syndrome and proximal myopathy.

Fig. 59.1 Acromegalic macroglossia.

Diagnosis. The clinical picture is in most cases suggestive of the diagnosis. Serum GH and prolactin levels are generally elevated, but vary considerably; plasma IGF-1 is a more reliable test of chronically elevated GH levels [5]. Failure of GH levels to suppress during glucose challenge, and GH-RH stimulation tests, help to confirm the diagnosis. Magnetic resonance imaging (MRI) confirms the site of the tumour in most cases.

Treatment. Neurosurgical removal of the tumour is the preferred treatment. Patients in whom this fails to achieve a cure may be treated with somatostatin analogues such as octreotide, or with bromocriptine [1–3,5,6].

Pituitary insufficiency [1–3,7]

Insufficiency of the adenohypophysis (anterior pituitary) may involve individual or multiple hormones. In classical hypopituitarism, all endocrine cell functions of the pituitary gland are involved to a varying degree. However, the clinical picture is influenced by the cause of hypopituitarism; for example, adenomas may produce GH or prolactin, but may also cause compression atrophy of cells producing gonadotrophins. Concurrent loss of function of the posterior pituitary may occur if there is a hypothalamic lesion, such as Langerhans' cell histiocytosis.

Aetiology. Over 95% of cases of hypopituitarism are due to pituitary cell destruction [6]. Familial hypopituitarism has a genetic basis due to mutations in Pit-1 or its precursor Prop-1, resulting in deficient production of GH, prolactin and thyrotrophin. Insufficiency of the adenohypophysis may occur due to:

- Neoplasia—adenomas (most), craniopharyngioma, metastases
- Infection—tuberculosis, abscess
- Trauma, surgical, iatrogenic
- Congenital—familial, 'empty sella syndrome'
- Vascular—Sheehan's syndrome (postpartum) and other infarction, bleeding, diabetes mellitus, vasculitis, antiphospholipid syndrome
- Idiopathic
- Hypothalamic—due to hypothalamic tumours, trauma, infiltration (Langerhans' cell histiocytosis, sarcoidosis), congenital causes of hypothalamic failure.

Clinical features. The various endocrine dysfunctions are typically insidious and less impressive than those seen in the primary glandular disorders. Pallor of the skin due to decreased MSH secretion results in generalized hypopigmentation, most apparent in the skin of the nipple areola and genitalia; in contrast with anaemia, the mucous membranes retain their normal colour. There is an increased sunburn tendency and lack of tanning, and there may be a degree of carotenaemia due to hypothyroidism. Loss of terminal hair due to decreased gonadotrophin secretion is observed in all patients, first in the axillae and later, but not invariably, in the pubic area. Fine wrinkling and dryness of the skin simulates advanced age. The face appears expressionless due to diminution of the facial skinfolds. The activity of sebaceous and sweat glands is reduced. Onycholysis, longitudinal ridging and brownish discoloration of the nail plate may be seen.

Pituitary dwarfism is characterized by proportionate retardation of somatic growth in conjunction with normal mental development. The cutaneous changes of old age may develop prematurely from the third decade onwards.

Diagnosis and treatment. Measurement of hormone levels—prolactin, IGF-1, thyroid-stimulating hormone (TSH) and thyroxine (T_4), cortisol, gonadotrophins—is required to detect subnormal levels; prolactin or IGF-1 may be elevated if the cause of hypopituitarism is a pituitary tumour. Posterior pituitary function should also be assessed, and visual field testing and MRI should be performed. Treatment is of the primary cause, together with hormone replacement [6,7].

Adrenal syndromes

Cushing's disease and syndrome [1–3]

Chronic glucocorticoid excess may occur due to increased secretion of adrenocorticotrophic hormone (ACTH, corticotrophin), usually from the pituitary (MIM *219090), due to glucocorticoid hypersecretion of adrenal origin (ACTH-independent, MIM *219080) or due to exogenous administration of glucocorticoids.

Aetiology. The commonest ACTH-dependent cause is that due to a pituitary adenoma (Cushing's disease or pituitary-dependent Cushing's syndrome), which accounts for about 70% of spontaneous cases; pituitary overproduction of ACTH leads to adrenal hyperplasia and thus to glucocorticoid excess. Other ACTH-dependent causes include the ectopic ACTH syndrome (for example, from small cell lung cancer or bronchial carcinoids) and, rarely, ectopic corticotrophin-releasing hormone (CRH) syndrome. ACTH-independent causes include cortisol-producing adrenocortical adenomas and carcinomas, various types of bilateral adrenal hyperplasia (including the Carney complex), and commonly iatrogenic causes such as long-term administration of systemic glucocorticoids. The glucocorticoid hormones, among other effects, impair synthesis of collagen and mucopolysaccharides and thus lead to atrophy and vascular fragility of the skin.

Clinical features. The cutaneous manifestations are quite similar whether caused by endogenous or iatrogenic hypercorticism, although there are additional effects mediated by androgens in patients with adrenal disease. Truncal obesity (classically deposits of fat over the clavicles and back of the neck, the 'buffalo hump') and facial fullness and plethora ('moon facies') are most frequent, and contrast with the slender limbs. Other frequent cutaneous features are skin atrophy and fragility, poor healing, telangiectasia, bruising, striae (typically wide and red), hirsuties and acneiform lesions. In contrast with acne vulgaris, the lesions are uniform, and comedones and cysts are absent. Clitoral hypertrophy and male-pattern baldness may occur in women. Dermatophyte and yeast infections occur. In iatrogenic hypercorticism, hypertrichosis is limited and usually confined to the cheeks in the form of lanugo hair. About 6–10% of patients with pituitary Cushing's disease have Addisonian-like pigmentation [1], as oversecretion of the common precursor

pro-opiomelanocortin causes overproduction of both ACTH and MSH.

Diagnosis. Twenty-four-hour urinary cortisol (95–100% sensitivity and 94–98% specificity) and/or a 1-mg overnight dexamethasone suppression test (98–100% sensitivity, lower specificity, using a cut-off of plasma cortisol below 50 nmol/L) are generally considered to be satisfactory screening tests. A midnight plasma cortisol level (100% specific if over 50 nmol/L) or a 2-day low-dose dexamethasone suppression test may resolve equivocal results. Additional tests may be required [2].

Treatment. Trans-sphenoidal selective adenomectomy is the treatment of choice for Cushing's disease in adults, with radiotherapy as second choice; radiotherapy is more effective in children. Bilateral adrenalectomy is the third-choice definitive cure for pituitary Cushing's syndrome, and is the treatment of choice when the disease is caused by bilateral adrenal hypersecretion; lifelong replacement therapy with glucocorticoids and mineralocorticoids is required. A substantial number of such patients eventually develop a pituitary adenoma and cutaneous hyperpigmentation (Nelson's syndrome); this is best treated by pituitary surgery [3]. Unilateral adrenal disease (adenoma or carcinoma) is treated by unilateral adrenalectomy. Medical treatments may act at hypothalamic–pituitary level (serotonin antagonists, dopamine or GABA agonists, somatostatin analogues), at corticosteroid receptors (mifepristone, a relatively new treatment) or on adrenal glands (metyrapone, aminoglutethimide and others). Most of these agents have significant potential side effects.

Adrenal insufficiency [1–6]

SYN. ADDISON'S DISEASE; HYPOCORTICISM; HYPOADRENALISM

This condition is due to insufficient secretion or supply of adrenocortical hormones or hormonal compounds—mainly cortisol and mineralocorticoids.

Aetiology. Most cases of adrenal insufficiency occur due to prolonged supraphysiological glucocorticoid therapy for a variety of inflammatory and other diseases; this suppresses ACTH production, so abrupt discontinuation of treatment may cause acute adrenal insufficiency.

Primary adrenal insufficiency (Addison's disease) in developed countries is most commonly due to autoimmune adrenalitis. Most such patients show circulating antibody to the cortex cells; about 40% of adults and virtually all children with Addison's disease have other autoimmune-related disorders as part of a polyglandular syndrome [2,4–6]. Other causes of primary adrenal damage include infections (tuberculosis is the commonest cause, others include histoplasmosis and viral infections), metastatic malignant disease or (rarely) haemorrhage. The latter is of some dermatological importance, as it may rarely occur due to sepsis (Waterhouse–Friderichsen syndrome); this is classically described as a consequence of meningococcaemia, but in a study of paediatric deaths due to sepsis with bilateral adrenal haemorrhage the commonest cause was *Pseudomonas* infection.

Secondary adrenal insufficiency may occur due to hypothalamic or pituitary disease, leading to insufficient secretion of ACTH; patients with pituitary hyposecretion of ACTH lack the pigmentary changes that are characteristic of primary adrenal insufficiency, and mineralocorticoid production is generally maintained.

Clinical features [1–6]. General symptoms include wasting, fatigue, orthostatic hypotension, dizziness, anorexia, abdominal pain and amenorrhoea. Hyperpigmentation of the skin, due to increased secretion of pituitary MSH and ACTH as a response to low adrenal corticosteroid levels, is the cardinal dermatological feature. This develops insidiously and is often not recognized as abnormal by the patient. It is most pronounced in the following main distributions:

1 Light-exposed areas—face, dorsa of hands
2 Areas subject to friction—elbows, knees, waistline, under bra straps
3 Areas of high pigmentation normally—genital, perineum, axillae, areolae, umbilicus
4 Palmar creases
5 Tongue and mucous membranes
6 In scars
7 Hair and nails—longitudinal melanonychia.

There may be speckled skin pigmentation, and darkening of existing pigmented lesions. Mucous membrane lesions are usually spots or patches rather than diffuse pigmentation, and the oral pigmentation may persist after glucocorticoid replacement therapy. Scar pigmentation only occurs in scars acquired during adrenal insufficiency and is permanent—scars that precede the disorder or occur during therapy are unaffected [6]. In women, in whom the adrenal gland is the main source of androgens, there may be loss of axillary and pubic hair and improvement in acne. Features of associated autoimmune disease may be present, notably vitiligo in 15% of patients with autoimmune causation. Calcification of the pinna has been described [7], but may occur in other endocrine conditions and is more commonly the result of frostbite or injury.

Similar pigmentation may be seen in Nelson's syndrome and in tumours causing ectopic ACTH secretion; in the latter case, cortisol production is increased, so the clinical picture and electrolyte changes may be those of Cushing's syndrome.

Nelson's syndrome is due to development of an ACTH-producing pituitary tumour in patients who have previously undergone bilateral adrenalectomy to treat Cushing's syndrome.

Diagnosis. Anaemia, lymphocytosis, hyponatraemia, hyperkalaemia and hypoglycaemia are expected. A short Synacthen test demonstrates impaired cortisol secretion in response to corticotrophin, and ACTH and cortisol production are subnormal in response to an insulin stress test. Adrenal calcification may be present in autoimmune or tuberculous disease. Primary adrenal failure can be identified by demonstrating elevated ACTH levels, presence of adrenal autoantibodies, and by stimulation tests such as the metyrapone test or CRH test.

Treatment. Primary adrenal failure requires glucocorticoid and mineralocorticoid replacement [5,6]. In secondary cases related to pituitary insufficiency, usually only cortisol is required [3]. During stress, such as when undergoing major surgery and in severe systemic infections, the need for cortisol is increased. The hyperpigmentation may start to regress within days, but generally takes weeks to months to fully resolve—the process is slower in hair and nails, and pigmented scars remain pigmented [6].

Hyperthyroidism [1–4]

SYN. THYROTOXICOSIS

This is a hypermetabolic state that results from excessive production or administration of thyroid hormones—thyroxine (T_4) and triiodothyronine (T_3). It is most common in women.

Aetiology. Hyperthyroidism is usually due to Graves' disease (diffuse toxic goitre, Basedow's disease), but 10–15% of cases are due to other causes, including toxic multinodular goitre, adenoma, thyroiditis, and iatrogenic or factitious ingestion of T_4 or iodine. Secondary hyperthyroidism may occur due to production of TSH or thyrotrophin-releasing hormone (TRH) from the pituitary or from tumours at other sites. Graves' disease is an autoimmune disorder in which there is a high incidence of antithyroid antibodies and of other autoimmune diseases. Thyroid-stimulating immunoglobulins (TSIs) such as long-acting thyroid stimulator (LATS, a 7S immunoglobulin) are typically present in Graves' disease. These bind to TSH receptors, acting as thyroid gland agonists.

Clinical features. Most of the features of hyperthyroidism (Table 59.1) are not specific to the cause. Increased sympathetic nervous system activity causes vasodilatation, leading to warm skin, flushing, palmar erythema and increased sweating (especially of palms and soles). Hair is fine, with diffuse alopecia in about a third of patients.

Table 59.1 Cutaneous features of hyperthyroidism.

Skin
Soft, smooth, velvety
Increased skin temperature
Palmar erythema, facial flushing
Increased sweating
Pruritus
Hyperpigmentation
Pretibial myxoedema*
Vitiligo*
Others—urticaria, palmoplantar pustulosis*
Nails
Fast nail growth
Soft nails, koilonychia
Distal onycholysis
Thyroid acropachy*
Hair
Fine thin hair, diffuse alopecia
Alopecia areata*

* Associated with autoimmune thyroid disease; not a feature of hyperthyroidism *per se*.

Nails may be thin, with koilonychia and onycholysis (Plummer's nails); the onycholysis typically commences on the fourth digit of the hands [5]. Hyperpigmentation, similar to that of Addison's disease, may occur due to increased corticotrophin (ACTH) levels, and may be diffuse or localized to scars, but usually spares the buccal mucosa. Hyperpigmented eyelids have been described (Jellinek's sign).

Pretibial myxoedema, thyroid acropachy (both discussed separately below) and exophthalmos are features of Graves' disease (collectively known as Diamond's triad), although pretibial myxoedema can also occur in Hashimoto's thyroiditis. The combination of *e*xophthalmos, pretibial *m*yxoedema and hypertrophic *o*steoarthropathy has also been termed the EMO syndrome. In addition to these linked conditions, cutaneous features of associated autoimmune disease may be present, especially vitiligo.

The associations between thyroid diseases and other dermatoses are considered separately below.

Diagnosis [6]. In most instances, negative feedback mechanisms cause suppressed serum TSH levels before T_4 or T_3 levels are elevated. The exception is when hyperthyroidism is of secondary type, due to increased TRH or TSH levels. Thyroid antibodies are less helpful, as they are common in euthyroid individuals, and TSI levels are not usually measured. Isotope scanning can confirm the cause (diffuse goitre, adenoma, etc.).

Treatment. Beta-blockers may be used in the initial phase of therapy to suppress the increased sympathetic activity. The hyperthyroid state can be reversed by surgery, radioactive iodine or therapy with antithyroid drugs (propylthiouracil and carbimazole). However, changes that are unrelated to the hormone production tend to persist. Ophthalmopathy is not influenced by a return to euthyroidism, and the prognosis in severe cases is doubtful.

Pretibial myxoedema

SYN. LOCALIZED MYXOEDEMA

Localized oedematous and thickened pretibial plaque formation occurs in 1–10% of patients with hyperthyroidism. It is usually a late feature, occurring after ophthalmopathy and diagnosis of hyperthyroidism (sometimes only becoming evident after antithyroid treatment has been initiated), but it can occasionally precede other features [1,2]. Almost all patients with pretibial myxoedema have ophthalmopathy [1]. The same process often occurs on the dorsum of the hallux, and may affect other sites, including the lower abdomen, arms, shoulders, neck and pinnae [3].

Aetiology. It is unclear whether circulating or local factors are the main determinant of pretibial myxoedema. It was demonstrated over two decades ago that serum of pretibial myxoedema patients caused a two- to threefold increase in hyaluronic acid production by cultured fibroblasts from the pretibial area of patients and normal subjects, but had no effect on those from the shoulder or prepuce [4]. Most patients with pretibial myxoedema, whether thyrotoxic or not, have elevated levels of LATS in their serum, so this specific antibody does not seem to be causally involved [5]. A role for TSI was proposed, as fibroblasts from the pretibial and orbital regions have TSH receptors; TSIs have agonist effects on TSH receptors. Ribonucleic acid sequences encoding parts of the TSH receptor, and TSH receptor-like immunoreactivity, have been demonstrated in fibroblasts from these sites in affected patients [6]. There is, however, no obvious association between the clinical manifestations and the presence of TSH receptor autoantibodies. Recent research demonstrated that patients with pretibial myxoedema, but not control subjects, have circulating immunoglobulin A2 (IgA2) fibroblast antibodies capable of binding to a 54-kDa antigen of dermal fibroblast cell lines [7]. IGF-1 has also been suggested to have a role in the pathogenesis [8]. However, the occurrence of pretibial myxoedema in both the donor and recipient site in a patient who had excision of pretibial myxoedema, with normal skin grafted into the area, suggests that there are local factors operative which are not explained by site-specific properties of the dermal fibroblasts [9].

Pretibial myxoedema also occurs in other situations, especially in chronic stasis dermatitis [10].

Histopathology. The dermis is thickened, especially in the mid-dermis and deeper part, by extensive deposits of acid mucopolysaccharides, which may cause separation of the collagen fibres. Stellate, mucin-producing fibroblasts may be prominent.

Clinical features. In many instances, the lesions first appear on the anterolateral aspect of the lower limbs and

Fig. 59.2 Pretibial myxoedema. (Courtesy of Dr S.O.B. Roberts, Addenbrooke's Hospital, Cambridge, UK.)

only later extend to the back of the legs, and feet (Fig. 59.2). The nodules are pink or skin-coloured, sometimes yellow and waxy, with prominent hair follicles giving a 'peau d'orange' appearance. They may occur in old or recent scars [9,11,12]; localized hypertrichosis over the lesions may be a feature, and localized hyperhidrosis has also been reported [13,14]. Three clinical types are recognized:
1 Sharply circumscribed, in which both nodular and tuberous lesions appear on the shins and toes.
2 Diffuse, producing solid non-pitting oedema of the shins and feet.
3 Elephantiasic, in which there is both oedema and nodule formation.

Treatment. Topical glucocorticoids, with or without occlusive dressings, or intralesional glucocorticoid injections, may be useful [1,15]. The long-term benefits of surgery vary, although debulking procedures may be of benefit (for example, for lesions on the toes) [16]. Octreotide [17,18], plasmapheresis (perhaps acting by removal of TSIs, although not all patients respond) [19], photochemotherapy, intravenous immunoglobulin [20] and gradient pneumatic compression [21] have all been used.

Thyroid acropachy [1,2]

Clubbing of the fingers and toes in Graves' disease, associated with soft-tissue swelling of hands and feet and with periosteal new bone formation, is termed thyroid acropachy. It occurs in less than 1% of thyrotoxic patients, and is usually associated with exophthalmos and pretibial myxoedema (Diamond's triad), occurring in about 5% of patients with these other features. Acropachy usually appears some time after the other components of the syndrome, usually after treatment of Graves' disease. Pathologically, there is periosteal new bone formation involving the phalanges and other distal long bones, which is manifest radiologically as a feathery pattern of lamellar new bone parallel to the diaphyses, sometimes with perpendicularly orientated new bone spicules, and which can be demonstrated as osteoblastic activity using a bone scan [2]. The proximal phalanges and first or second metacarpals are most commonly affected. Most patients have minimal or no symptoms, but in those with symptoms, stiffness is the most frequent; by comparison with hypertrophic pulmonary osteoarthropathy, pain and heat are absent. Pachydermoperiostosis (Chapter 12) shows some resemblance to acropachy, but other features of the syndrome are absent.

Hypothyroidism [1–3]

SYN. MYXOEDEMA; HYPOTHYREOSIS

In hypothyroidism, there is a slowed metabolic rate involving all organs. It is caused by a decreased concentration of free thyroid hormone in the blood, or target cell resistance to thyroid hormone.

Aetiology. The most common cause is idiopathic (primary) hypothyroidism, which is an autoimmune disease, usually affecting women from the fourth decade. A high percentage of patients with Hashimoto's thyroiditis (who may initially be thyrotoxic) eventually develop hypothyroidism, and iatrogenic hypothyroidism may occur as a late effect of radio-iodine treatment of thyrotoxicosis. Secondary hypothyroidism due to pituitary disease is uncommon, TSH production being relatively spared compared to sex hormone and ACTH production, but pituitary infarction, haemorrhage or neoplasm may lead to hypothyroidism in some cases. Severe iodine deficiency, or drugs such as lithium, may cause hypothyroidism. Congenital hypothyroidism (cretinism), usually due to absence of the thyroid, is rare. Tertiary hypothyroidism is due to hypothalamic failure of TRH production.

Clinical features. Cutaneous changes of hypothyroidism (Table 59.2) [1–7] were well known in the latter part of the 19th century [4]. The most prominent manifestation of hypothyroidism is related to dermal accumulation of mucopolysaccharides, in particular chondroitin sulphate and hyaluronic acid, which bind water in the tissue and lead to puffiness of the skin. Whilst characteristic, the features may be insidious in development, and some are of low specificity. For example, loss of the outer third of the eyebrow (madarosis, Hertog's sign) is common in many euthyroid elderly individuals. The yellowish skin colour is due to a combination of alterations in connective tissue of the dermis, carotenaemia and vasoconstriction (due to the slowed metabolic rate). The connective tissue changes also cause loss of support of dermal vessels and, along with decreased levels of clotting factors, predispose to purpuric lesions or bruising. Asteatotic eczema [5] and keratoderma of palms and soles [6] may occur, sometimes as the presenting feature. Features of previous autoimmune thyrotoxicosis, or of associated autoimmune diseases, may also be present.

In congenital hypothyroidism ('cretinism'), coarseness of features, lethargy, periorbital puffiness, swelling of hands and feet, macroglossia, cold and dry skin with livedo, umbilical hernia and poor muscle tone are pathognomic, but may not be apparent until a few months of age. Cutis marmorata occurs due to vasoconstriction. Without treatment, physical and mental development is retarded. The scalp hair is coarse, and the eyebrows may be confluent.

In juvenile hypothyroidism, abnormal physical and mental development is the principal manifestation of the disease. Some children develop hypertrichosis of the upper back and shoulders. The waxy, yellowish skin changes may be prominent, but the puffiness may be less apparent than in older individuals. Rarely, juvenile hypothyroidism is associated with sexual precocity; the penis and scrotum enlarge in males, or menstruation and galactorrhoea occur in females, but axillary and pubic hair do not develop.

Table 59.2 Cutaneous and oral features of hypothyroidism.

Skin
Pale, cold, scaly and wrinkled skin
Xerosis, asteatotic eczema, itch
Palmoplantar keratoderma
Absence of sweating
Ivory-yellow skin colour
Puffy oedema of hands, face and eyelids
Purpura and ecchymoses
Punctate telangiectases on arms and fingertips
Delayed wound healing
Xanthomatosis (secondary to hyperlipidaemia)
Nails
Brittle and striated nails
Slow nail growth
Hair
Coarse sparse scalp hair
Loss of pubic, axillary and facial hair
Loss of lateral eyebrows (madarosis)
Oral
Large tongue
Gingival swelling (in congenital hypothyroidism)
Oral candidosis

Diagnosis. Protein-bound iodine, T_4 and T_3 levels are low. In primary hypothyroidism, the TSH level is elevated; in pituitary failure, it is low or undetectable. The histological changes in the dermis may be helpful in difficult cases [8]. Recognition of hypothyroidism in the elderly may be difficult. Symptoms and signs develop insidiously and may easily be taken as evidence of arteriosclerotic disease. Serum TSH is recommended as the primary investigation for screening of elderly patients.

Thyroid disease and other dermatoses

Thyroglossal cysts are in the differential diagnosis of other congenital cysts in the neck, such as branchial cysts or ectopic bronchial mucosa.

Thyroid cancer may give rise to cutaneous metastases, or to thyroxine-producing metastases which therefore cause features of thyrotoxicosis. Thyroid cancer is also a feature of syndromes such as Cowden's disease and multiple endocrine neoplasia (MEN) type 2, discussed elsewhere in this chapter.

There are associations between either the presence of antithyroid antibodies, or of overt thyroid dysfunction or thyroiditis, with a number of other skin diseases and disorders with cutaneous manifestations (Table 59.3) [1–13]. Some of these associations are based on small studies, but associations with disorders such as dermatitis herpetiformis and chronic urticaria are strongly supported by the available literature. About 20% of children with alopecia areata have thyroid antibodies, although clinical thyroid dysfunction is rare [13]. It is debatable to what extent management is altered by routinely testing for thyroid antibodies or thyroid dysfunction in the absence of other clinical symptoms, although there are reported instances where chronic urticaria, for example, has resolved after treatment of associated thyrotoxicosis; it has also been recommended that T_4 treatment should be considered in euthyroid patients with chronic urticaria if they have evidence of thyroid autoimmunity [7].

Table 59.3 Some skin disorders and other diseases with prominent cutaneous manifestations that have been associated with thyroid dysfunction or with the presence of antithyroid antibodies.

Bullous diseases
Dermatitis herpetiformis
Bullous pemphigoid
Pemphigus
Pemphigoid gestationis
Endocrine diseases
Pernicious anaemia
Diabetes mellitus
Addison's disease
Acanthosis nigricans with insulin resistance
Autoimmune polyglandular syndromes I–III
Other autoimmune conditions

Parathyroid disease

Skin changes are not a particular feature of hyperparathyroidism, although subcutaneous calcification may occur (especially in hyperparathyroidism secondary to renal failure; see below) [1–4].

Itch is occasionally felt to be related to hyperparathyroidism [5], although this is poorly documented [6] and some of the documentation is inferred (from resolution in some instances of renal itch after parathyroidectomy, or paraneoplastic itch after resection of parathormone (PTH)-producing bronchial tumours). Hyperparathyroidism has also been linked to cutaneous T-cell lymphoma [7].

Hypoparathyroidism may cause skin changes somewhat similar to those of hypothyroidism—the skin may be dry, keratotic and puffy, with sparse, coarse hair. Nails are brittle and ridged, with cracking at the free margin, or crumbling of the distal nail plate. Chloasma or pellagra-like pigmentary disturbance is less common [1,3,8].

Chronic mucocutaneous candidiasis, especially of the nails and oral mucosa, may occur in conjunction with hypoparathyroidism when this occurs as part of the polyglandular autoimmune syndrome (see below) or in association with immunological defects such as Di George's syndrome [1], but it is not a feature of post-thyroidectomy, iatrogenic hypoparathyroidism.

Subcutaneous ossification is a feature of Albright's hereditary osteodystrophy, which encompasses both pseudohypoparathyroidism type Ia and pseudopseudohypoparathyroidism [1,9–11]. The somatic features include obesity, short stature and short metacarpals—Albright's sign is dimpling over the knuckle of the typically affected fourth metacarpal. The dominant condition occurs due to a heterozygous functional defect of the α-subunit of the stimulatory G protein (G_s α protein) of adenylate cyclase, with which PTH interacts at the cell surface. This is encoded by the *GNAS1* gene on chromosome 20q13.3, but there are tissue-specific differences in expression of G_s α and other *GNAS1* transcripts that are different for the maternal and paternal alleles [10]. It is now known that pseudopseudohypoparathyroidism is the same disorder as pseudohypoparathyroidism type Ia, but with the genetic defect inherited from the father; patients have the somatic features of pseudohypoparathyroidism, but with normal hormone responses [11].

Multiple endocrinopathy syndromes

It is common that autoimmune conditions may occur simultaneously—due to, for example, human leukocyte antigen (HLA) linkage. Some of these produce an overlap between endocrine disease and:

- Other autoimmune conditions, e.g. polyglandular autoimmune syndrome (see below), various combinations of Sjögren's syndrome and sarcoidosis with endocrine autoimmune conditions [1,2].
- Infections, such as in autoimmune polyglandular syndrome type I (see below).
- Ectodermal changes, e.g. alopecia areata (commonly), ANOTHER syndrome (*a*lopecia, *n*ail dystrophy, *o*phthalmic complications, *t*hyroid dysfunction, *h*ypohidrosis, *e*phelides and enteropathy, *r*espiratory tract infections) [3].
- Gastrointestinal disease, e.g. the triple A syndrome (Allgrove's syndrome) of achalasia, addisonianism and alacrima (MIM #231550).
- Pigmentary change, e.g. vitiligo (commonly), Carney complex (see cardiac disease, below), POEMS syndrome (see cardiac disease, below).
- Bone disease, e.g. McCune–Albright syndrome (MIM #174800). G protein mutations cause dysregulation of cyclic adenosine monophosphate (cAMP), leading to growth and hyperfunction of many organs—features include hypophosphataemic osteodystrophy, hyperparathyroidism, hyperthyroidism, large irregularly shaped café-au-lait macules, Cushing's syndrome, acromegaly and hyperprolactinaemia.
- Cerebral disease, e.g. triple H syndrome—*h*ippocampus (anterograde memory loss), *h*air follicle (alopecia areata), *h*ypothalamic–pituitary–adrenal axis (isolated ACTH deficiency) [4].

Autoimmune polyglandular syndromes [5–9]

Three types of autoimmune polyglandular syndrome (APS) are described—types 1–3. The most important example dermatologically is APS type 1 (MIM *240300), which is usually due to the R257X mutation of the *AIRE* gene on chromosome 21q22.3 [9]. It is also termed

mucocutaneous candidiasis–endocrinopathy syndrome, multiple endocrinopathy syndrome, autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED) syndrome, or Whitaker's syndrome. It is defined by the presence of two or more of the three major features, which are chronic mucocutaneous candidiasis (usually by age 5 years, present in about 80%), chronic hypoparathyroidism (usually by age 10 years, present in about 90%) and autoimmune adrenal insufficiency (usually by age 15 years, present in about 70%). Other features are hypergonadotrophic hypogonadism (45%), diabetes mellitus, and thyroid antibodies or overt thyroid dysfunction. Alopecia areata (25%) and vitiligo (10%) are both relatively common. An interesting feature of vitiligo in this condition, which does not occur in isolated vitiligo or in other autoimmune combinations, is the presence of complement-fixing melanocyte autoantibodies [9]. Most patients also have adrenal cortex autoantibodies, and those with gonadal failure have steroid-producing cell antibodies. Nail dystrophy and tooth enamel defects comprise the ectodermal dystrophy component. Epidermolysis bullosa acquisita has also been reported in type 1 syndrome [10].

Patients with APS types 2 and type 3 more commonly have diabetes, but less commonly have alopecia or vitiligo, and do not have chronic mucocutaneous candidiasis. Addison's disease is present in all patients with APS type 2 and may occur with autoimmune thyroid disease (Schmidt's syndrome) and/or with immune-mediated diabetes (Carpenter's syndrome). It is not a feature of APS type 3, which is defined as co-occurrence of autoimmune thyroid disease with two other autoimmune disorders in the absence of Addison's disease [11]. APS type 2 is due to defects in the *HLA* region on 6p21 or in *CTLA4* on 2q33.

The MEN syndromes are discussed later in this chapter.

Cutaneous markers of internal malignancy [1–9]

The different types of skin change associated with internal malignancy are so numerous that to report all documented associations here is impracticable. The above references serve as more detailed compendia. Various criteria may be used to group changes [5,6]. It is, however, convenient to classify into several broad categories:

1 Direct tumour spread/cutaneous metastasis.
2 Genetically determined syndromes with cutaneous manifestations, where there is a recognized predisposition to internal malignancy.
3 Cutaneous markers of exposure to carcinogens, those affected being at higher risk of internal malignancy.
4 Paraneoplastic syndromes—a medley of cutaneous reaction patterns that have a statistical association with neoplasia involving various internal organ systems.

Direct tumour spread/cutaneous metastasis [1–3]

Other than primary skin neoplasms, the skin may be involved by tumour as a result of cutaneous metastases from an internal tumour, or by direct involvement in continuity with an adjacent organ (as occurs in Paget's disease [4], discussed in Chapter 36). Local and in-transit metastases from primary epidermal tumours are discussed in relevant chapters; melanoma is the most important tumour to behave in this fashion.

Direct invasion of the skin manifests itself by tumid

Fig. 59.3 Paget's disease of the breast with underlying ductal carcinoma. (Courtesy of Dr R. Emmerson, Royal Berkshire Hospital, Reading, UK.)

Fig. 59.4 Carcinoma erysipeloides. (Courtesy of Dr R. Emmerson, Royal Berkshire Hospital, Reading, UK.)

ulceration or inflammation. The most frequent cause is carcinoma of the breast, which may present as skin ulceration, scaly plaques of Paget's disease (Fig. 59.3), or more rarely as carcinoma erysipeloides (Fig. 59.4), carcinoma telangiectoides or as peau d'orange-like carcinoma en cuirasse. The next commonest cause is carcinoma of the oral cavity, usually squamous cell carcinoma (SCC) ulcerating onto the face [5]. Direct cutaneous metastasis may also occur after therapeutic manoeuvres, such as draining a malignant pleural effusion.

Paget's disease of the breast presents with scaling and erythema on or around the nipple, which can mimic eczema. It is an epidermal manifestation of an underlying adenocarcinoma, usually ductal in origin; early recognition may allow curative intervention. Extramammary Paget's occurs in apocrine gland-bearing areas such as anogenital and axillary sites. It may be a marker of underlying neoplasia [6], and, whilst this is not mandatory [7], it does warrant investigation of adjacent tracts.

Specific cutaneous infiltrations of the skin may occur with myeloproliferative disorders; this is commonly recognized with lymphoma, but can occur with leukaemia [8].

Cutaneous metastasis from tumours affecting other organs [1,2]

The skin is a relatively uncommon site for distant metastatic deposits, compared with organs such as liver, lung and bone. Autopsy studies suggest a higher frequency of skin metastasis than may be apparent from clinical studies [5,9–11]; up to 9% of patients with internal cancer may have skin metastasis (3–4% is probably a representative figure) and in about 0.5–1% it is the presenting feature [1,2]. The most common sources of cutaneous metastases are breast, lung, colon, stomach, upper aerodigestive tract, uterus and kidney.

Cutaneous metastases generally present as solitary or multiple painless, firm to hard nodules, which may be skin-coloured, blue-brown or reddish-purple. Other patterns include a morphoea-like sclerotic pattern. Although they may occur on skin in the vicinity of the affected organ (for example, prostatic tumour metastases are often on the lower abdomen), the head, neck and upper trunk are disproportionately commonly affected [11]. Other sites that are notable as sites for skin metastasis include the umbilicus (Sister Mary Joseph's nodule) [12,13] and recent operative scars (often for the primary tumour). Breast tumour metastasis to skin typically affects the chest wall, with patterns as discussed above. Metastases to the scalp may give rise to focal alopecia, with breast, lung and kidney being the commonest sources. Renal and thyroid skin deposits have a reputation for being vascular in appearance, both clinically and pathologically [14], and are occasionally misdiagnosed as benign haemangiomas or pyogenic granuloma; hypernephroma metastases may even be pulsatile. Generally, cutaneous metastases may be mistaken for cysts or inflammatory lesions.

Metastasis to the skin occurs as a result of lymphatic or haematogenous dissemination of tumour. This may give rise to showers of metastases in some patients. The tumour cells may be identifiable as having a specific organ of origin, or may be highly anaplastic. In general, they resemble the cells of the primary tumour. Immunohistochemistry is generally of little value in determining the diagnosis of the primary tumour, except in the case of prostatic metastases (prostate-specific antigen) or thyroid metastases (thyroglobulin). In some instances, there may be marked oedema or dilated lymphatic vessels, which may make diagnosis difficult. In some specific tumours such as hypernephroma, or in some clinical patterns such as carcinoma telangiectoides, the tumour cells may either be scanty or the vascular proliferation may dominate the histopathological appearance. The lymphatic spread of

tumour cells may lead to an 'Indian filing' appearance in some cases, sometimes with fibrosis.

Cutaneous metastases are usually indicative of disseminated disease and a correspondingly poor prognosis; survival is typically only about 3 months in patients with disseminated skin metastases [10]. Patients with solitary metastases without other evidence of dissemination may have a better survival [15]. Infrequent cases of tumour regression after primary tumour removal are documented [16]. It is noteworthy that cutaneous metastases do not necessarily relate to a prior, documented tumour; the histological pattern, localization and temporal relationship may occasionally point to a second primary [17]. Treatment options, depending on the primary tumour, may include excision or other destructive therapy (e.g. laser destruction, radiotherapy, photodynamic therapy) for limited numbers of lesions, and chemotherapy or other systemic treatment for disseminated lesions.

The genetic group

Most cutaneous signs of neoplasia do not involve direct spread of tumour to the skin but are paraneoplastic. Genodermatoses account for a significant minority of paraneoplastic skin lesions [1–6].

Gardner's syndrome (MIM *175100) (Chapter 12) [7,8] is an autosomal-dominant condition of multiple cutaneous epidermoid cysts, fibromas and pilomatrixomas associated with a high incidence of early malignant change in intestinal adenomatous polyposis to adenocarcinoma. Oldfield's syndrome [9] represents the same condition. Other malignancies include papillary and follicular thyroid cancer, adrenal adenomas and adenocarcinoma, hepatoblastoma and duodenal carcinoma around the ampulla of Vater. These are also discussed in the section on gastrointestinal polyposis; linkage with the familial cancer syndrome of familial adenomatous polyposis (FAP), via the adenomatous polyposis coli (APC) gene mutation, seems likely [10].

Familial cases of simple epidermal cysts are more common and do not have a recognized correlation with malignancy.

Peutz–Jeghers syndrome (PJS; MIM #175200) (Chapter 39) is an autosomal-dominant condition comprising the complex of mucocutaneous pigmentation, particularly in the peri- and intraoral regions, and gastrointestinal polyposis, predominantly hamartomatous involvement of the small intestine, but with increase in cancer frequency [11]. Pigmentation can also occur on the palms, fingertips and soles; cutaneous changes fade with age. As well as an increased risk of gastrointestinal malignancy, there is also a substantive increase in non-gastrointestinal malignancy. The PJS gene, localized on chromosome 19p13.3, has been termed *STK11* (*LKB1*), mutations in which interfere with the protein regulatory function of a group of enzymes—serine/threonine protein kinase—that may act to suppress cell growth [10]. There is a fuller discussion in the section on gastrointestinal polyposis.

Palmoplantar keratoderma (Howel-Evans syndrome) (Chapter 34) is the association of autosomal-dominantly inherited keratoderma of the palms and soles (tylosis) with the eventual development of oesophageal carcinoma in most cases [12]. Since the original description, other families linked with inherited tylosis and carcinoma of the oesophagus have been described [13,14]. However, in diffuse palmoplantar keratoderma starting in infancy, there is no genetic susceptibility to neoplasia. Acquired palmar hyperkeratosis may also occur as a cutaneous paraneoplastic phenomenon, or as a marker of carcinogen ingestion (pp. 59.18–59.19), principally arsenic. The relationship with arsenical keratoses, punctate keratoderma and internal malignancy is a matter of conjecture. A possible familial association has been described with gastrointestinal malignancy [15]. Palmoplantar punctate keratoses are linked with internal malignancy via Cowden's disease

(Chapter 12). Punctate porokeratotic keratoderma has been tentatively associated with internal neoplasia [16]. Palmar hyperkeratosis is linked with malignancy via the paraneoplastic condition, acrokeratosis of Bazex (Chapters 34 & 62).

Basal cell naevus syndrome (BCNS; Gorlin's syndrome, MIM #109400) (Chapter 36) [17–19]. In this autosomal-dominant trait of multiple basal cell carcinomas (BCC), mandibular keratocysts, skeletal anomalies, abnormal calcification and dyskeratotic pits of palms and soles, the most common reported malignancies are medulloblastoma [20] and ovarian tumours, but astrocytomas, meningiomas, craniopharyngiomas, fibrosarcomas and ameloblastomas have occasionally been reported [18]. It is important to note that individuals may have only the family history, without themselves having developed BCC; neoplasia may also commence early in life, with a median age of onset of BCC by 20 years. The BCCs may present as small brown papules on the face, neck, back, chest and upper limbs. They may become more aggressive as the patient ages, and metastases are rarely possible. The gene for BCNS has been mapped to chromosome 9q22.1–q31, with a high percentage of germ-line mutations in the *PTCH* gene [10].

Familial melanoma syndrome (B-K mole syndrome, dysplastic naevus syndrome, MIM 155600) (Chapter 38). This is a variable group of disorders, linking multiple melanomas, on a background of multiple atypical melanocytic naevi and a familial history, with probably polygenic inheritance. Large multiple and irregular naevi are the norm, with an early onset of melanoma, potentially multiple primaries and in some groups an increase in non-cutaneous malignancies such as pancreatic, gastrointestinal, lung, breast and laryngeal sites, as well as ocular melanoma and cutaneous SCC of the head and neck. The *CDKN2A* germline mutation in the 9p21 gene region has been implicated in a high percentage of cases [10].

Xeroderma pigmentosum (XP; MIM 194400, 278700–278800) [21]. A complex of disorders that is autosomal-recessive in inheritance, it is dealt with in more detail in Chapter 12. XP characteristically presents at an early age with severe photosensitivity, marked reduction in threshold for sunburn and myriads of lentigines, principally in a sun-exposed distribution. Early onset of photoageing is found in infants, followed by sun-induced dysplasias, BCC, SCC and malignant melanomas, commencing in the first decade of life. There is significant resultant surgical scarring from multiple excisions, and reduced life expectation. A marked increased incidence of internal malignancy is also found, in part related to ocular and intraocular non-melanoma and cutaneous melanoma skin malignancy, but associations with other tumours such as central nervous system (CNS) sarcomas, leukaemia, lung and gastric cancers. The mutations causing XP cause abnormal fibroblast sensitivity to ultraviolet radiation, resulting from a defective DNA repair process; different mutations are classified as complementation groups A to G. Inactivation of tumour suppressors and activation of oncogenes due to these mutations results in development of multiple tumours [10].

Werner's syndrome (adult progeria; MIM #277700) [22]. An autosomal-recessive condition of premature ageing, with onset in the second to third decade of life. It is due to mutation of the *WRN* gene on chromosome 8p12. The Werner's syndrome gene product is a DNA helicase belonging to the RecQ family; it unwinds double-stranded DNA and is able to resolve aberrant DNA structures, so that aberrations occurring during repair, recombination and replication are made good, together with those that result from direct DNA damage [23]. Neoplasms develop in about 10% of cases, although the commonest cause of death is arteriosclerosis. Sarcomas, melanomas, leukaemia and a variety of epithelial-derived carcinomas have been reported [24,25]. Meningiomas are a recognized association, and an astrocytoma has been documented [26]. Werner's syndrome is a chromosome-instability syndrome and, as with XP, ataxia–telangiectasia, Bloom's syndrome and Fanconi's anaemia, is likely to be associated with a high incidence of neoplasia [2,10].

Von Hippel–Lindau syndrome (VHL; MIM *193300). A rare, autosomal-dominantly inherited condition characterized by benign and malignant tumours of various systems, particularly haemangioblastomas of the CNS, angiomatosis of the retinae, phaeochromocytoma [27], renal [28] and pancreatic adenoma, carcinoma and cysts [29]. The non-specific cutaneous manifestations include haemangiomas and café-au-lait spots [3]. The VHL gene has been located on chromosome 3p25; although different mutations have been found to be causative, the gene is a tumour-suppressor gene following the Knudson 2-hit model. Families may be characterized by the presence (type 2, missense mutations) or absence (type 1, deletions/protein-truncating mutations) of phaeochromocytoma. Type 2b has, in addition to an association with phaeochromocytoma, a high incidence of renal cell carcinoma and haemangioblastomas, whereas in type 2a there is a lower incidence of renal cell carcinoma and in type 2c an exclusive association with phaeochromocytoma [30].

Neurofibromatosis types 1 and 2 (NF1, von Recklinghausen's disease, MIM *162200; NF2, MIM *101000) (Chapter 12). There are two main forms of neurofibromatosis, type 1 (NF1) and type 2 (NF2). Both have an autosomal-dominant trait with a high incidence of new mutation, which—as a result of abnormal neural crest cell function—

produces multiple peripheral neurofibromas, as well as CNS tumours and café-au-lait macules [31]. NF1 is the commonest form of neurofibromatosis, with a prevalence of approximately one in 4000, with NF2 at around one in 200 000. There are several different clinical presentations, depending on the localization of the lesions. Clinical overlap between NF1 and NF2 occurs particularly in children, who may have café-au-lait macules and peripheral nerve tumours; flexural freckling is indicative of NF1. The associations with benign tumours, malignancy and systemic manifestations are varied [2]. Lisch nodules (pigmented iris hamartomas) are found with slit-lamp analysis in 90% of adult patients with NF1. Around 80% of patients with NF2 have posterior subcapsular cataracts. In general, NF2 patients have fewer skin lesions than in those with NF1, but more severe disease in NF2 is linked with greater prevalence of skin tumours [10].

NF2 patients develop vestibular and peripheral nerve schwannomas, together with CNS tumours such as meningiomas, astrocytomas and ependymomas. Perhaps the commonest neoplasia developing in patients with neurofibromatosis is a malignant neurofibrosarcoma [32,33]. Most superficial neurofibromas have a low malignant potential, change occurring more often in the deep plexiform neurofibromas and those more in continuity with nerves, designated schwannomas. Benign tumours such as acoustic neuromas, dumb-bell tumours and optic gliomas can result in disastrous sequelae when occurring in confined, pressure-sensitive sites. The commonest CNS malignancy is an astrocytoma. Other malignancies include nephroblastoma (Wilms' tumour), fibrosarcoma, rhabdomyosarcoma and leukaemia, especially in children [34–36]. Ocular melanoma has also been reported [37] and there is an increased frequency of phaeochromocytomas. The *NF1* gene, located on chromosome 17q, has a role as a tumour-suppressor gene, and although 50% of cases are inherited, 50% come through new mutation of the *NF1* gene. A genotype–phenotype association is the early onset of cutaneous neurofibromas and abnormal facial features, with a complete deletion of one copy of the *NF1* locus. These patients appear to have a higher incidence of malignant neurofibrosarcoma. It appears that transformation of benign neurofibromas to malignant peripheral nerve sheath tumours involves the loss of other tumour-suppressor genes such as p53 and p16. The gene product in *NF1* is called neurofibromin, and in its non-mutated role inhibits oncogenic activity of *ras* proteins [10,38].

The *NF2* gene locus appears to be that of a tumour suppressor on chromosome 22. The product of this gene, termed merlin, has an uncertain effect on tumour suppression [10].

Tuberous sclerosis complex (TSC; Bourneville's disease; TSC1, MIM #191100 and TSC2, MIM *191092) (Chapter 12). An autosomal-dominant condition of angiokeratomas, epilepsy and mental retardation. It may be associated with multisystem tumour involvement, mostly hamartomatous. The CNS, renal and cardiopulmonary systems are most significantly affected [2]. Malignant, sarcomatous change can occur, particularly with angiomyolipomas and rhabdomyomas, although this development and subsequent metastases are uncommon [3]. Renal cell carcinoma is a recognized, infrequent complication [39]. There are two known causative genes—*TSC1* on chromosome 9q34, encoding hamartin, and *TSC2* on chromosome 16p13, encoding tuberin. There are large numbers of different mutations, but in familial cases about half of the families show linkage to *TSC1* and the other half to *TSC2*. Attempts to identify a specific phenotype associated with mutations in either specific *TSC* gene have so far proved unrewarding, although there does seem to be a higher prevalence of mental retardation for *TSC2* mutation carriers [38].

Multiple endocrine neoplasia syndrome (multiple endocrine adenomatosis, MEA). This is now divided in to MEN1, MEN2A and MEN2B.

Multiple endocrine neoplasia type 1 (MEN1; Wermer syndrome; MIM *131100) is an autosomal-dominant familial cancer syndrome, with parathyroid, pancreatic islet cell and pituitary gland tumours, as well as cutaneous findings. It is caused by mutations in the *MEN1* gene, located on chromosome 11, which codes for the production of a protein named menin. The cutaneous findings in MEN1 are mostly multiple facial angiofibromas and collagenomas. Café-au-lait macules and lipomas are also encountered [40,41].

MEN1 is, at least in part, a tumour-suppressor gene. MEN1 is characterized by tumours of the parathyroid, anterior pituitary, pancreatic islet cells, neuroendocrine origin, foregut carcinoid and adrenal cortex. It is associated with 20–25% of cases of Zollinger–Ellison syndrome (ZES). In MEN1, 80–100% of cases have pancreatic endocrine tumours (pancreatic polypeptidomas or non-functional 80–100%, ZES 54%, insulinoma 21%, glucagonoma 3% and vasoactive intestinal peptide (VIP)oma 1%). Associated endocrine disease consists of parathyroid hyperplasia > 95%, anterior pituitary adenomas around 60% (range 14–100%), adrenal adenomas about 30%, lung carcinoids 7% and gastric carcinoids 13–30%. The pituitary adenomas are prolactinomas in 14–76% and cause acromegaly in 11–33% and Cushing's syndrome in 5–19%. The commonest tumours in MEN1 secrete PTH or gastrin. Secondary dissemination from malignant neuroendocrine tumours (carcinoid) may be one of the commonest causes of mortality in MEN1; most of these, unlike non-MEN1 cases, arise from the foregut (bronchi, thyroid, stomach, duodenum and pancreas) [10,42,43].

Multiple endocrine neoplasia type 2A (MEN2A, Sipple's syndrome; MIM #171400—mucosal neuromas, medullary

thyroid carcinoma and phaeochromocytoma; MEN type 2B or 3, MIM #162300) [2,4]. This can be divided into type 2A (Sipple's syndrome) and type 2B (formerly type 3). MEN2A and 2B affect principally the thyroid, parathyroid glands and the adrenal medulla and are linked with familial medullary thyroid carcinoma (FMTC) [44,45]. They are caused by mutations of the *RET* oncogene. Type 2A can present with pruritus, prior to recognition of the syndrome. Symmetrical, bilateral skin lesions overlying the scapular area have been described, with hyperpigmentation and hyperkeratosis in the intervening skin. Cutaneous deposits of amyloid have also been reported [10,43].

Type 2B patients tend to have a characteristic facial appearance. The lips and eyelids are thickened and bumpy, with multiple mucosal neuromas, causing blubbery, protuberant lips; other mucosal surfaces, such as buccal, gingival and pharyngeal surfaces may occasionally be affected, as can corneas and conjunctivae. Neuromas manifest as flesh-coloured papules or nodules. Prognathism can be evident, and patients often have a marfanoid appearance; muscle weakness and musculoskeletal anomalies may also be present [45].

Type 2B is additionally associated with medullary thyroid carcinoma (MTC) and phaeochromocytoma. The MTC in type 2B presents earlier and more aggressively than MTC in type 2A. It is often multicentric and bilateral, starting in those as young as 3 years, and early lymphatic spread may occur. Parathyroid hyperplasia or adenomatosis is seen more in MEN types 1 and 2A than in type 2B. Intestinal ganglioneuromatosis is more common in type 2B than 2A. Mucosal neuromas and a marfanoid appearance are not apparent in type 2A. Type 2A is linked to a mutation of the *RET* oncogene, located on chromosome 10, compared to a sporadic *RET* oncogene in 2B; both are autosomal-dominant in inheritance. Phaeochromocytomas, often bilateral, occur in many cases. Cutaneous café-au-lait spots occur and, rarely, a progressive striated pigmentary change of hyperplastic dermal nerves on the trunk [46]. The risk of medullary carcinoma is high, and this is the major cause of mortality; in MEN2, the mortality is greater from MTC than phaeochromocytoma. *RET* testing has replaced calcitonin screening to diagnose *MEN2* carrier status. The specific *RET* codon mutation will delineate the course of the disease and degree of aggression [2,10,42,47]. Prophylactic thyroidectomy may be indicated.

Carney complex (CNC; Carney's syndrome; NAME syndrome; LAMB syndrome; type I MIM #160980, type II MIM *605244). A group of disorders associated with cutaneous pigmented lesions, cutaneous, subcutaneous and internal myxomas, at various sites with endocrinopathy, principally endocrine tumours. NAME syndrome consists of *n*aevi (congenital melanocytic), *a*trial myxomas, *m*yxoid neurofibromas and *e*phelides. LAMB syndrome consists of *l*entigines, *a*trial myxomas, *m*ucocutaneous myxomas and *b*lue naevi. Cardiac myxomas are the most important internal myxomas, due to the causation of cardiac symptoms and potentially life-threatening effects (see also the section on cardiac disease later in this chapter). Likewise with endocrine involvement, adrenal-linked Cushing's syndrome can have critical, life-threatening effects. Gonadal hormone-secreting tumours, together with pituitary tumours producing GH, may produce their expected clinical effects; both benign and malignant thyroid tumours also occur [43,47].

Carney's complex, which often affects the adrenal cortex, thyroid and pituitary glands and gonads, is due in over half the patients to mutations in genes coding for a regulatory subunit type 1A of protein kinase A. CNC is clinically and probably genetically heterogeneous. At least two gene locations have been proposed, one on chromosome 2p16 and another on 17q2 [10,47].

Multiple hamartoma and neoplasia syndrome (Cowden's disease, CD; MIM #158350) [48–54]. This is a rare, cancer-associated genodermatosis, which is inherited as an autosomal-dominant trait with incomplete penetrance. It is due to mutations in the *PTEN* (*MMAC1*) gene on chromosome 10q23.3. It has been proposed that *PTEN* mutations produce their effects in Cowden's disease and allied hamartomatous disorders due to a failure to regulate cell death [10,55,56].

Multiple hamartomatous lesions of ectodermal, endodermal and mesodermal origin are associated with a predisposition to neoplasia; this can involve nearly all internal malignancies, but particularly the breast [54], colon and thyroid. The eponymous family was first described by Lloyd and Dennis [49].

The disease is most readily recognized by its characteristic mucocutaneous appearances, which are a consistent finding. The clinical picture is of warty, 'cobblestone' hyperplasia of the mucosal surfaces (Fig. 59.5), particularly the tongue and buccal mucosa, periorificial facial papules, acral warty keratoses and palmoplantar semitranslucent, punctate keratoses. The lesions, which are grouped especially around the mouth, nose and ears, have a hyperkeratotic, flat-topped, wart-like appearance, as do many lesions elsewhere; these are mostly trichilemmomas or related benign tumours of the follicular infundibulum [48,52]. Other inconstant cutaneous lesions include ganglioneuromas, lipomas, angiomas, angiolipomas, epidermoid cysts and a variety of pigmentary changes. Craniomegaly commonly occurs. Other occasional findings include an adenoid facies, kyphoscoliosis and a high-arched palate.

Benign internal anomalies are legion. The commonest internal organ affected is the thyroid; goitres and adenomas are the expected finding, although carcinomas

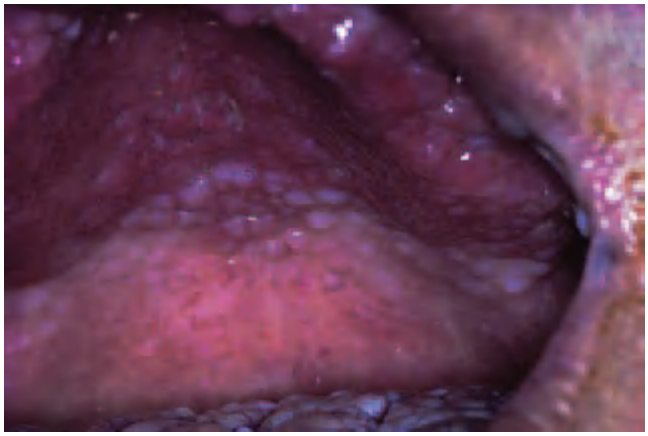

Fig. 59.5 Warty papillomatosis of the hard palate in Cowden's disease. (Courtesy of Dr R. Emmerson, Royal Berkshire Hospital, Reading, UK.)

also occur [53]. Gastrointestinal polyposis and cysts or polyps of the female genitourinary system also frequently occur. Less often, in these tracts, malignant change has been recorded in both male and female patients. The association with meningioma does appear real, although it is difficult to be certain with more varied and possibly secondary phenomena such as seizures and mental retardation.

The most important association of Cowden's disease is with breast pathology. The majority of women have severe fibrocystic disease of the breasts, and around 50% develop malignant change in the form of adenocarcinoma. These changes may have an early onset, and screening of at-risk family members is therefore recommended. Even prophylactic mastectomy has been suggested [54]. Benign gynaecomastia has been reported in the male, but malignancy of the breast or thyroid is exceptional. The disorder therefore appears more sinister in the female. It has been linked with several other hamartomatous disorders; Lhermitte–Duclos disease, in which hamartomatous outgrowths of the cerebellum occur, is now viewed as part of CD. Criteria for this disease have been established by the International Cowden Disease Consortium [10].

Bannayan–Zonana syndrome (BZS) has many hamartomatous findings in common with Cowden's disease, but lacks the extent of the malignant degeneration seen in Cowden's disease. BZS is characterized by microcephaly, vascular anomalies, lipomas, thyroid disease, gastrointestinal polyposis and speckled genital pigmentation [10].

Sebaceous tumours, keratoacanthomas and visceral malignancy (Muir–Torre syndrome, MTS, Torre's syndrome; MIM 158320) [3,57–59]. This is a cancer-associated genodermatosis in which there is an association between sebaceous lesions and, to a lesser extent, keratoacanthomas and internal malignancy. Inheritance is probably autosomal-dominant. It is thought that this may represent a variant of the 'cancer family syndrome' [3,60], as internal malignancy may be equally common in members of some of these families who do not exhibit pilosebaceous cutaneous lesions. Similarities exist between MTS and hereditary non-polyposis colon cancer (HNPCC) syndrome; analysis has demonstrated overlap on chromosome 2p and correlation with *MSH2* gene mutations, the product of which involves DNA mismatch repair enzymes. Defects result in varying lengths of repetitive DNA sequences, a finding in HNPCC which has also been commented on in MTS's keratoacanthomas and sebaceous tumours [10].

Sebaceous tumours are usually multiple, but occasionally solitary. Although sebaceous adenoma is the commonest, sebaceous carcinoma and epithelioma frequently occur, and within the same patient a variety of different pilosebaceous-derived skin lesions including keratoacanthomas may arise. Multiple or solitary keratoacanthomas associated with SCC of the larynx and lower gastrointestinal tract [61,62] probably represent a variant of MTS in which expression of sebaceous tumours and adenocarcinomas is not exhibited. The cutaneous manifestations of MTS have been reported to be exacerbated by immunosuppression. The world literature, reviewed by Serleth *et al*., contained 162 reported cases with 316 internal malignancies [63]. Colorectal and urogenital malignancies predominated, and nearly half of the patients had two or more internal malignancies. Many such tumours have an early onset—around 10 years earlier than in the normal population—but despite this, the survival is often quite good (the 50% survival time is about 12 years [59]) and the incidence of metastases relatively low. Tumours may also arise in a variety of other sites; there is also an association with non-Hodgkin's lymphoma [64].

Wiskott–Aldrich syndrome (MIM #301000) (Chapter 14) [65,66]. A sex-linked, recessive condition of immunodeficiency, associated with the development of malignancy, usually of the lymphoreticular system, such as lymphoma (especially large cell or immunoblastic) and leukaemia. The small intestine is a particular site for lymphomatous involvement. Astrocytoma and leiomyosarcoma have also been reported [67]. The incidence of malignancy is probably high, but the statistics are modified by the frequent childhood mortality [68].

Chediak–Higashi syndrome (MIM #214500) (Chapter 14) [69]. A fatal autosomal-recessive illness, with features of partial albinism, photophobia, neurological abnormalities and severe, recurrent bacterial infections. In the terminal accelerated phase, patients develop fever, jaundice, hepatosplenomegaly, lymphadenopathy, pancytopenia and a deterioration of neurological changes. Death may result from bleeding due to thrombocytopenia, or from

infection. Although strongly suggestive of lymphoma, the infiltrate of affected organs is reported to be of a reactive, diffuse, mononuclear cell type, rather than neoplastic [69].

Ataxia–telangiectasia syndrome (AT; Louis-Bar syndrome; MIM *208900) (Chapter 14) [70]. A condition of autosomal-recessive inheritance, characterized by progressive cerebellar ataxia and oculocutaneous telangiectasia. There is a variable but progressive immune deficiency of both the cell-mediated and humoral types, which results in frequent infections and a reduction in immune surveillance [70]. As a result, there is a high incidence of neoplasia, approximately 10%, usually in or before the teenage years [71,72]. The majority of tumours are lymphoproliferative or leukaemic, although carcinomas of various sites also occur [2]. T-cell leukaemia occurs in younger patients and an aggressive prolymphocytic leukaemia in older cases, although B-cell leukaemias are also encountered. A higher risk of breast malignancy in females who are heterozygotes for AT has been reported, but may not manifest with early onset [10]. The *ATM* gene has been associated with chromosome 11q22; a large gene has been described in this region. There may be many different germ-line mutations that alter the product, ATM protein, which is involved in the handling of chromosome strand breaks and activation of the p53 oncogene [10].

Bloom's syndrome (MIM *210900) (Chapter 14) [73]. An autosomal-recessive disorder that affects principally the Ashkenazi Jewish ethnic group. It is characterized by small stature and slight build, a sun-sensitive telangiectatic rash and café-au-lait macules. Minor anatomical abnormalities and congenital anomalies commonly occur. Levels of IgA and IgM are low and bacterial infections frequent. The occurrence of lymphoproliferative neoplasia and epithelial tissue cancers, particularly gastrointestinal, is high [71,74]. Mutations of the gene designated *BLM* on chromosome 15q26 lead to inhibition of the function of the protein product, a DNA helicase enzyme. There is a predisposition to malignancy through mutations in other target genes [10].

Rothmund–Thomson syndrome (RTS; poikiloderma congenitale; MIM #268400) (Chapter 12). RTS is a rare autosomal-recessive genetic disease, characterized by developmental abnormalities in the skin and skeletal systems, including photosensitivity, poikiloderma, small stature and juvenile cataracts. Premature ageing and a predisposition to certain malignancies occur; malignancies include an approximate 30% incidence of osteosarcoma, whilst fibrosarcoma, myelodysplasia and non-melanoma skin cancer also occur. A mutation of genes for RecQ helicase is thought to be responsible for at least some, if not all, cases of RTS. Two other human RecQ helicase gene mutations are recognized in the recessive conditions Bloom and Werner syndromes—all three conditions predispose to abnormal growth, premature ageing and increased incidence of site-specific malignancies [75–77].

Dyskeratosis congenita (Zinsser–Engman–Cole syndrome; MIM #305000) (Chapter 14) [78]. An X-linked recessive genodermatosis delineated by atrophy and pigmentation of the skin, nail dystrophy and mucous membrane changes. The latter change, termed mucosal leukokeratosis, is prone to develop carcinoma; there is also a raised incidence of malignancy, particularly gastrointestinal, including pancreatic adenocarcinoma and severe haematological disorders, similar to those found in Fanconi's anaemia and Hodgkin's disease, which may evolve into leukaemia [71,79]. Data exist to suggest that there is a defect in cell-mediated immunity involving suppressor T cells, which may be linked to the premature ageing sometimes associated with this syndrome [80].

Follicular atrophoderma (Bazex–Dupré–Christol syndrome; MIM *301845) [81]. A rare, X-linked, dominant condition of follicular atrophoderma, milia, epidermoid cysts, hypotrichosis, basal cell epitheliomas and occasional generalized or localized hypohidrosis, which appears to have an association with leukaemia. The characteristic perioral, pigmented cutaneous manifestations may assist early recognition [82].

In many of the above conditions, it has been presumed that defective immunosurveillance is responsible for the raised incidence of neoplasia. However, exact mechanisms have often been uncertain and/or multifactorial; increasingly, the expansion of our understanding of the human genome is elucidating the mechanisms underlying these syndromes. Clearly, chromosome instability and failure of DNA-repair mechanisms have been thought to be and are now shown to be partially responsible in some groups. The need for identification, screening and early detection of neoplasia in all at-risk cases should be emphasized.

Exposure to carcinogens [83]

Nicotine staining of the fingers is one of the commonest signs that a patient may be predisposed to bronchial carcinoma, together with other tobacco-linked neoplasia.

X-ray damage to the skin may indicate that underlying tissues are at increased risk of neoplasia; this is particularly relevant for neck and thyroid carcinoma. X-ray damage and/or multiple basal cell carcinomas over the spine following radiotherapy for ankylosing spondylitis may indicate the patient is predisposed to leukaemia.

Arsenic-induced pigmentation (Fig. 59.6; Chapter 73), keratoses (Chapter 36), Bowen's disease, superficial BCCs and multiple sebaceous tumours can be linked to an increased risk of internal neoplasia (especially bronchial).

Fig. 59.6 Arsenical keratoses on the hand. (Courtesy of Dr P. Dufton, Clatterbridge Hospital, Wirral, UK.)

The relationship between Bowen's disease of non-sun-exposed skin and an increased risk of internal neoplasia has been a long-standing controversy [84]. If the link with arsenic is excluded, the association appears unsubstantiated [85,86].

Vinyl chloride-related acrosclerosis, acro-osteolysis and papular skin changes are variable markers of heavy industrial exposure in polyvinyl chloride manufacture. An occasional link with angiosarcoma of the liver has been noted [87].

Paraneoplastic syndromes [83]

Acanthosis nigricans (Chapter 34) [88,89] may be divided into two important categories: benign and malignant. Schwartz [89] describes eight types of acanthosis nigricans: benign, obesity-associated, syndromic, malignant, acral, unilateral, medication-induced and mixed types. When its onset is in adult life and is not associated with a predisposing cause such as positive family history, obesity, various endocrinopathies (particularly insulin-resistant types [90]) or drug ingestion (especially nicotinic acid), then there is a high correlation with internal malignancy. Malignancy-associated acanthosis nigricans is much less common than the non-malignancy-associated types. It may have a rapid onset and spread [89]. Paediatric occurrence does not necessarily, however, imply a benign form. Whilst it has been associated with a number of different malignancies, the most common site of underlying neoplasm is the gastrointestinal tract (90%), especially gastric adenocarcinoma [2]. Rarely, an association with lymphoma has been recorded [91]. The prognosis with malignant acanthosis nigricans is generally poor, which at least in part is related to the low survival rate from the neoplasia concerned. However, the changes may resolve with eradication of the cancer [92]. The clinical dilemma is often to exclude malignancy, especially as acanthosis nigricans can be a presenting sign; an algorithm for evaluation is therefore useful [93]. Malignancy-associated acanthosis nigricans may occur in association with the sign of Leser–Trélat, florid cutaneous papillomatosis and acanthosis palmaris. More rarely associated paraneoplastic phenomena include pachydermoperiostosis, paraneoplastic pemphigus and acquired hypertrichosis lanuginosa [1–6,94].

Acanthosis palmaris (tripe palms, pachydermatoglyphy) [95]. This consists of thickened palms and/or occasionally soles with an enhanced dermatoglyphic change, which gives rise to a velvety or honeycombed pattern of the hand. Acanthosis palmaris usually occurs in association with neoplasia; it can occur in isolation without neoplasia, or as a reflection of exfoliative psoriasis [96]. Coexistence with acanthosis nigricans is recognized. Acanthosis palmaris occurring alone was more often associated with bronchial carcinoma (53%) compared with combined acanthosis nigricans and acanthosis palmaris, in which 35% had gastric carcinoma and only 11% bronchial neoplasia [97]. Resolution of the palmar changes has been described with resection of the tumour [97]. As the condition can frequently be the presenting sign of neoplasia, it requires appropriate evaluation and investigation.

Dermatomyositis (Chapter 56) [98]. Both dermatomyositis and polymyositis in adults may be associated with internal malignancy. The frequency of the link varies between 6% [99] and 50% [100], depending on the age range of the series reported and the numbers involved. The association with neoplasia is much stronger for dermatomyositis than for polymyositis or dermatomyositis/autoimmune disease overlap conditions. Conventional teaching has been to implicate a malignancy association with dermatomyositis in the over-40 age group, and this is normally the case; however, paediatric cases with neoplasia are reported [101]. As there is a lower incidence of malignancy in the younger age group, it is difficult to judge the association without age-matched comparative studies against a control population [98]; until these data are available, no absolute judgement in this respect should be made on the basis of age alone.

The validity of the temporal association of polymyositis–dermatomyositis with neoplasia is still questioned by some workers, but even so the important 2-year initial period has a four to five times increased incidence of malignancy [102]. Accounts of specific malignant associations seem subject to bias by rare-case reporting. In reality, the malignancies seem to some extent to reflect tumour prevalence in the general population; lung cancer in men, breast and gynaecological tumours, particularly ovarian, in women [103,104]. The value of extensive screening for neoplasia in dermatomyositis is questionable. Emphasis should be attached to thorough clinical evaluation, simple investigations and then specific investigations as indicated [104]. Exceptions to this are if previous neoplasia has been present, when the therapeutic response is poor, and perhaps a recognition of the possibility of hidden tumours in the female genitourinary tract.

Digital ischaemia [105]. Persistent, painful digital ischaemia, often progressing to gangrene and having an unusual Raynaud's syndrome-type appearance, has been linked to a variety of solid tumour and reticuloendothelial neoplasia [105,106]. The process may have a vasculitic element [107]. Often, however, the aetiology is uncertain, but clearly there may be a merging of malignancy-associated systemic sclerosis [108] or dermatomyositis with mixed connective tissue disease overlap. Hyperviscosity syndromes such as polycythaemia rubra vera or myeloma-linked cryoglobulinaemia may give rise to cutaneous ischaemia and phlebitis by a more direct vascular sludging effect.

Vasculitis and malignancy [107]. There appears to be an association of cutaneous vasculitis with neoplasia, particularly in myeloproliferative disorders [109], although clearly there is overlap with digital ischaemia. The dermatological manifestations include palpable purpura, maculopapular, urticarial and petechial lesions; these presumably reflect a small-vessel vasculitis or even, when ulceration occurs, a necrotizing vasculitis [107]. The changes often appear to antedate bone marrow involvement, as opposed to the more predictable purpura due to thrombocythaemia, which reflects bone marrow infiltration by myeloproliferative disease or carcinoma. Leukocytoclastic vasculitis has been variably associated with infections, cryoglobulinaemia and drug reactions, but a paraneoplastic aetiology is specifically recognized, including a rare presentation of multiple myeloma [110].

Migratory erythemas

There are three main variants, which may be associated with internal neoplasia to a very variable extent.

Erythema gyratum repens (p. 59.71). This is a rare, bizarre cutaneous eruption consisting of mobile concentric, often palpable, erythematous, wave-like bands, which give a 'wood-grain' appearance to the skin (Fig. 59.7). A peripheral scale or collarette may be present. The complete torso is frequently affected. There is a substantial association with internal malignancy, but this is not absolute [111]. It is, however, mandatory to investigate for this possibility. Perhaps the commonest underlying neoplasm is lung cancer [112], but many solid cancers have been implicated and some myeloproliferative disorders. Resection of the tumour can result in resolution of the eruption.

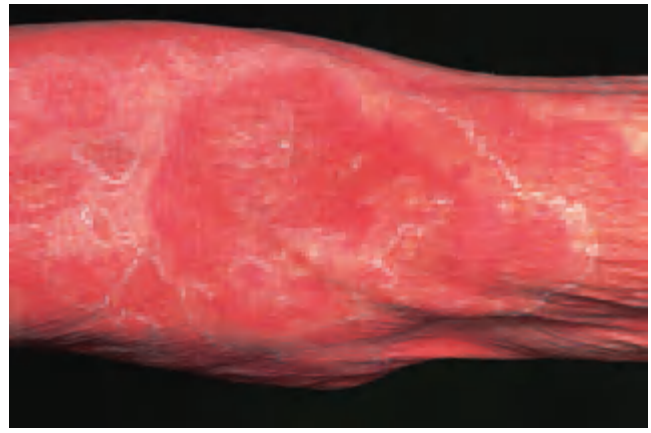

Fig. 59.7 Erythema gyratum repens of the arm secondary to carcinoma of the bronchus. (Courtesy of Dr A.W. McKenzie, Norfolk and Norwich Hospital, Norwich, UK.)

Necrolytic migratory erythema (glucagonoma syndrome) [113–115]. This is the characteristic eruption associated with an α-cell tumour of the pancreas. It is discussed in the section on pancreatic disease later in this chapter.

Erythema annulare centrifugum [116,117]. Most annular erythemas of this type are not associated with neoplasia (p. 59.72). Rarely this can occur, particularly with myeloproliferative disorders [117]. Clinical examination and routine screening tests are the only investigation required, rather than an exhaustive search for malignancy, unless there are additional clinical pointers.

Multicentric reticulohistiocytosis (lipoid dermatoarthritis; reticulocytoma cutis) [118,119]. In this rare condition, approximately 28% of cases are associated with internal neoplasia, virtually always solid tumours such as those of the breast, ovary or cervix [118,119], although haematological malignancies have been reported [120]. Tumours may coexist at the presentation of the disorder, usually in adult life. The characteristic papulonodular lesions occur most often on fingers or other extremities, and mucous membranes. A severe polyarthritis is frequently associated [121].

Paraneoplastic acrokeratosis (Bazex's syndrome) [122–128]. This is a rare condition, associated particularly with SCC of the upper respiratory or gastrointestinal tracts, particularly when there are metastases in the cervical lymph nodes. Rare associations such as metastatic adenocarcinoma of the prostate and transitional cell carcinoma of the bladder have been reported [125,126]. It is much commoner in males than females [127,128]. The cutaneous changes develop gradually, often in several phases, initially with violaceous erythema and scaling on the peripheries, especially ears, nose, hands and feet. The eruption then becomes more hyperkeratotic, with a keratoderma on hands and feet. Subsequently, the eruption may become more generalized. Nail dystrophy and paronychia are often present. Changes on the face may appear more eczematous or lupus erythematosus-like, whereas acral changes are often psoriasiform. The differential diagnosis can include dermatitis, especially seborrhoeic or contact-allergic types. Alternatively, acral psoriasis with the possibility of Reiter's syndrome may be considered. The course mostly parallels the underlying neoplasm; resolution may occur with successful tumour resection, and recurrence may develop on relapse of malignancy. When resection is felt inappropriate or impracticable, systemic retinoids may improve the cutaneous changes [124]. The histological changes are non-diagnostic, but essentially reflect the clinical appearance with hyperkeratosis, parakeratosis, focal spongiosis and a mixed, inflammatory cell infiltrate [127].

Acquired ichthyosis [129,130]. Sudden onset of ichthyosis similar to the pattern of ichthyosis vulgaris in adult life does appear to be associated with internal malignancy, particularly lymphoreticular tumours. However, cases linked with solid tumours are also well documented [130]. The acquired change should not be confused with asteatosis, which of course is a common problem in elderly people. Acquired ichthyosiform changes can be a manifestation of other systemic disorders, including nutritional deficiencies, sarcoidosis, leprosy, hypothyroidism, lupus erythematosus and drug reactions. Again, in such reports it is important to distinguish ichthyosis from dry-skin changes. Pityriasis rotunda—a fixed, annular, scaling, dry-skin change more often seen in the African and Asian races—has been associated with neoplasia, particularly hepatocellular carcinoma. However, it may also be seen in other systemic diseases and in leprosy [131].

Pruritus [132]. Haematological disorders and lymphoma may cause generalized pruritus; in particular, itch may be a severe problem in patients with Hodgkin's disease and may indicate a poorer prognosis [133]. Sézary syndrome, mycosis fungoides, myelomatosis and leukaemia may also cause generalized pruritus [132]; the mechanisms in these conditions are poorly understood. In polycythaemia rubra vera (PRV), the initiating factor appears to be rapid cooling of the skin, as encountered after bathing. This is thought to be due to the release of pruritogens by degranulated mast cells [134]. However, patients with PRV can also develop intractable itching unrelated to bathing.

Internal carcinoma is a non-specific, rare, but important cause of pruritus. Clearly, this can occur through secondary metabolic effects such as uraemia or cholestasis. Alternatively, changes such as iron-deficiency anaemia, acquired ichthyosis or xerosis may be involved. Even excluding these mechanisms, virtually any of the visceral carcinomas can cause pruritus; again, the mechanisms are frequently poorly understood. Brain tumours can be an uncommon cause of pruritus. If itching or paraesthesiae are localized to the nostrils, a tumour invading the floor of the fourth ventricle may be the cause, but sometimes generalized itching can occur with intracranial neoplasia [17]. Unfortunately, senile pruritus and asteatosis are not uncommonly encountered in elderly patients, a group who are more at risk from malignancy. It is therefore difficult to dissociate chance from real occurrence, which can lead to difficulties in deciding whether screening is indicated on a cost-effective basis [135]. In a 6-year study of 125 patients with generalized pruritus, Paul *et al*. [135] found no significant increase in malignancy, although of the eight patients with malignancy detected, two had lymphoma—a higher than expected incidence.

Bullous eruptions. Bullous pemphigoid has, in isolated reports, been associated with underlying neoplasia [136–138]. However, when large series have been examined, the results indicate that there is not a significant association with malignant disease [139,140]. Despite this, the issue remains controversial, and more selective studies have shown there may be a correlation when immunofluorescent findings are negative and mucosal involvement is present [139,141]. Some cases may also reflect the difficulty in diagnosing or excluding epidermolysis bullosa acquisita, in which saline–split skin immunofluorescence, immunoelectron microscopy or immunoblotting may be required [142]. Malignancies have been reported from breast, lung, thyroid, larynx, skin, soft tissue, stomach, colon, lymphoreticular system, prostate, cervix, bladder, kidney and uterus [143]; in a Japanese population, there was an association with gastric carcinoma [144]. Clearly, in a disorder that principally affects elderly people, who are more prone to internal neoplasia, a reported association with choriocarcinoma is interesting, as this tumour usually occurs in a younger age group [145]. It is likely that this association is with pemphigoid gestationis (herpes gestationis); nevertheless, in such circumstances it is also a paraneoplastic phenomenon. Perhaps particular consideration should also be given to an association with malignancy in the young and those who respond poorly

to therapy. The debate will continue—hopefully supported by carefully controlled studies—as to whether there is a definite association in onset, course and resolution. This may be particularly true of squamous tumours of the genitourinary tract [143], where SCC-related, cross-reacting antigen could be a factor. However, an exhaustive search for internal neoplasia is not generally warranted; rather, the emphasis should be on thorough clinical examination, evaluation and routine screening tests.

Pemphigus and paraneoplastic pemphigus (PNP). Historically, pemphigus has been linked with various tumours; some of these, such as thymoma [146] and Castleman's pseudolymphoma [147] are rare and the association therefore seemed likely to be real. Pemphigus foliaceus has been associated with acanthosis nigricans-like lesions and hepatocellular carcinoma [148], and pemphigus in Japanese subjects has been associated with lung cancer [144]. The concurrence of internal malignancy and pemphigus, as with bullous pemphigoid, may be a true association [149], although critical reviewers suggest this to be coincidence [150].

A specific condition, now termed PNP, has been delineated [151–154]. This may represent one manifestation of a heterogeneous, multiorgan, autoimmune syndrome in which patients may display a spectrum of five different mucocutaneous manifestations including pemphigus-like, pemphigoid-like, erythema multiforme-like, graft-versus-host disease-like and lichen planus-like; in addition, there is an association with small-airways occlusion [152] and deposition of autoantibody complexes in different organs. The mucosal disease is often severe and progressive. Associated neoplasms in one large review series were mainly B-cell proliferations and thymoma or thymoma-like neoplasms; specific neoplasms included Hodgkin's lymphoma (42%), chronic lymphocytic leukaemia (29%), Castleman's tumour (10%), thymoma (6%), spindle cell neoplasms (6%) and Waldenström's macroglobulinaemia (6%) [151]. PNP is distinguished from pemphigus by its clinical features and by the presence of serum autoantibodies to a range of antigens of 250, 230, 210, 190 and 170 kDa (which include bullous pemphigoid antigen, desmosomal and hemidesmosomal proteins); high sensitivity and specificity for this differential diagnosis has recently been reported by taking account of the association with a lymphoproliferative disorder, indirect immunofluorescence of rat bladder, and recognition of envoplakin and/or periplakin bands on immunoblotting [154].

Linear IgA disease appears to have a higher-than-predicted association with lymphoproliferative malignancy. However, it is uncertain whether this is due to a common aetiological factor or represents a true paraneoplastic phenomenon [155]. Lymphoma is known to occur with increased frequency in gluten-sensitive enteropathy, and a questionable raised incidence of lymphoma has been reported in dermatitis herpetiformis [156]; but again, there is considerable doubt whether this should be regarded as a cutaneous paraneoplastic manifestation.

Transient acantholytic dermatosis has been linked with internal malignancy, particularly with myelogenous leukaemia and carcinoma of the genitourinary tract. However, this may be linked in part with therapy [157].

Porphyria cutanea tarda, acute intermittent and variegate porphyrias have been associated with hepatocellular carcinoma [158]. Myeloma and visceral carcinoma have also been reported [159]. Acquired epidermolysis bullosa has been reported to occur in association with neoplasia, particularly myeloma and lymphoma; problems may arise in distinguishing the condition from porphyria cutanea tarda, as well as from bullous pemphigoid.

Erythema multiforme, erythema nodosum and subcutaneous fat necrosis. With erythema multiforme and erythema nodosum, any association is hard to evaluate, as both may be reactions to drugs, radiotherapy or infections—all of which are likely scenarios in patients with neoplasia. Erythema multiforme-like eruptions do occur with carcinomas, lymphomas and leukaemias [2], particularly myelomonocytic types. However, histological analysis of the latter lesions sometimes demonstrates the presence of abnormal cells. In acinar cell carcinoma of the pancreas, a syndrome of panniculitis, polyarthritis and eosinophilia can occur [1]. This form of subcutaneous fat necrosis is similar to the changes in Weber–Christian disease (Chapter 55). It seldom occurs with islet cell tumours.

Migratory thrombophlebitis (Trousseau's sign) [2]. Unlike superficial thrombophlebitis of the lower limbs, this recurrent and migratory type is often associated with neoplasia, particularly carcinoma of the pancreas, stomach and lung. A variety of sites, especially the upper extremities and trunk, can be involved. Deep veins, particularly on the lower limbs, are rarely affected; lesions are usually multiple. The mechanism is thought to be an intravascular, low-grade hypercoagulation, which responds poorly to anticoagulant therapy. Skin manifestations may be the only presenting sign and may point to a highly malignant and often metastatic malignancy of correspondingly poor prognosis [1].

Pyoderma gangrenosum and neutrophilic dermatoses. These are discussed in greater depth in Chapter 49. Pyoderma gangrenosum, particularly in a superficial and bullous (Fig. 59.8) form, has been associated with myeloproliferative diseases, including acute and chronic mye-

Fig. 59.8 Bullous pyoderma gangrenosum of the leg. (Courtesy of Dr P. Dufton, Clatterbridge Hospital, Wirral, UK.)

loid leukaemia, acute lymphocytic leukaemia, myeloid metaplasia, PRV, multiple myeloma, lymphoma and myelofibrosis [160,161]. The association of pyoderma gangrenosum with monoclonal gammopathy is uncertain, but it does occur at a frequency higher than expected in the general population and is usually of IgA type, whereas IgG gammopathy is the commonest type overall [110]. Solid tumours reported include carcinoid, colon, bladder, prostate, breast, bronchus, ovary and adrenocortical carcinoma [161].

Sweet's syndrome has likewise been associated with several malignancies, especially haemopoietic.

Erythroderma (Chapter 17). Whilst this may be an expression of mycosis fungoides and its leukaemic variant, Sézary syndrome, there is still a small number of patients who have neither condition, but present with erythroderma and eventually develop lymphoma or leukaemia. The incidence is uncertain and rare; a report in an Asian population failed to demonstrate one association in 80 patients [162]. Immunophenotypic studies do not appear to help distinguish benign from malignant cases. Ofuji papuloerythroderma has also been associated with peripheral T-cell non-epidermotrophic cutaneous lymphoma [163]. Correlations with solid tumours such as lung, colon, stomach, prostate, liver, pancreas and thyroid have been infrequently recorded, often in late-stage disease [164].

Leser–Trélat sign [165,166]. Internal malignancy associated with the sudden development of numerous seborrhoeic keratoses, in an eruptive fashion with or without pruritus, is generally accepted as the sign of Leser–Trélat. Unfortunately, multiple seborrhoeic keratoses are such a common occurrence, especially in elderly people, that caution should be exerted when attempting to make this diagnosis. Even the most positive pointer of multiple, rapidly erupting seborrhoeic keratoses is an unreliable guide. Care should also be taken when interpreting multiple eruptive seborrhoeic keratoses in association with a generalized dermatosis, as this is a recognized occurrence with certain primary dermatoses, rather than necessarily being linked to internal malignancy [167].

A closer association is found between internal malignancy and the seborrhoeic keratosis-like lesions of acanthosis nigricans. Of the cases reported, the most frequent link is with adenocarcinoma, especially of the gastrointestinal tract and breast. However, this in part may just reflect the incidence of these tumours in an age group at risk of seborrhoeic keratoses. Rare associations have been documented with a variety of other neoplasms, including those of the reticuloendothelial system [168], malignant haemangiopericytoma [169], malignant melanoma [170] and transitional cell carcinoma of the bladder [171].

The inclusion of the sign of Leser–Trélat as a paraneoplastic phenomenon can at best be regarded as tenuous, but the sign may have clinical relevance when associated with acanthosis nigricans and/or an appropriate eruptive history. Weakened subepithelial matrix from the effects of neoplasm on the extracellular matrix of the host has been postulated as a possible cause for the changes seen in Leser–Trélat and acanthosis nigricans [172].

A variety of other eruptive lesions have been reported rarely as paraneoplastic phenomena, including keratoacanthomas in MTS (p. 59.17), angiomatous lesions [173] and telangiectasia. Campbell de Morgan angiomas are a common normal finding with age, but unusually rapid onset may be an important feature [2].

Seed-like keratoses of the palms and soles [174]. Acquired punctate keratoses of the palms and soles may be associated with internal malignancy. They are a common

normal finding in healthy subjects (36%) over 50 years old, but are apparently more common in individuals with carcinoma of the bladder (87%) and bronchus (71%) [174]. There are, however, problems with differentiation from keratosis punctata et plantaris occurring as an inherited condition and associated with adenocarcinoma of the colon [175]. Punctate keratoderma occurring in Cowden's syndrome (Chapter 12) and seed-like keratoses with arsenic ingestion may also be associated with internal malignancy.

Flushing is a normal physiological response and may be a problematic menopausal symptom. However, it may also suggest a diagnosis of carcinoid syndrome. The gastrointestinal system is the most commonly affected site, especially the appendix and ileum. Flushing and other symptoms such as diarrhoea, abdominal pain and breathing difficulties do not usually occur until liver metastases have developed. Ovaries and bronchi may be alternative primary sites. Flushing is the commonest feature of carcinoid syndrome, often affecting the face or upper extremities, and at least initially is transient in nature. Skin manifestations can therefore be the presenting symptoms and may also include a persistent erythema with or without telangiectasia, scleroderma-like change, pigmentary anomalies and a pellagra-like dermatitis [1].

Confusion can occur between the plethoric appearance seen in PRV and the facial suffusion found in superior vena caval obstruction.

Unilateral lymphoedema. Acquired unilateral lymphoedema of reasonably rapid onset, especially over the age of 40 years, suggests regional lymphatic obstruction proximally, which may be explained by malignant deposits or compression by an expanding tumour.

Clubbing and hypertrophic osteoarthropathy of the airways. Clubbing and secondary hypertrophic osteoarthropathy of the airways (HOA) have been documented with many neoplasms, the commonest being carcinoma of the bronchus. A high incidence of HOA occurs particularly with mesothelioma; but it may also occur with malignancies of the pulmonary, cardiovascular, gastrointestinal and hepatobiliary systems [176].

Cutis verticis gyrata. In its secondary form, this may on occasion occur as a paraneoplastic phenomenon [177].

Scleroderma-like skin changes may be a cutaneous manifestation of carcinoid syndrome, but without Raynaud's phenomenon [1]. However, in scleroderma there does appear to be an association with malignant disease [108], at least on a temporal basis. Some cases do seem to be linked with management of the malignant disease, in particular when radiotherapy has been employed [178].

Herpes zoster occurs more severely, with higher incidence and wider dissemination, in patients with reticuloendothelial or myeloproliferative neoplasia [179]. However, the uncomplicated form is common in elderly people and does not demand intensive investigation.

Infections. A variety of viral, bacterial and fungal infections may occur with internal malignancy, particularly when the patient has a severely compromised immune response, either as a result of the malignant process or therapy.

Urticaria. With the exception of cold urticaria and peripheral gangrene as a result of circulating cryoglobulins, where there is a possible, but uncommon, link with myeloma and lymphoma [180], associations of urticaria and neoplasia are difficult to evaluate. Certainly it cannot be regarded as an established paraneoplastic phenomenon, other than in Schnitzler's syndrome (a distinct disorder of chronic urticaria, bone pain, hyperostosis, high erythrocyte sedimentation rate and monoclonal IgM gammopathy). IgM κ is the commonest paraprotein found; the urticaria under histological analysis is described as neutrophilic inflammation within dermal venules with some perivascular involvement, but can rarely extend to a leukocytoclastic vasculitis. Although the overall prognosis is reasonable, around 10–15% of patients develop lymphoplasmacytic lymphoma [110].

Acquired hypertrichosis lanuginosa (Chapter 63). An exceedingly rare condition, for which, once drug-induced causes such as diazoxide and minoxidil have been excluded, there is a reliable link with internal malignancy.

Generalized hyperhidrosis. A rare occurrence, which may be associated with malignant disease.

Lichen planus may rarely be induced by neoplasia [181]. There is also an increased risk, particularly in males, of oral squamous carcinoma; this may be due to a combined direct effect and co-factors such as smoking [182].

Conclusion

Potential cutaneous markers of internal malignancy vary in their reliability for predicting underlying neoplasia. A clinical decision on the extent of investigation and screening, if any, must therefore be made. No absolute directive can be given. A good history, careful clinical examination and simple investigations such as chest radiography, full blood count, urine analysis and stool examination for occult blood are often sufficient. The identification of genes linked with a high incidence of malignant disease, where appropriate, will assist with diagnosis and therapy.

The gastrointestinal tract

Skin changes related to nutritional defects, a consequence of many gastrointestinal diseases, are discussed in Chapter 57, and oral disease in Chapter 66. This section concentrates on bowel, hepatic and pancreatic diseases in which skin manifestations are prominent [1–4]. Links between skin disorders and abdominal pain are not specifically considered, but many of the disorders in this section may cause this symptom; less overt causes of skin eruption with abdominal pain include disorders such as hereditary angio-oedema (Chapter 47), vasculitides (Chapter 49), porphyrias (Chapter 57), and periodic fevers (see the section on bone and joint disease). Cutaneous metastases and paraneoplastic eruptions due to gastrointestinal

malignancy are discussed in the preceding section of this chapter.

Oesophagus and stomach

Bleeding from the oesophagus or stomach may be associated with skin and nail changes of iron deficiency, such as koilonychia, smooth tongue and angular cheilitis (Chapter 57). Iron deficiency is associated with dysphagia and development of a postcricoid web as in the Paterson–Brown–Kelly (Plummer–Vinson) syndrome. Skin disorders that are associated with gastrointestinal bleeding, or with polyps, are discussed later. Cutaneous metastases may occur from tumours of the oesophagus or stomach. Paraneoplastic eruptions linked to the upper gastrointestinal tract, such as tylosis with oesophageal carcinoma (Howell–Evans syndrome), acrodermatitis and nail dystrophy with upper gastrointestinal carcinoma (Bazex's syndrome), or acanthosis nigricans with gastric carcinoma, are discussed earlier in this chapter.

Bullous diseases may affect the pharynx, oesophagus, or stomach. Epidermolysis bullosa (EB) is of particular relevance; dystrophic EB may cause oesophageal scarring [1], with a risk of SCC, and gastric outflow is affected in junctional EB, resulting in pyloric atresia [2,3]. Cicatricial pemphigoid may cause oesophageal scarring and stenosis. Lichen planus may also occur in the oesophagus [4,5].

Sclerodermatous processes also affect the oesophagus, in particular CREST (*c*alcinosis, *R*aynaud's phenomenon, o*e*sophagus, *s*clerodactyly, *t*elangiectasia). This disorder is discussed more fully in Chapter 56. The oesophageal abnormality consists of decreased and disordered peristalsis. Scleroderma is also associated with decreased peristalsis throughout the bowel, leading to malabsorption, constipation and diverticulae. Sjögren's syndrome may also cause dysphagia, as may dermatomyositis in cases in which there is involvement of the pharyngeal musculature.

Helicobacter pylori has been implicated as an aetiological factor in some cases of urticaria, rosacea, vasculitis, Sweet's syndrome, erythema multiforme, alopecia areata, chronic itch and prurigo nodularis, and atopic and nummular dermatitis [6–8]. Although there are some individuals in whom eradication therapy coincides with resolution of a dermatosis, most larger studies in which there is adequate control for confounding factors such as age and social class have failed to demonstrate either a higher prevalence of *H. pylori* infection, higher titres on ^{13}C urea breath test, or a higher rate of response to eradication therapy in infected individuals compared with controls [9–12].

Crohn's disease (regional ileitis)

Skin lesions are frequently seen in Crohn's disease [1–4]. These include:

- Crohn's disease occurring as direct extension from the bowel
- Cutaneous lesions of Crohn's disease at other skin sites
- Reactive lesions that are associated with Crohn's disease, but which do not have granulomatous histology
- Skin lesions related to malabsorption (Chapter 57)
- Skin lesions related to treatment: drug reactions, stoma dermatoses, etc.
- Other associated dermatoses.

Direct skin and mucosal involvement in continuity with the bowel

Cutaneous Crohn's disease may occur at sites in continuity with the bowel, such as the lip, stoma sites [5] or, commonly, the perineal skin. Orofacial granulomatosis and the overlap with Crohn's disease is discussed in Chapter 66. The umbilicus, a site connected to the bowel by a vestigial tract, may also be involved [6].

Perineal abscesses and multiple fissures and fistulae occur in about a quarter of patients ('watering-can peri-

neum'). This is more frequent in individuals with colonic disease [7] and may affect about 60% of patients, although symptoms may be absent. By contrast, such lesions are rare in ulcerative colitis. Anal tags, which may be oedematous or have granulomatous histology, are common.

Oral Crohn's disease is manifest as a thickened, corrugated appearance of the oral mucosa and lips. Granulomatous cheilitis may precede other features of Crohn's disease (Chapter 66).

Cutaneous Crohn's disease at other sites ('metastatic Crohn's disease')

Cutaneous Crohn's disease may also occur at sites separated from the bowel by normal tissues—a situation that is termed 'metastatic Crohn's disease', although not technically correctly [8–11]. Lesions may parallel gastrointestinal disease activity, or may occur with a totally separate temporal pattern.

Lesions of cutaneous Crohn's disease may be solitary or multiple, and may have varied morphology, including intact or eroded plaques and nodules, or sinus formation. The lower legs are involved in half of the cases, with lesions sometimes mimicking erythema nodosum, but cutaneous Crohn's disease may affect the abdominal wall, groin and inframammary flexures, face and other sites. Genital involvement may be a presenting feature, affecting the perineum [11], vulva [12], scrotum or penis [4,13]. Unusual patterns include perifollicular papules [14], erysipelas-like lesions [15] and necrobiotic lesions [16]. In any of these morphological variants, there is a granulomatous histology in the dermis and subcutis.

Treatments for both contiguous and 'metastatic' Crohn's disease include topical and intralesional corticosteroids, agents used to treat the bowel disease (oral corticosteroids, sulphasalazine and split products such as mesalamine, immunosuppressive agents), oral metronidazole, hyperbaric oxygen and recently antitumour necrosis factor-α monoclonal antibodies.

Reactive dermatoses associated with Crohn's disease

These include oral aphthae, erythema nodosum and a variety of neutrophilic dermatoses. As most of the reactive processes can occur with either type of inflammatory bowel disease, but most are more commonly associated with ulcerative colitis than with Crohn's disease, they are discussed later in this section.

Other dermatoses that have been associated with Crohn's disease

Epidermolysis bullosa acquisita (EBA) has been associated with both Crohn's disease and ulcerative colitis, mainly the former [17] (see also Chapter 41). In most instances, Crohn's disease had been established for several years prior to development of EBA, although EBA may precede diagnosis of the bowel disease [18]. This condition may be very refractory to treatment; drugs that may improve both the bowel disease and the cutaneous lesions of EBA include corticosteroids, azathioprine and ciclosporin.

Other bullous disorders that have been linked with Crohn's disease include *oral intraepidermal IgA pustulosis* [19] and *subcorneal pustular dermatosis* [20]; it has been suggested that the latter eruption was actually pustular pyoderma gangrenosum [21].

Polyarteritis nodosa (PAN) has been associated with Crohn's disease, but not specifically with ulcerative colitis [22,23]. It may be difficult to distinguish PAN from 'metastatic' Crohn's disease in patients with both disorders, as the histological features include a granulomatous component with the arteritis [24]; PAN may also resemble erythema nodosum or early pyoderma gangrenosum. The presence of livedo may suggest the diagnosis, but this can also occur due to cryoglobulinaemia. Other patterns of vasculitis associated with inflammatory bowel disease are discussed in the section on ulcerative colitis.

Psoriasis has been associated with Crohn's disease in several epidemiological studies [25], and vitiligo may also be associated.

In patients with Crohn's disease, apparently unrelated skin disorders may develop granulomas, for example hidradenitis suppurativa [26]. The presence of granulomas within predominantly neutrophilic infiltrates may cause diagnostic difficulty [27].

Disorders of keratinization that have been linked to Crohn's disease include *porokeratosis* [28] and *parakeratotic horns* [29].

Acrodermatitis enteropathica due to secondary zinc deficiency is a well-documented consequence of Crohn's disease [30] (Chapter 57).

Ulcerative colitis [1–4]

Skin lesions occur in up to a third of patients with ulcerative colitis [2], although usually in the region of 10–15%. As with Crohn's disease, these fall into several categories:

- Reactive lesions (a similar spectrum, but commoner in ulcerative colitis than in Crohn's disease)
- Direct involvement contiguous with the bowel (fissures and fistulae; rare)
- Skin lesions related to malabsorption (Chapter 57)
- Skin lesions related to treatment: drug reactions, stoma dermatoses, etc.
- Other associated dermatoses.

Reactive lesions associated with ulcerative colitis and Crohn's disease

A variety of non-specific eruptions may occur with either ulcerative colitis or Crohn's disease, usually paralleling the activity of inflammatory bowel disease [5]. However, all of these may occur for other reasons or in isolation. They include:

- Erythema nodosum—this occurs in about 5% of patients with ulcerative colitis and in about 2% with Crohn's disease, and is the predominant pattern of reactive skin lesions in children [6].
- Aphthous ulceration [1]—this occurs in about 5–8% of patients with ulcerative colitis and a rather smaller proportion with Crohn's disease. In some instances, the mechanism may be malabsorption, leading to iron and vitamin deficiency. Oral aphthae also occur in isolation, in association with numerous medications and in other medical disorders (including other bowel disorders, such as coeliac disease).
- Erythema multiforme [7,8]—this may occur in either disorder, usually associated with active disease (or as a side effect of treatment).
- Urticaria and angio-oedema.
- Neutrophilic dermatoses—these also occur in association with other disorders, but pyoderma gangrenosum and pyostomatitis vegetans in particular are strongly associated with inflammatory bowel disease. These disorders are discussed in more detail below.
- Vasculitis and intravascular coagulation disorders—these also occur as a consequence of inflammatory bowel disease, most commonly active ulcerative colitis, and are discussed separately below.

Neutrophilic dermatoses

Pyoderma gangrenosum [9–12]. Pyoderma gangrenosum occurs as a complication of inflammatory bowel disease, haematological disorders, inflammatory arthritides and other medical conditions [10] (it is discussed more fully in Chapter 49). It is estimated to occur in about 2–5% of patients with ulcerative colitis, this disorder being the single commonest cause of pyoderma gangrenosum; it is three to five times commoner in patients with ulcerative colitis than in those with Crohn's disease. The ulcerative and pustular variants in particular are associated with inflammatory bowel disease. It may also occur in other bowel diseases, such as the bowel-associated dermatosis–arthritis syndrome (see below) and diverticular disease [13], as a peristomal dermatosis [14] and in patients with hepatitis. The characteristic lesions are rapidly progressive necrotic skin ulcers with a bluish-coloured undermined border, but nodular and pustular lesions may occur, especially in early disease. Trauma is sometimes a predisposing factor. Pyoderma gangrenosum generally parallels the activity of the colitis [1–4], but may precede the diagnosis [15] or occur many years after complete removal of the diseased bowel [16]. Treatments for pyoderma gangrenosum include corticosteroids (topical, oral, intralesional), dapsone, azathioprine, ciclosporin, mycophenolate mofetil, tacrolimus, chlorambucil, intravenous immunoglobulin,

and antitumour necrosis factor-α monoclonal antibodies [17–19].

Pyodermatitis–pyostomatitis vegetans [20,21] is a rare disorder of the oral mucosa and skin; the skin lesions were previously termed *pyodermite végétante*. The oral lesions consist of multiple pustules, plaques and erosions, which may have a 'snail's-track' appearance. The skin lesions are crusted papules and plaques, which coalesce into annular lesions, mainly affecting the major flexures and the scalp. There are similarities to pemphigus vegetans, but this is associated with strongly positive direct immunofluorescence of lesional skin, which is either negative or weak in pyodermatitis–pyostomatitis vegetans. Oral and skin lesions show the same histological features, having intraepidermal and superficial dermal microabscesses containing neutrophil and eosinophil polymorphs, and a more mixed deeper dermal inflammatory infiltrate. Acanthosis, acantholysis and pseudoepitheliomatous hyperplasia occur especially in the oral lesions. Most cases of pyodermatitis–pyostomatitis vegetans are associated with inflammatory bowel disease, usually ulcerative colitis, although the condition has also been reported with sclerosing cholangitis and in isolation. It is difficult to control; high-dose, systemic corticosteroids are the first-line therapy, but dapsone or azathioprine may be of benefit. Remission may occur following colectomy.

Acute febrile neutrophilic dermatosis (Sweet's syndrome) has been associated with inflammatory bowel disease, especially ulcerative colitis [22–25]. It may coexist with pyoderma gangrenosum [22,24], and may also occur after colectomy in patients with inflammatory bowel disease. It is discussed more fully in Chapter 49. Treatment options include corticosteroids, dapsone, non-steroidal anti-inflammatory drugs, colchicine, tetracyclines, ciclosporin and other immunosuppressive agents and, in the context of inflammatory bowel disease, metronidazole [25]. A neutrophilic colitis in a patient with Sweet's syndrome and acute myeloid leukaemia, and with previous Crohn's disease, was felt to be histologically distinct from Crohn's disease or ulcerative colitis [26].

Vesicopustular eruption and other neutrophilic dermatoses. A vesicopustular eruption may occur in ulcerative colitis [1,2,27,28], or less commonly in Crohn's disease [29]. The lesions consist of a dense neutrophilic infiltrate similar to that of pyoderma gangrenosum or Sweet's syndrome, and may be a variation of these [2,9]. In practice, many of the group of neutrophilic dermatoses may overlap, coexist or evolve from smaller papular or pustular lesions. Morphologically similar lesions in the bowel-associated dermatosis–arthritis syndrome may have vasculitic histology; features of this syndrome may also occur in patients with inflammatory bowel disease [30]. Treatment is similar to that of the other neutrophilic dermatoses.

Erythema elevatum diutinum has been reported with both Crohn's disease and with ulcerative colitis [31,32], as has oral intraepidermal IgA pustulosis [33,34].

Vasculitis and intravascular coagulation disorders

Vasculitis and purpura [1,2,35–37] may occur in either ulcerative colitis or Crohn's disease, most commonly in ulcerative colitis. The clinical picture is of a leukocytoclastic vasculitis with palpable purpura, typically affecting the lower legs and sometimes causing nodules or ulceration. Pustular lesions may have vasculitic histology. Joint pain and malaise may be prominent. Polyarteritis nodosa in Crohn's disease is discussed above.

Antineutrophil cytoplasm antibodies (ANCA) are present in 60–70% of patients with ulcerative colitis and 5–10% with Crohn's disease [38].

Cutaneous gangrene and focal thrombosis [39] is a rare complication. Patients with ulcerative colitis have significant coagulation defects; in one large early series, this was sufficient to complicate the clinical course in more than 1% of patients [40]. Abnormalities underlying this tendency include thrombocythaemia, elevated levels of fibrinogen, factor VIII and factor V, and decreased levels of antithrombin III. Microvascular thrombosis of the skin may result in cutaneous gangrene. High-dose systemic steroids have no effect on the thrombotic complications, which should be treated with anticoagulant therapy. Similar features have been reported due to cryoglobulinaemia associated with inflammatory bowel disease.

Other cutaneous disorders associated with ulcerative colitis

Linear IgA disease. Linear IgA disease may be relatively common in patients with ulcerative colitis, which usually precedes the dermatosis by several years [41]. Linear IgA disease may resolve after colectomy has been performed [42]. Whether these patients actually have ulcerative colitis or a specific colitis associated with linear IgA disease is uncertain; two recent patients with preceding bowel symptoms developed oral ulceration and were found to have linear IgA deposition in mouth and colon. The bowel histology was that of a lymphocytic colitis or Crohn's disease [43]. Linear IgA disease has also been associated with Crohn's disease [44].

Hermansky–Pudlak syndrome (MIM #203300) (Chapter 39) may be associated with inflammatory colitis that resembles ulcerative colitis but has a granulomatous infiltrate pathologically; this appears to be distinct from either ulcerative colitis or Crohn's disease [1,45].

Ulcerative colitis has been linked with a variety of autoimmune disorders and with sarcoidosis [46,47], although the strength of this association is not clear. Finger clubbing

may be associated with inflammatory bowel disease, particularly ulcerative colitis [48], as well as with several other gastrointestinal diseases, including tumours, chronic infections, protein-losing enteropathy and laxative abuse [49]. Acne fulminans has also been reported in association with inflammatory bowel disease [50].

Bowel-associated dermatosis–arthritis syndrome [1–6]

SYN. BLIND LOOP SYNDROME; BOWEL BYPASS SYNDROME; INTESTINAL BYPASS ARTHRITIS–DERMATITIS SYNDROME

This is a serum sickness-like illness which is related to bacterial overgrowth in the bowel. Bacterial antigens in the form of peptidoglycans are probably released from the

intestinal flora, particularly *Escherichia coli* [2]. Circulating immune complexes can be demonstrated in most patients actively developing skin lesions [3].

It was originally linked with bowel bypass surgery for obesity [1–4], which created a 'blind loop' of bowel. Most cases now are related to other causes of a blind loop, or simply to areas of stasis, and the condition has attracted the name 'bowel bypass syndrome without bowel bypass' [6]. Causes include achalasia [7], strictures and inflammatory bowel disease [5], as well as surgical procedures. Pyoderma gangrenosum secondary to diverticular disease [8] is probably in the same spectrum of disease.

The characteristic skin lesions are crops of erythematous papules, sterile vesicopustules similar to those associated with ulcerative colitis, or overtly indurated or necrotic vasculitic lesions. Erythema nodosum-like and panniculitis-like lesions may occur. Associated constitutional symptoms include fever, polyarthritis, tenosynovitis, myalgia and nephritis. Raynaud's phenomenon has been described, as has Sweet's syndrome. The joint involvement is variable and similar to the type of arthritis recognized in regional ileitis and ulcerative colitis. The bypass enteropathy may manifest itself as acute massive abdominal distension resembling intestinal obstruction, but milder and chronic forms have been described.

Histological examination shows dilated dermal venules and capillaries with a marked perivascular neutrophilic infiltrate. This is most pronounced in vesicopustular lesions, in which the resulting dermal oedema may lead to dermal–epidermal separation. Epidermal necrosis may be found. Treatments include oral corticosteroids, antibiotics such as metronidazole, a variety of immunosuppressive medications and restorative surgery.

Skin complications of stomas [1,2]

Dermatoses associated with a stoma include those related to the function of the stoma (irritation from faecal leakage, infections, contact dermatitis), Koebner reaction of existing or new dermatoses (psoriasis, lichen sclerosus) and disorders related to bowel disease (peristomal pyoderma gangrenosum, cutaneous Crohn's disease) [1,2].

The skin around a gastrointestinal or urinary tract stoma is liable to irritation from the effluent, the wafer and pouch, and substances applied as barriers, adhesives and cleaners. The collection pouch is either attached to a wafer or directly to the skin; a barrier/sealant may be applied before adhesion. This is either a gelatin–pectin formulation, karaya (a hygroscopic partially acetylated polysaccharide), or a flexible plastic, applied in liquid form. The adhesives are usually acrylic, silicone or latex. Ideally, the wafer should adhere perfectly to the skin, with a rim of skin 1–2 mm between the stoma and the appliance. If this rim is too narrow, chafing against the stomal mucosa will occur, and if it is too wide there is a higher risk of dermatitis. Any surface irregularities beneath the attachment surface will allow effluent to track beneath. This may occur if there are changes in body weight, or if there is incorrect or unavoidable siting of the stoma in body folds or adjacent to scars.

Enzyme-degradation dermatitis, caused by proteolytic enzymes in an alkaline fluid medium, is commonest with ileostomies [3], and presents with maceration, erythema and erosions. Because of the tracking of the fluid downwards, the pattern of dermatitis depends on the patient's predominant position. Diversion of the urinary stream also causes problems because of stagnation and ammonia production.

Treatment. Most peristomal skin disease is irritant and is treated by judicious use of topical corticosteroids together with soothing and barrier preparations. Infections such as *Candida* or pyogenic bacterial infection should be treated with an appropriate specific antimicrobial agent. Many types of protective wafer and protective powders are available. These contain gelatin, pectin, polyisobutylene and sodium carboxy-methylcellulose. They adhere to moist skin and allow healing to take place if they are left for about 3 days. Creases and crevices around a stoma or fistula can be filled using pastes, which generally consist of gelatine, sodium carboxy-methylcellulose, triacetin, fixin and ethanol. They are applied in layers, moulded into the creases with a moist finger and built up to the required level. If the drainage application can then remain in position for several days, this will usually allow the damaged skin to heal. Other topical treatments for irritant peristomal dermatoses include soothing compresses (for example, saline or 1 : 40 aluminium acetate), karaya and sucralfate [3].

Allergic contact dermatitis can occur to the adhesive [4], the barrier or any part of the appliance. Epoxy resins have been a problem in pouch materials, even though they are often present in small amounts only [5]. It has been suggested that patch testing should be carried out on the symmetrically opposite part of the abdomen [1]. It

is usually possible to provide substitutes for materials causing the allergic reaction.

Urostomy encrustations and acanthotic chronic papillomatous dermatitis (pseudoverrucous lesions). The encrustations are crystals of phosphates and sometimes uric acid that form on the stoma and can damage the mucosa and even the bag. Pseudoverrucous lesions are grey or reddish-brown, warty papules at the mucocutaneous junction. They are more common around urostomies than around gastrointestinal stomas, occurring in about 20% of urostomy patients. There may be a non-specific erythematous and erosive change [6]. Stagnation and urinary infection are important in the aetiology of both encrustations and pseudoverrucous lesions and, as well as treating infection, acidification of the urine is helpful—for example, with cranberry juice or vitamin C in large doses [1]. Peristomal viral warts are a particular differential-diagnostic problem.

Parastomal fistulae and ulcers [7] are particularly associated with ileostomy for Crohn's disease and may represent or herald recurrent disease. Fistulae are often preceded by abscesses, and may be multiple. The parastomal ulcer is defined as a defect in the surface 1.5 cm or more across. It is typically accompanied by severe burning pain and erythema, and often associated with induration and erythema of the stoma [8]. Low-grade infection should be considered as a possible cause in parastomal ulcers that occur early after formation of the stoma, but in late-appearing ulcers, recurrent Crohn's disease is probably the most important underlying cause. Treatment of both parastomal ulcers and fistulae is usually surgical.

Dermatoses. Psoriasis and pemphigus have been described as a result of the Koebner reaction around 'ostomies' [9], and pyoderma gangrenosum can localize to the peristomal skin after colectomy for inflammatory bowel disease [10,11], and much less commonly in relation to urostomies. A papular, erythematous condition similar to granuloma inguinale infantum has been described following intensive use of a potent fluorinated steroid around a colostomy site [12].

Neoplasms. BCC has been described as a long-term complication of colostomy [13]. Metastatic carcinoma at the stoma site, sometimes invading the surrounding skin, has been reported following ureterosigmoidostomy [14] and in patients who have had colectomy for ulcerative colitis [15–18].

Coeliac disease

Coeliac disease usually presents due to malabsorption and diarrhoea. There may be cutaneous features of malabsorption of nutrients (Chapter 57). The association with dermatitis herpetiformis (DH) is of specific dermatological relevance and is discussed in detail in Chapter 41; some degree of abnormality of small-bowel mucosa is present, even if minimal and asymptomatic, in all patients with DH. A significant increase in the frequency of coeliac disease in patients with inflammatory bowel disease has been suggested recently.

Diagnosis of coeliac disease can be made by serological tests for IgA antiendomysial antibodies—sensitivity is reported as 85–98% and specificity as 97–100% [1]. These antibodies recognize tissue transglutaminase, which acts as an autoantigen—it deaminates gliadin to create negatively charged glutamic acid residues that activate T cells. IgA antigliadin antibodies are less specific. Antigliadin, antiendomysial and tissue transglutaminase antibody levels all become undetectable after a period of 3–6 months on a strict gluten-free diet (GFD). Other tests include documentation of malabsorption and small-bowel biopsy. Darkening of previously white hair has been reported after starting GFD to treat coeliac disease [2]. Coeliac disease occurs in association with other autoimmune disorders, notably Addison's disease [3], and has been

reported following interferon treatment for hepatitis C and other disorders [4].

Improvement of psoriasis in a small number of patients who were treated with GFD suggested the possibility that coeliac disease and psoriasis might be associated. Patients with psoriasis have a high frequency of positive IgA antigliadin antibodies, which correlate with lymphocytic infiltration of the duodenal mucosa but do not have an increased incidence of coeliac disease, and there is no increase in antireticulin or antiendomysial antibodies [5,6].

There is an association between DH and internal malignancies, the most important being lymphoma of the small bowel (enteropathy-associated lymphoma) [7,8]. GFD exerts a protective effect [8].

Vasculitis, sometimes with cryoglobulinaemia, may occur in association with coeliac disease [9].

Whipple's disease

This disorder is another cause of malabsorption and diarrhoea, which may be accompanied by skin manifestations. Diffuse pigmentation is frequent, and may resemble Addison's disease, but buccal pigmentation is not a feature. Subcutaneous nodules may occur, resembling rheumatoid nodules or sarcoidosis [1–3]. The disorder usually presents with arthralgia and general malaise; abdominal features (pain, diarrhoea and malabsorption leading to weight loss) occur in most individuals with more advanced disease. Cardiac, pleural, ophthalmological or neurological symptoms also occur, and there may be generalized lymphadenopathy. The diagnosis has historically been confirmed by demonstration of periodic acid–Schiff-positive particles in biopsies from infected tissue (usually bowel mucosa). The diagnosis can now be made using polymerase chain reaction (PCR) amplification of sequences from the causative organism *Tropheryma whippelii* in infected tissue [4].

Skin disorders associated with gastrointestinal bleeding

These are listed in Table 59.4. Most are discussed elsewhere in this section, or in other chapters. In addition, gastrointestinal tumours may metastasize to skin (see earlier in this chapter), some tumours may affect the skin and gastrointestinal tract (e.g. Kaposi's sarcoma), and skin tumours may rarely metastasize to the gastrointestinal tract (e.g. melanoma).

Several patterns of cutaneous vasculitis or collagen vascular disease may be associated with mesenteric vasculitis and/or thrombosis, leading to bleeding or ulceration. Various radiological signs of mesenteric vasculitis seen on computed tomography (CT) have been reviewed in relation to systemic lupus erythematosus, and include a palisade and comb-like pattern of vessels, peritoneal enhancement of ascitic fluid, thickening of the bowel wall, and a 'double-halo' or 'target sign' [1,2].

Intestinal polyposis [1,2]

A number of, usually inherited, gastrointestinal polyposis disorders also have cutaneous features. The most important are:

- Peutz–Jeghers syndrome
- Gardner's syndrome
- Cowden's disease (multiple hamartoma syndrome)
- Bannayan–Riley–Ruvalcaba syndrome (Ruvalcaba–Myhre–Smith syndrome, Bannayan–Zonana syndrome)
- Cronkhite–Canada syndrome
- Birt–Hogg–Dubé syndrome
- Naevoid BCC syndrome [3]
- Neurofibromatosis (Chapter 12).

Additionally, ganglioneuromas of the gastrointestinal tract and oral mucosal neuromas may be associated with Hirschsprung's disease and colonic diverticula as features of MEN type 2B syndrome.

Table 59.4 Skin lesions associated with gastrointestinal disorders that may present with bleeding.

Disease	Gastrointestinal lesion	Skin symptom
Vascular defects and inherited		
Osler–Weber–Rendu disease (Chapter 50)	Telangiectasia	Telangiectasia
Blue rubber bleb naevus (Chapter 15)	Haemangiomas	Haemangiomas
Pseudoxanthoma elasticum (Chapter 46)	Involvement of visceral arteries	Yellowish papules and plaques
Ehlers–Danlos syndrome (type IV) (Chapter 46)	Fragility of visceral arteries	Hyperelasticity of skin and joints
Polyposis (see text in this chapter)		
Neurofibromatosis (von Recklinghausen)	Neurofibromas	Café-au-lait spots, neurofibromas
Cronkhite–Canada syndrome	Gastrointestinal polyposis	Diffuse hyperpigmentation, alopecia, nail defects
Gardner's syndrome	Polyposis of colon (cancer)	Lipomas, epidermoid cysts
Peutz–Jeghers syndrome	Polyposis, especially small intestine	Hyperpigmentation on lips, circumoral area and fingertips
Cowden's disease	Polyposis	Papules, lipomas, angiomas
Inflammatory bowel disease		
Crohn's disease, ulcerative colitis	Inflammatory changes of the intestinal wall	Erythema nodosum Aphthous stomatitis Pyoderma gangrenosum, other neutrophilic dermatoses Necrotizing vasculitis Acquired epidermolysis bullosa Erythema multiforme
Vasculitis and systemic disease		
Henoch–Schönlein purpura and other vasculitides (Chapter 49)	Mesenteric vasculitis, gastric ulcers (polyarteritis nodosa)	Purpura, livedo, nodules, necrosis
Cholesterol emboli (Chapter 48)	Intestinal arterial occlusion	Vasculitis, necrosis, livedo
Degos' disease (Chapter 48)	Intestinal perforation	White atrophic lesions
Amyloidosis (Chapter 57)	Vascular fragility	Purpuric lesions
Neoplasia		
Primary gastrointestinal cancers	Neoplasm	Metastases, paraneoplastic eruptions, features of polyposis syndromes
Kaposi's sarcoma (Chapter 26)	Kaposi's sarcoma of bowel	Kaposi's sarcoma of skin

Peutz–Jeghers syndrome (MIM #175200) [4]. This is an autosomal-dominant or sporadic condition due to mutations in the *STK11* (*LKB1*) gene on chromosome 19p13.3 [5–7]. Polyps occur mainly in the small intestine, but also in the stomach and colon. The usual presentation is with intussusception or melaena. Polyps can also be found in the genitourinary and respiratory tracts, and occasionally in the gallbladder.

The cutaneous feature is lentiginosis, with a predominantly perioral, periorbital and intraoral distribution; perianal and acral lentiginosis (occasionally causing longitudinal melanonychia) also occurs. The pigmented macules appear in early childhood and may fade with increasing age, although the mucosal lesions persist [4].

Cancers may occur in the gastrointestinal tract, but the frequency is relatively low, as the polyps are hamartomatous. However, there is an increased risk of non-gastrointestinal cancers, with an overall risk estimated at 18-fold greater than that of the general population [8]. Other associated neoplasias include pancreatic adenocarcinoma (100-fold more common than expected [8]), and less commonly breast and pulmonary adenocarcinoma. Multiple myeloma may occur more frequently than expected. Precocious puberty may occur in either sex, and a variety of genital cancers have been associated with PJS, including Sertoli cell tumours; there is a particular link with multifocal sex-cord tumours and an aggressive variant of adenocarcinoma of the cervix [1]. Finger clubbing may occur in conjunction with the ovarian sex-cord tumours.

Gardner's syndrome (MIM *175100) [6,7,9]. This is the association of adenomatous colonic polyposis with large numbers of subcutaneous fibromas, epidermoid cysts (both mainly on the upper trunk and head), desmoid tumours (mainly abdominal wall), retinal pigmentary changes, osteomas (especially of the facial bones), odontomas and other dental abnormalities, including supernumerary teeth [9]. The onset of cysts is generally prepubertal. Multiple pilomatricomas, or pilomatricoma-like areas within the epidermoid cysts, have also been recorded. The occurrence of fibromas may involve a general tendency to fibromatosis, including desmoid tumours, mesenteric and retroperitoneal fibrosis. Nuchal-type fibromas [10], especially if multiple or at unusual sites [11], may be an early sign of the syndrome. Leiomyomas, lipomas, neurofibromas and BCCs may also occur [9].

It is an autosomal-dominant condition with variable

expression, and is caused by mutations in the same APC gene on chromosome 5q21 that also causes familial polyposis coli without associated cutaneous abnormalities [1,6,7]. The phenotype is not simply determined by different mutations of the gene, as exactly the same mutation may on occasions give rise to a phenotype with or without skin lesions—suggesting that other genes influence the disease expression. There are also subsets of this condition in which skin lesions may be limited in type; for example, epidermoid cysts and colonic polyposis without the other features has been termed Oldfield's syndrome [12]. Skin lesions are usually the earliest manifestation of this group of diseases, although the retinal pigmented lesions (hypertrophy of the pigment epithelium) occur in 90% and are probably congenital. The latter are dark, roughly oval-shaped lesions, at the periphery of the retina; they are generally multiple, bilateral, and also occur in first-degree relatives [13].

The bowel polyps are premalignant, and virtually all untreated cases will eventually develop colonic cancer, even in childhood occasionally, so regular colonoscopy and early colectomy is advised for affected individuals. The colon and rectum are the main cancer sites, but gastric and small-bowel polyps may occur. There is also an increased incidence of other neoplasia, which may be gastrointestinal (especially duodenal), bony (osteosarcoma and chondrosarcoma), hepatic (hepatoblastoma), neurological (medulloblastoma), endocrine (thyroid and adrenal) or soft tissue (liposarcoma) [8]. The diagnosis is usually suspected from the family history, can be supported by funduscopy and dental radiological studies and is confirmed by genetic testing.

Cowden's disease (multiple hamartoma syndrome; MIM #158350) [1,2,14–17]. Gastrointestinal polyposis and less commonly malignant change occur. However, the main neoplastic condition in Cowden's disease is breast cancer; this condition is therefore discussed in more detail in the section on paraneoplastic dermatoses earlier in this chapter.

Bannayan–Riley–Ruvalcaba syndrome (Ruvalcaba–Myhre–Smith syndrome; Bannayan–Zonana syndrome MIM *153480). This multiply named syndrome comprises gastrointestinal polyposis with vascular malformations, lipomas, penile pigmentation, macrocephaly and thyroid disease. There is considerable overlap with Cowden's disease, and recent studies have demonstrated mutations that suggest a common genetic background [18,19].

Birt–Hogg–Dubé syndrome (Hornstein–Knickenberg syndrome; MIM #135150) [20–22]. These two conditions probably represent the same entity, in which there is autosomal-dominant inheritance. Birt–Hogg–Dubé syndrome consists of multiple fibrofolliculomas, trichodiscomas and acrochordons; several cases have also had intestinal polyposis. Hornstein–Knickenberg syndrome is the association of perifollicular fibromas with intestinal polyposis. Lipomas, angiolipomas, parathyroid adenomas, renal tumours, lung cysts and flecked choroidoretinopathy have also been linked with these conditions.

Cronkhite–Canada syndrome (MIM 175500) [23–25]. This rare syndrome is characterized by skin pigmentation, alopecia, nail-plate defects and polyposis of the gastrointestinal tract, from oesophagus to anus. The cause is unknown, and only sporadic cases have been reported. Affected patients are middle-aged or elderly, with a male/female incidence ratio of 3 : 2.

Chronic diarrhoea due to protein-losing enteropathy associated with the intestinal polyposis is the usual presenting feature, leading to hypoalbuminaemia, hypokalaemia and hypocalcaemia. There is diffuse macular pigmentation of the skin (but not intraorally) with accentuation over the face, neck and extremities; histologically, there is an increased number of melanin granules in keratinocytes and an increased number of melanosomes in melanocytes, with marked hyperkeratosis and a perivascular inflammatory infiltrate in the dermis. The palms and volar aspects of the fingers are also involved. The scalp hair becomes thin and sparse, initially resembling alopecia areata; later, total loss of hair occurs. All fingernails and toenails are dystrophic, undergoing onycholysis, onychoschizia and onychomadesis with a peculiar, triangular, residual nail plate. The course is usually slowly progressive; therapy is symptomatic and non-specific.

Acrochordons (fibroepithelial polyps, 'skin tags'). Several studies have suggested a link between acrochordons and colonic polyposis [1,2]. However, most of these studies were either small or examined only a population who were being investigated for bowel disease. A meta-analysis that divided patients into those with colonic symptoms and those who were asymptomatic demonstrated that the association was only sustained in the former group, and that this was therefore an artefact of patient selection [26].

Liver disease

Hepatobiliary diseases are frequently associated with abnormalities of the skin, nails and hair. However, most are non-specific, as they may be present in other diseases and absent even in patients with advanced liver dysfunction—jaundice, for example, may occur due to haemolysis rather than due to liver damage. Additionally, many diseases may share the same cutaneous features (for example, most causes of cirrhosis cause the same clinical signs), and there is no clear correlation between the degree of the skin changes and the severity of liver dysfunction. However, there may be constellations of features that suggest specific diagnoses (e.g. pigmentation, jaundice and xanthomas in primary biliary cirrhosis). The overall picture of the patient may therefore be as useful as the presence of particular cutaneous signs.

This section will discuss some of the main groups of hepatobiliary disease, followed by some of the more important symptoms and signs.

Hepatitis and acute liver disease

Acute hepatic damage is most often due to viral hepatitis, alcohol or other drugs. Cutaneous features may be absent, or there may be jaundice. Other features may occur, depending on the cause. Most of the cutaneous features of alcohol excess are related to chronic abuse and are considered later; flushing and, uncommonly, urticaria may occur as short-term effects. This section considers the dermatological associations of infective hepatitis [1–10].

Hepatitis A virus infection is usually asymptomatic and transient. Dermatological features, if present, are jaundice, urticaria (less than 2%) and exanthem. Chronic liver disease is not a feature, but a relapsing variant has been described in which itch, purpura and urticarial lesions occur [2]. Histology in such cases demonstrates a small-vessel vasculitis. More severe vasculitis or panniculitis is rare.

Hepatitis B virus (HBV) infection [1,3,4] is of major relevance to health care workers, as it may be transmitted parenterally. It is also transmitted sexually, and HBV infection may be associated with other sexually transmitted diseases. HBV screening and vaccination are recommended for all health care workers; routine HBV screening may be recommended for patients attending genitourinary medicine clinics, but at present is usually targeted to high-risk groups (human immunodeficiency virus (HIV)-positive individuals and parenteral drug abusers). Vaccination is not without dermatological side effects—provocation of granuloma annulare, lichen planus, Gianotti–Crosti syndrome, urticaria and contact reactions to excipients have all been reported [11–14].

Dermatological features of acute HBV infection include:

- Urticaria, non-specific erythema or a serum sickness-like picture (generalized malaise, fever and arthralgia)—this occurs in 20–30% of patients with hepatitis [3]. Angioedema, erythema multiforme or erythema nodosum-like lesions may occur. Circulating immune complexes are probably involved [4], and skin biopsy shows small-vessel vasculitis with positive direct immunofluorescence for IgG, IgM, complement C3 and hepatitis B surface antigen (HB_sAg). This eruption may precede other features of infection, or may occur as recurrent urticaria after infection.
- Gianotti–Crosti syndrome (papular acrodermatitis of childhood, papulovesicular acrolocated syndrome)—this eruption was originally linked with HBV infection, although accumulated knowledge documents that it is a

feature of numerous viral infections. Lesions consist of small, umbilicated papules, often affecting the knees, buttocks, cheeks and extremities; the lesions usually last about 6–8 weeks and are associated with non-specific malaise in the early phase.

- Polyarteritis nodosa (PAN)—about 20% of patients with PAN may have positive HBV serology, but the frequency has decreased considerably over the last 20 years, some units that previously expected HBV positivity in 30–50% of cases only finding this in 10% now. PAN is discussed in Chapter 49.
- Cryoglobulinaemic vasculitis—about 15% of patients with HBV have detectable cryoglobulins, although most have no symptoms. The association is more important in hepatitis C.
- Other skin lesions—pyoderma gangrenosum, lichen planus and dermatomyositis have been reported with HBV infection.

Hepatitis C virus (HCV) infection (previously termed non-A, non-B hepatitis) is usually transmitted parenterally. Acute HCV infection is usually only mildly symptomatic; chronic hepatitis occurs in about 75%, but progression varies considerably [6–8]. The main dermatological features [1,6–9] are:

- Mixed cryoglobulinaemia, usually type II (polyclonal IgG and monoclonal IgM rheumatoid factor) and less commonly type III (polyclonal IgG and polyclonal IgM rheumatoid factor). About 70% of type II cryoglobulinaemia is HCV-associated; the major idiotype in the monoclonal rheumatoid factor is different from that in rheumatoid arthritis, but commonly present in primary Sjögren's syndrome. Features of the cryoglobulinaemic vasculitis include small-vessel vasculitis (mainly on the legs), livedo reticularis, acrocyanosis, arthralgia, glomerulonephritis, peripheral neuropathy, hepatosplenomegaly and hypocomplementaemia. Other patterns of vasculitis may also occur.
- PAN—in patients with 'classic' PAN in whom hepatitis virus is of relevance, the association is usually with HBV rather than HCV infection, but preceding HCV infection has been reported in up to 30% of patients with the cutaneous variant of PAN [15]. Hypocomplementaemia seems to be more common in patients with cutaneous PAN who also have HCV infection, but the numbers of patients studied is small.
- Porphyria cutanea tarda (PCT) is most commonly associated with alcoholic liver disease and with hereditary haemochromatosis. However, in countries where there is a low prevalence of haemochromatosis, serological evidence of chronic HCV infection can often be demonstrated in patients with PCT; the prevalence of positive HCV serology in PCT varies from about 10% to 90%, depending on geography [16]. HCV has also been linked to variegate porphyria. A case–control study in the USA found that 16 of 17 patients with PCT were HCV-positive (94%), compared with 0.17% of nearly 150 000 volunteer blood donors (although these may not be fully representative of the general population) [16], and HCV positivity is now viewed as an important risk factor in development of PCT [17,18]. However, PCT appears to be uncommon as a manifestation of HCV positivity. A large study of patients with HCV or HIV infection, or both, only found one of 177 patients to have a PCT porphyrin excretion pattern and did not support a direct role of HCV in provoking PCT. However, the mean coproporphyrin level was significantly raised in HCV-positive patients and especially in those who were also HIV-positive [19].
- Autoimmune disorders. There are associations between HCV infection and lichen planus, autoimmune thrombocytopenic purpura, Behçet's disease, vitiligo and a Sjögren's syndrome-like sialadenitis.
- Other dermatological symptoms. Pruritus may be a presenting symptom of HCV infection, and persistent itch may occur [9]. Urticaria, erythema multiforme and erythema nodosum have been reported, but are not a specific feature. Necrolytic acral erythema is a recently described and apparently specific, if rare, feature of acute HCV infection [10].

Treatment of HCV infection and associated cryoglobulinaemia is with antiviral agents, typically interferon with ribavirin.

Hepatitis D causes cutaneous features similar to those of HBV. Hepatitis E is generally mild, but may cause disseminated intravascular coagulation [1]. Hepatitis F is disputed, and hepatitis G is usually transmitted parenterally [20].

Cirrhosis of the liver

Cutaneous features of chronic liver disease are listed in Table 59.5 [1,2]. Causes include chronic hepatitis (above), alcohol abuse and others—some of the idiopathic causes are discussed below, as each has some specific features in addition to those that occur in liver failure of any cause.

Haemochromatosis [1–8]

Hereditary (idiopathic or HLA-linked) haemochromatosis (bronze diabetes) is an autosomal-recessive disorder that is usually associated with mutations C282Y (cysteine 282 tyrosine) or H63D (histidine 63 asparagine) of the *HFE* gene [4,5]. Other genes in which mutations cause haemochromatosis include the gene for ferroportin (*SCL11A3*) [6]. Haemochromatosis usually presents in males over the age of 40 years. An acquired form also occurs, secondary to haemosiderosis or alcohol abuse. There is increased iron absorption leading to iron deposition in various organs, including the liver, pancreas, heart, pituitary and endocrine organs. Skin pigmentation, diabetes, hepatic cirrhosis and cardiac failure are prominent features [2,3,7]. Dryness of the skin and koilonychia may have been underestimated in the past [8]; stigmata of chronic hepatic failure may also be present. Deposition of iron in the skin has been used as a surrogate for deposition in other organs [9,10]; in idiopathic haemochromatosis, iron deposition includes deposition in eccrine sweat glands [8]. However, the pigmentation of haemochromatosis is due to melanin rather than to haemosiderin [2,3,7]. It typically has a grey hue, and is most prominent on exposed skin, similar to Addisonian pigmentation. Keratin cysts with a black colour have also been reported [11].

There is a 200-fold increase in the risk of hepatocellular carcinoma compared with the general population [3].

PCT has been linked with haemochromatosis for some years [7,12,13]. It has subsequently been shown that homozygosity for the C282Y mutation and seropositivity for HCV are the greatest risk factors for expression of PCT [14] and that they appear to act as independent co-factors [15]. In patients with mutations in uroporphyrinogen decarboxylase, which leads to PCT, coinheritance of C282Y homozygosity is associated with earlier age of onset of PCT [16].

Table 59.5 Skin lesions associated with chronic liver disease.

Spider angiomas, telangiectasia
Palmar erythema
Dilated abdominal/chest veins (including periumbilical caput medusae)
Jaundice
Increased melanin pigmentation
Thin 'paper-money' skin, striae
Excoriations
Loss of secondary sexual hair in males
Bruising, purpura
Nail changes: clubbing, pallor, Muehrcke's bands, Terry's nail
Features of malnutrition (see Chapter 57)
Associated lesions
Xanthomas (primary biliary cirrhosis)
Porphyria cutanea tarda (alcoholic liver disease)
Vasculitis/capillaritis/pyoderma gangrenosum (chronic active hepatitis)
Lichen planus (primary biliary cirrhosis)

Primary biliary cirrhosis and biliary tract disease

From the dermatological standpoint, primary biliary cirrhosis (PBC) is the most important biliary tract disease. The cutaneous features of significance are marked itch (discussed in more detail below), excoriation, hyperpigmentation and various xanthomatous lesions due to secondary hyperlipidaemia [17,18]. Xanthelasma, palmar crease, tuberous and tendinous xanthomas may all occur. PBC occurs mainly in middle-aged women as an autoimmune disease, is strongly associated with the presence of antimitochondrial antibodies (AMA), and has been associated with numerous other autoimmune conditions, including CREST, morphoea and other scleroderma spectrum disorders, lichen planus and lichen sclerosus [17–23]. The constellation of CREST with PBC is also known as Reynolds' syndrome, and is usually associated with M2 antibodies. Sarcoidosis [24] and other patterns of granulomatous disease such as granuloma annulare are also reported. There is a strong link with Sjögren's syndrome—about 10% of patients with Sjögren's syndrome have AMA, sometimes with abnormal liver function tests

or liver histology, and over half of patients with PBC have some evidence of Sjögren's syndrome [25]. Itch is often the first symptom of PBC, so serology to detect AMA is a useful screening test in women with unexplained pruritus; AMA-negative PBC causes particular diagnostic difficulty.

Cholestasis and bile stones may cause acute or chronic jaundice and other features of liver disease. Pigment bile stones may occur due to erythropoietic protoporphyria.

Congenital biliary tract hypoplasia is a feature of Alagille's syndrome (MIM #118450) [26], a dominantly inherited disorder due to a gene mutation on chromosome 20p12. Affected individuals have a characteristic facies, jaundice, pruritus and retardation of growth and mental development. Various skeletal, ocular and vascular defects are associated.

Drugs and the liver

Drug-related links between the skin and the liver include the following:

- Drugs used to treat the skin, whose hepatic metabolism is altered by liver disease or by other drugs that are also metabolized in the liver, e.g. ciclosporin.
- Drugs used to treat skin disease that may cause hepatitis or other liver damage, e.g. azathioprine, methotrexate.
- Drugs used to treat liver disease that may have cutaneous side effects, e.g. local reactions to vitamin K (Texier's syndrome), elastosis perforans serpiginosa due to penicillamine for Wilson's disease.
- Drugs used to prevent liver disease that may have cutaneous side effects, e.g. local reactions due to thimerosal or other preservatives in hepatitis vaccines.
- Drugs that cause liver changes with secondary cutaneous signs, e.g. oestrogens leading to PCT.
- Drugs that may cause concurrent hepatitis and rash, e.g. phenytoin and other anticonvulsants.

Systemic diseases and the liver

A large number of systemic diseases may affect the liver, many with cutaneous features. Most are discussed in other chapters. For example, sarcoidosis is associated with subclinical hepatic involvement in over 50% of patients, but may cause overt hepatomegaly or abnormalities of liver function in conjunction with skin lesions.

Porphyrias, especially PCT, may occur as a consequence of liver disease (see Chapter 57 and the discussion of PCT below); severe liver disease is also a feature in some patients with erythropoietic protoporphyria.

Dermatological features and dermatoses associated with liver disease

Pruritus

Pruritus is the most common skin symptom associated with liver disease. It may precede the onset of jaundice of

any cause, and may be a feature of hepatitis, as discussed above. Liver diseases in which itch is most prominent are PBC, sclerosing cholangitis and any other biliary tract obstruction, and disorders causing cholestasis; itch is less prominent in haemochromatosis, alcoholic cirrhosis and autoimmune chronic active hepatitis [1]. The symptoms are generally most severe at acral sites and areas of tight clothing, and are more prominent nocturnally. Disappearance of pruritus may accompany severe deterioration in hepatic function [2].

The precise mechanism of itch in obstructive liver disease remains unclear. It was believed to be due to the presence of bile salts in the skin [3,4], but the intensity of itch does not reliably correlate with bilirubin or bile acid levels in chronic liver failure, and this theory is not supported by more recent research [1,5]. Other proposed mediators of cholestatic itch include alternative liver metabolites, histamine or other mast cell mediators, and endogenous opiates. Although patients with cholestasis may have elevated plasma histamine levels, the therapeutic response to antihistamines is limited, and it is unlikely that release of histamine plays an important role in the pathogenesis of hepatobiliary itch [1]. Improvement in hepatic itch after administration of drugs that block the action of opiates suggests that endogenous opiates may be important in the mechanism of this type of itch [6–8].

Treatment where possible is for the underlying cause—for example, drug withdrawal in drug-induced cholestasis, surgery for mechanical biliary obstruction, interferon and ribavirin for chronic HCV infection, etc. Less specific options include ursodeoxycholic acid, cholestyramine, phenobarbital, anabolic steroids such as stanozolol, rifampicin, antihistamines and dietary manipulation to supplement polyunsaturated fatty acids [1,9,10]. Phototherapy of various types—daylight, ultraviolet A (UVA), ultraviolet B (UVB), photoirradiation of plasma and extracorporeal photophoresis—can be effective, but ongoing treatment is generally required [1,11,12]. Other treatments that have been used with success include haemoperfusion or plasma perfusion through charcoal-coated beads (which can produce benefit lasting several weeks), plasmapheresis, infusions of albumin (benefit for a few days) and slow injection of intravenous lidocaine (lignocaine) (which produces short-term benefit only). On the basis that endogenous opiates play a role in this symptom, and that these have a circadian rhythm regulated by light, bright-light therapy to the eyes was studied and found to reduce cholestatic itch in a short-term study [13].

Skin pigment changes in liver disease [1–3]

Jaundice (icterus) is first visible as a yellowish hue of the sclerae and soft palate before it becomes generalized. It is due to hyperbilirubinaemia. Carotenaemia may have a similar appearance but does not affect sclerae; skin discoloration following mepacrine and busulphan therapy may simulate jaundice, but these usually also cause subungual pigmented bands.

Green-coloured sweat [4] and green discoloration of the gingivae may occur due to jaundice.

A muddy-grey coloured hyperpigmentation occurs in chronic liver disease of any cause. It is due to hypermelanosis with normal numbers of melanocytes, but the precise mechanism is uncertain. There may be a yellowish tinge due to associated jaundice. Usually, pigmentation is more prominent in sun-exposed areas. It may be blotchy or diffuse, may be exaggerated in the perioral and periorbicular areas (resembling chloasma), may resemble freckling and may localize to palmar creases. Males frequently show increased pigmentation of the areola in association with gynaecomastia and testicular atrophy.

Spotty hypomelanosis may occur on the back, buttocks and thighs, often in relation to spider angiomas.

Associated dietary deficiency may cause the pigmentary changes of pellagra (Chapter 57).

Vascular changes

Spider angiomas are a characteristic feature in patients with severe chronic liver disease (Fig. 59.9). Contributory factors [5] include decreased hepatic metabolism of oestrogen leading to hyperoestrogenaemia (which also

Fig. 59.9 Telangiectasia in alcoholic liver cirrhosis.

accounts for loss of secondary male-pattern hair, gynaecomastia and testicular atrophy); alcohol-induced vasodilatation and altered central vasomotor control may also be involved. The same factors lead to palmar erythema ('liver palms'), which is most pronounced on the thenar and hypothenar regions and may also affect the soles of the feet, and also to facial plethora. None of these vascular features are specific for liver disease. Diffusely scattered tiny telangiectatic vessels are referred to as 'paper money skin'. Increased peripheral blood flow with dilatation of digital pulp arteriovenous anastomoses is thought to be the cause of finger clubbing, which occurs in about 15% of patients with hepatic cirrhosis.

Purpuric lesions including scurvy may occur as a result of poor nutrition, especially in alcoholic liver disease (see Chapter 57). Altered production of prothrombin and deficiency of vitamin K may lead to frank ecchymoses.

In progressive liver disease with portal hypertension, collateral blood flow creates visible coiled varicose veins on the abdominal wall. When these are in a pattern radiating from the umbilicus, the appearance is termed 'caput Medusae'.

Hair, nail and collagen changes [1–3]

The body hair is often thinned or partially lost, and males tend to develop a female pubic-hair pattern. There is both increased production and decreased metabolism of oestrogens, as well as decreased production and increased metabolism of testosterone. When there is severe loss of scalp hair, zinc deficiency should be suspected (Chapter 57).

Nail colour changes include diffuse white colour with an invisible lunula, proximal white colour with distal pink colour (Terry's nails) and white bands (Muehrke's bands [6]). Altered digital blood flow, soft-tissue overgrowth and hypoalbuminaemia may all contribute. Lunulae may be red in patients with hepatic cirrhosis, and occasionally an azure-blue colour in hepatolenticular degeneration (Wilson's disease). Nail-plate changes include clubbing (see above) and its milder variant, the 'watch-glass' deformity; flattened nails or koilonychia may occur if there is poor nutrition or altered iron metabolism (e.g. haemochromatosis).

Striae occur in both sexes, especially on the lower abdomen, thighs and buttocks. Chronic alcoholism also alters metabolism of corticosteroids, leading to 'pseudo-Cushing's syndrome'.

Porphyria cutanea tarda

Chronic liver disease is involved in the skin changes of porphyria cutanea tarda. Lesions consist of bullae, scarring and hyperpigmentation of sun-exposed skin areas and hypertrichosis of the face. This is discussed in more detail in Chapter 57.

Other cutaneous lesions associated with liver disease

Lichen planus has been reported in a number of diseases with abnormal immune function. The association of erosive oral lesions in PBC [7] and chronic active hepatitis [8] may be related to a common immunological pathogenesis. Most reported patients have received penicillamine therapy which is believed by some to trigger the eruption [9–11]. HCV infection is associated with lichen planus [12].

In chronic active hepatitis (juvenile cirrhosis, lupoid hepatitis) and in PBC, firm reddish papules resembling pityriasis lichenoides chronica or lymphomatoid papulosis have been reported [8,13]. The lesions erupt on the trunk and extremities and may heal leaving slightly depressed atrophic scars. Histological examination reveals a capillaritis of the skin. Pityriasis lichenoides has also been reported in association with HCV seropositivity.

Pyoderma gangrenosum has also been reported in chronic active hepatitis [14]. The Gianotti–Crosti syndrome has been discussed in relation to hepatitis. Skin changes simulating classical glucagonoma syndrome have been reported in cirrhosis and termed the 'pseudoglucagonoma syndrome' [15].

Acquired zinc deficiency (Fig. 59.10) may occur in chronic alcoholic liver disease due to increased loss of urinary zinc in cirrhosis and poor nutrition [16,17]. Clinical features are a crackled and reticulate eczema on the trunk and extensor aspects of the limbs, erosive crusted changes in the perianal and genital areas, cheilitis, hair loss and multiple Beau's lines on the nails. Increased hair growth, often with a deeper pigmentation, may occur. Beer, wine and spirits are practically free of zinc, but most beer brands contain vitamin B in significant amounts and the typical zinc-deficient beer-drinker does not show additional clinical signs of vitamin B depletion [17].

Fig. 59.10 Chronic zinc deficiency in alcoholic liver cirrhosis. Widespread eczema craquelé on the trunk.

Pancreatic disease

Apart from jaundice and panniculitis, skin changes associated with pancreatic disease are uncommon. As with other causes of chronic, localized pain, erythema ab igne has been described in the skin overlying the pancreas in cases of chronic pancreatitis. The glucagonoma syndrome is a rare but highly characteristic skin disorder, which is discussed below. The pancreas is often involved in haemochromatosis (see the section on liver disease, above). Skin disorders associated with diabetes mellitus are discussed in Chapter 57.

Acute pancreatitis [1–3]

Jaundice and fat necrosis (see below) may both be prominent. Purpura or bruising of the left flank (Grey Turner sign) or of the periumbilical area (Cullen's sign) may occur in about 5% of patients with acute pancreatitis. Features of causative factors may also be present, such as signs of alcohol abuse or hepatic cirrhosis, or xanthomas due to hypertriglyceridaemia.

Subcutaneous fat necrosis [1–7]

SYN. NODULAR PANNICULITIS

Systemic nodular fat necrosis is a rare condition that affects 2–3% of patients with pancreatic disease [6]. It may be associated with acute or chronic pancreatitis, post-traumatic pancreatitis or pancreatic carcinoma [1–3]. Pancreatitis accounts for about two-thirds, and carcinoma one-third, of reported cases [4]. Most of the reported pancreatic neoplasms are acinous adenocarcinoma, which is rare. Subcutaneous fat necrosis associated with acute pancreatitis in a newborn has been reported [5].

The mechanism of fat necrosis is not fully understood, but the condition is probably due to the effect of enzymes released from the damaged pancreatic tissue. However, the condition does not simply relate to release of amylase or lipase from the pancreas. Not only is fat necrosis relatively uncommon in pancreatitis, but the eruption does not correlate with enzyme levels—it may occur in patients with normal lipase levels, or fail to occur in subjects with grossly elevated levels. Furthermore, incubation of skin with lipase or with patient's serum *in vitro* fails to demonstrate fat necrosis [4]. Thus, other enzymes are presumably involved.

Clinical features. Pancreatic nodular fat necrosis is accompanied by fever, abdominal pain (less common in those with underlying carcinoma), blood eosinophilia and synovitis of the small joints. Either the nodules or the

arthralgia may predominate. Nodular lesions are usually 1–3 cm in diameter and tender or symptomless. The areas of predilection are the trunk and the lower extremities, especially the anterior shins, but lesions may occur anywhere. They persist for 2–3 weeks and usually heal without scar formation, leaving slightly depressed hyperpigmented spots. More severe changes due to periarticular fat necrosis may occur. Polyserositis may be part of the syndrome [7]. Increased serum amylase or lipase levels can be demonstrated in most cases, but may be normal in cases due to carcinoma.

Histopathology. There are foci of subcutaneous fat necrosis, with ghost cells and a surrounding inflammatory infiltrate of neutrophils and eosinophils. At the periphery of the lesion histiocytes, foam cells and foreign-body giant cells are seen. Secondary calcification may be observed in necrotic areas.

Migratory thrombophlebitis [1–3,8–11]

Pancreatic cancer is one of the classical associations with Trousseau's sign, in which multiple migratory superficial thromboses occur. Recent studies indicate that lung cancer is the most common associated neoplasm in men aged over 40 years, but pancreatic cancer is still an important cause; historically, pancreatic cancer accounts for about 25–30% of cases of migratory thrombophlebitis. Cancers elsewhere in the gastrointestinal tract may also cause this condition. The usual interval to diagnosis is about 4 months from onset, but pancreatic neoplasia may present later than this [9]. The phlebitis is distributed on the trunk, neck and extremities and is usually limited to a short segment of the vein. A significantly increased frequency of deep venous thrombosis is also found. The cause is unknown, but probably related to increased levels of clotting factors and disordered fibrinolysis, a form of disseminated intravascular coagulopathy. The combination of thrombotic change with haemorrhage (purpura fulminans) may also occur as a paraneoplastic phenomenon. Thrombotic change may coexist with other paraneoplastic features; it was demonstrated in the skin of a patient with malignancy-associated fasciitis due to a pancreatic carcinoma [11]. Other signs of pancreatic carcinoma include cutaneous metastasis; about 10% of cases of Sister Mary Joseph's nodule (metastasis to the umbilicus) are due to pancreatic carcinoma [2].

Other dermatological features of pancreatitis

The main dermatological features of acute and chronic pancreatitis have been described above, or are the result of malabsorption in the chronic disease (Chapter 57). Livedo reticularis has also been described in both acute and chronic pancreatitis as 'Walzel's sign' [12,13].

Necrolytic migratory erythema, pancreatic islet cell tumours and glucagonoma syndrome [1–6]

Necrolytic migratory erythema

Aetiology. Necrolytic migratory erythema is a cutaneous reaction that occurs in the context of hyperglucagonaemia. The syndrome was described in 1941 [1] and there have been several subsequent reviews [2–6]. The same condition occurs in dogs and other animals. It is usually due to a glucagonoma, an α-cell tumour, which is usually in the tail of the pancreas [4,7]. However, it may also occur due to other causes such as pancreatic insufficiency [8], intestinal causes of malabsorption [6,8,9], hepatic cirrhosis [10,11], and aberrant glucagon-secreting tumours such as bronchial or nasopharyngeal carcinoma [12,13]. It has also been documented as an iatrogenic condition after administration of glucagon [6] and in a heroin abuser [14]. MEN (discussed below) is associated with glucagonoma, which occurs in about 3% of cases and accounts for about 20% of glucagonomas.

Hyperglucagonaemia also causes diabetes; the 'diabetico-dermatogenic syndrome' occurs in almost 60% of patients with glucagonoma [4], but when only some of the features are present this may lead to delay in diagnosis.

The pathogenetic mechanism of the skin eruption is not certain, but the condition is probably due to hypoaminoacidaemia caused by high glucagon levels [5]. There may be a contributory role of essential fatty acid and zinc

Fig. 59.11 Glucagonoma syndrome. (Courtesy of Dr Kristian Thomsen, Finsen Institute, Copenhagen, Denmark.)

deficiencies, but abnormal zinc levels or response to zinc supplementation are not consistent, and correction of amino acid levels does not reliably lead to resolution of the skin eruption [14]. It is characteristic that all skin changes disappear after complete surgical removal of the tumour in cases in which this is the cause [15].

Clinical features. The typical patient with glucagonoma is a woman of 45–65 years. The usual features are weight loss (67%), anaemia (one-third), glucose intolerance (56%) and necrolytic migratory erythema (72%) [7]. The rash is itchy or burning and particularly affects flexural sites on the lower abdomen, groin, buttocks and thighs (Fig. 59.11). It is initially macular, extending to form superficially eroding areas of erythema that progress to fragile vesicle and bullae formation. Irregular centrifugal extension of the annular lesions causes a marginated, often crusted, polycyclic or geographical pattern. It has a prolonged, fluctuating course or cyclical pattern; the central part heals over 7–14 days, leaving postinflammatory pigmentation, while the erythematous periphery becomes crusted. Perianal and genital lesions are common. Angular cheilitis and a painful beefy-coloured glossitis occur in about one-third of patients with glucagonoma [7].

The clinical spectrum also includes diarrhoea (20%), weakness, venous thromboses (10%) and psychiatric disturbances. The plasma glucagon level is generally elevated several-fold above the upper limit of the normal range, but may show only minor elevation. The systemic features, such as weight loss, anaemia and hypoaminoacidaemia, are all more frequent in patients with glucagonoma with the diabetico-dermatogenic syndrome than in those without [4]. The same pattern of eruption has been described due to zinc deficiency with normal glucagon levels, usually in the context of liver disease.

Histopathology [2,3]. Biopsy should be taken from the edge of early lesions. The characteristic histological feature is well-demarcated necrolysis of the outer cell layers in the Malpighian stratum. Early lesions may present as a dyskeratotic dermatitis with superficial perivascular inflammation in the dermis, and minor spongiosis and dyskeratotic epidermal cells [3,16]. Clefts and separation occur, associated with necrotic keratinocytes and cellular debris surrounding the cleft. In the dermis, a mild perivascular lymphocytic and histiocytic infiltrate is seen. Older lesions show various degrees of dyskeratosis, acanthosis and a lymphocytic infiltrate in the dermis. The histological changes are similar to those observed in acute zinc deficiency, in which cell degeneration and the formation of clefts and vesicles are predominant at the level of the basal cells.

Diagnosis. Pancreatic and hepatic scans and arteriography are helpful in locating a primary pancreatic tumour and its metastases if present. Serum amino acid, glucose, zinc and plasma glucagon levels should be determined. In cases with an elevated plasma glucagon level and a clinical and histological picture suggestive of the disease, surgical exploration should be performed.

Treatment. Where there is a glucagonoma, surgical resection is indicated, with embolization of hepatic metastases, which are present in the majority at the time of diagnosis. Various forms of chemotherapy have been used [2,5,17–19], such as streptozocin (a nitrosourea compound used for the ablation of β-cell adenoma) with 5-fluorouracil. Octreotide, a somatostatin analogue, rapidly improves symptoms, especially the rash, by altering glucagon metabolism, but it does not influence tumour growth [7,18]; dacarbazine is also useful [19]. Parenteral amino-acid infusions and correction of any essential fatty acid deficiency may be helpful [17], although the benefit of amino-acid infusions does not appear to be sustained long term [15]. In the rare cases related to malabsorption, correction of this (for example, GFD in coeliac disease) is usually effective [4,9].

Other non-insulin-secreting pancreatic endocrine tumours

Although glucagonoma is more important dermatologically, the most common islet cell tumours are insulinoma of β-cells and gastrinoma of δ-cells (Zollinger Ellison syndrome, ZES). These do not have specific skin changes, but they may occur together with other tumours that secrete ACTH, MSH and serotonin; severe diarrhoea in ZES may

cause secondary hypovitaminosis and other nutritional deficiencies, giving rise to skin and hair changes. Both of these tumours occur sporadically or as part of the autosomal-dominant MEN type 1 syndrome (Wermer syndrome, MIM *131100), which is due to a mutation in the *MEN1* gene on chromosome 11q13. In this condition, as well as the endocrine tumours, other cutaneous features include angiofibromas, collagenomas, café-au-lait macules, lipomas and gingival macules [20]. MEN1 was associated with 13% of glucagonomas in one large series [4], and glucagonoma has also been reported in MEN2.

Tumours that produce vasoactive intestinal polypeptide (VIPomas) cause flushing (discussed in Chapter 44) with watery diarrhoea, hypokalaemia and achlorhydria [21]. A macular rash that resolved after tumour resection was reported in a patient with a pancreatic polypeptide-producing tumour of the pancreas (PPoma) [22].

Renal disease [1–4]

The skin and renal system may be affected not uncommonly by the same disease processes. The more important of these renocutaneous syndromes are listed in Table 59.6.

Angiokeratoma corporis diffusum (Fabry's disease; MIM *301500) (Chapter 57). Affected individuals often show proteinuria, microscopic haematuria and lipiduria. Renal disease eventually develops in most male patients, and as lipid deposition in the form of glycosphingolipids occurs, renal function deteriorates. The premature mortality in the condition is often a result of renal failure. Renal transplantation can supply a source of the deficient enzyme lysosomal hydrolase, α-galactosidase A, and results in an improvement in the condition; commercial preparations of this enzyme are also now available. Other enzyme defects may give rise to the same clinical phenotype.

Table 59.6 Renocutaneous syndromes.

Hereditary syndromes
Angiokeratoma corporis diffusum
Neurofibromatosis
Tuberous sclerosis
Nail–patella syndrome
Birt–Hogge–Dubé syndrome
Sickle cell disease
Pseudoxanthoma elasticum
Oral-facial-digital syndrome
von Hippel–Lindau disease
Hereditary haemorrhagic telangiectasia
Metabolic disorders
Primary systemic amyloidosis
Calcinosis
Collagen disease and vasculitis
Allergic vasculitis
Systemic lupus erythematosus
Polyarteritis nodosa
Scleroderma
Nephrogenic fibrosing dermopathy
Wegener's granulomatosis
Erythema multiforme
Anaphylactoid purpura
Drug-induced toxic epidermal necrolysis

Neurofibromatosis (NF1, MIM *162200; NF2, MIM *101000; von Recklinghausen's disease) (Chapter 12). Urinary outflow obstruction may develop secondary to an impinging neurofibroma. Vascular lesions can result in renal artery thrombosis and subsequent hypertension. In patients with hypertension, normal plasma and urine catecholamine levels—especially those under the age of 20 years—renal artery stenosis should be suspected [5]. Raised blood pressure may also develop as a result of an associated phaeochromocytoma. Causes of hypertension in neurofibromatosis should be fully investigated [5]. Nephroblastoma is a recognized association in neurofibromatosis [6] and renal polycystic disease.

Tuberous sclerosis complex (TSC1, MIM #191100; TSC2, MIM *191092; Bourneville's disease) (Chapter 12). An increased incidence of rhabdomyomas and carcinoma may occur in this condition [7]. Malignant renal tumours may include renal cell carcinoma, malignant angiomyolipoma and Wilms' tumour [8] The classical renal lesion associated with tuberous sclerosis is an angiomyolipoma. Renal cysts also occur in conjunction with these, or as isolated findings [9].

Nail–patella syndrome (Fong's syndrome; hereditary osteo-onychodysplasia; MIM #161200) (Chapters 12, 62). Renal dysplasia presenting as chronic glomerulonephritis occurs in some cases, and electron-microscopic evidence of glomerular abnormalities in all cases, of nail–patella syndrome. Renal lesions are asymptomatic; patients show proteinuria, haematuria and reduced creatinine clearance. Although there is often a progressive course to renal failure, many patients with the complication do surprisingly well [10]. Helpful diagnostic signs include small, defective nails that do not reach the free nail border, triangular lunulae, the thumbnails being the most frequently and severely affected nails and the severity of the affect reducing from the index to little finger nails. The patellae are less well developed, potentially giving stability problems for the knee; other indicators include (radiologically) posterior iliac horns and (ophthalmically) irregular hyperpigmented pupillary borders. The defective gene is located on the long arm of chromosome 9 (9q34.1); this gene regulates type IV and VI collagen expression, which in turn affects skeletal and basement membrane structure and function [11].

Birt–Hogge–Dubé syndrome (BHD; Hornstein–Knickenberg syndrome; MIM #135150). Hereditary renal cell cancer syndromes include BHD, VHL, as well as hereditary papillary renal cell carcinoma, familial oncocytoma and hereditary clear cell renal cell carcinoma [12].

BHD has recognized cutaneous manifestations, which are described elsewhere in this chapter. Understanding the genetic basis of renal cell carcinoma, in which an imbalance of positive and negative genetic signals favours unregulated cellular growth and carcinogenesis, can help explain why the associated epithelial hamartomas (BHD) and other organ manifestations (VHL and BHD) occur [12].

Multiple cutaneous leiomyomas, which have an inherited predisposition, are linked to uterine leiomyoma and also appear to be associated with an increased incidence of renal cell carcinoma [12].

Multiple hamartoma and neoplasia syndrome (Cowden's disease; MIM #158350) is associated with an increased incidence of renal cell carcinoma, liposarcoma and transitional cell carcinoma of the bladder [8].

Linear IgA disease has been reported with renal cell carcinoma. Palliative treatment of the metastatic renal cell carcinoma with interferon-α replaced the need for conventional therapy for linear IgA disease [13].

Partial lipodystrophy. Renal disorders occur frequently in this condition, usually as a membranoproliferative glomerulonephritis; subsequent renal failure is common at an early age. There is a circulating C3 nephritic factor and reduced levels of complement (C3) [14]. An association with hereditary angio-oedema (C1 inhibitor deficiency) has been reported [15].

Familial Mediterranean fever with urticaria (FMFU) and Muckle–Wells syndrome (MWS) [16] (Chapter 47). In MWS, there is an association with urticarial eruptions, fever, arthralgia and deafness. Both FMFU and MWS are associated with a significant risk of renal failure secondary to amyloidosis, frequently resulting in premature death.

Primary and myeloma-associated systemic amyloidosis. Up to 40% of patients have waxy, purpuric cutaneous or mucosal changes [17], which may be diagnostically useful. Typically, patients may also have macroglossia, hepatomegaly, oedema and carpal tunnel syndrome. Cutis laxa-like clinical changes have also been reported [18]. Without dialysis, renal failure is often fulminant and fatal; peritoneal dialysis may be the most appropriate approach. Although renal amyloid may recur after transplantation, this is not completely contraindicated [17]. Primary cutaneous amyloid does not appear to have renal associations. Nodular or tumid amyloidosis often represents an early phase of systemic amyloid [19].

Sarcoidosis. This may explain polyuria and nocturia, through secondary effects such as hypercalcaemia; patients are therefore at risk of renal impairment. Nephrolithiasis and nephrocalcinosis occur in patients with sarcoidosis with a 20% higher frequency than in the

normal population. Renal sarcoidosis can give rise to diffuse interstitial nephritis, but it is seldom that there are identifiable granulomas or direct renal involvement. Rarely, cases of outflow obstruction from retroperitoneal sarcoidal masses and sarcoid of the urethra have been reported [20].

Oral–facial–digital syndrome. Polycystic disease of the kidneys and liver occurs commonly in this condition [21].

Von Hippel–Lindau syndrome (VHL; MIM *193300) (see earlier in this chapter, also Chapter 15). Renal lesions in VHL are either simple cysts or adenocarcinomas; usually they are a late manifestation [22]. Renal carcinoma may present with cutaneous metastases several years in advance of the systemic malignancy; alternatively, cutaneous deposits may indicate a recurrence of previously treated neoplasia [23]. VHL represents one of the hereditary kidney cancer syndromes in which a two-hit model of tumour genesis occurs, explaining the often late development of this complication [12,24].

The other tumours linked to VHL are dealt with in Chapter 15, but phaeochromocytomas and pancreatic tumours can occur with increased frequency in close anatomical association with each other.

Vasculitis (Chapter 49). Renal involvement commonly occurs in various types of vasculitis that present with cutaneous changes and is the main cause of mortality in many of these syndromes. This should be considered particularly in classical Henoch–Schönlein purpura (anaphylactoid purpura) (especially adult forms), where IgA nephropathy has become recognized as a fairly common form of glomerulonephritis. An association between anaphylactoid purpura and familial IgA nephropathy has also been described [25]. Patients labelled as having allergic vasculitis and arteritis with livedo reticularis [26] should also be regarded as being at risk of kidney damage. It can also occur in cases of erythema multiforme and drug-related toxic epidermal necrolysis [27,28].

Renal failure is a recognized, but rare complication of Behçet's syndrome, usually with immune-complex deposition [29]. Concomitant or delayed renal involvement is common in Wegener's granulomatosis, usually as a focal necrotizing glomerulitis. Deposits of IgM and IgG are present in renal vessels and circulating immune complexes are also frequently detected [30]. Renal changes that occur in these conditions and in collagen vascular disorders such as polyarteritis nodosa, systemic lupus erythematosus and scleroderma are considered in Chapter 56.

Bullous pemphigoid. Renal disease—including membranous glomerulopathy, diffuse proliferative and mesangioproliferative glomerulonephritis—has been infrequently reported in patients with pemphigoid [31].

Streptococcal impetigo. An acknowledged cause of acute glomerulonephritis, but most cases of acute nephritis are not the sequel of streptococcal infection [30].

Secondary syphilis. A rare cause of the nephrotic syndrome.

Herpes zoster. If affecting the appropriate dermatomes, this may cause neurogenic bladder dysfunction and pain [32], leading to acute urinary retention.

Signs of renal failure and dialysis

Cutaneous signs of renal failure are present only in fairly advanced cases, in which the findings are of limited diagnostic value. Urea frosting, in which crystalline urea is deposited on the skin, is rarely seen.

Uraemic patients tend to have a dry skin, sometimes with fine scaling. A reduction in the size of eccrine sweat glands in uraemia may contribute to this effect [33], although high-dose diuretic regimens are a co-factor [34].

Pigmentation. Anaemia presenting as pallor is an early and common sign in renal failure resulting from reduced erythropoiesis and increased haemolysis.

A muddy brown hyperpigmentation develops in many cases, attributed to retention of chromogens and deposition of melanin, possibly due to impaired renal processing of MSH [35]. Increased nail pigmentation usually confined to the distal aspect occurs in a proportion of patients [36]. This distal brown or more normal red colour, combined with a proximal white appearance gives rise to the 'half-and-half' nails, a distinctive pattern seen in about 10% of renal failure cases [37].

Purpura due to a mild thrombocytopenia or more marked platelet dysfunction is common and may be partly corrected by dialysis [38]. Wound healing is prolonged and patients may be more susceptible to pressure sores.

Pruritus. Generalized, severe pruritus occurs in about one-third of renal failure cases, less troublesome involvement in many more. Unfortunately, haemodialysis can initiate the symptom as well as improve it. Up to 85% of patients on haemodialysis suffered from itching in one study [39], one-third before dialysis, the others after; 12% had reduced pruritus after 6 months' dialysis. There seems to be an association with predialysis blood urea levels, and a less assured correlation with dry skin and secondary hyperparathyroidism [28]. Subtotal parathyroidectomy may be very helpful [40], but the problem can subsequently recur, and many cases are not related to secondary hyperparathyroidism. Moreover, many patients with this finding do not itch. A complete explanation for pruritus in renal failure is obscure, as pruritus is unusual in acute renal failure and a reduction in uraemia often does not improve the symptom. Slowly accumulated or

deposited pruritogen(s), of as yet uncertain nature, are the likely cause. In dialysis, lowering the magnesium concentration of the dialysate has been reported as helpful [41]. In intractable itching, UVB radiation is an effective therapy [42], benefit being associated with a reduction of skin phosphorus to normal values. UVA (without psoralen) has been reported nearly as effective [43]; oral cholestyramine and activated charcoal are alternatives [44,45]. Erythropoietin therapy can alleviate pruritus in some cases of renal failure.

Calcification and calciphylaxis. Calcifying panniculitis has been reported occasionally in renal failure, caused by a mechanism known as calciphylaxis [46,47]. It is usually, but not invariably, associated with a high serum calcium phosphate product. Metastatic skin calcification is a rare phenomenon in uraemic patients; it usually presents as papular or nodular cutaneous lesions around large joints or flexural sites. Non-cutaneous metastatic calcification is by comparison much commoner [48]. Metastatic calcification in blood vessel walls associated with hyperparathyroidism and renal failure may lead to cutaneous necrosis or gangrene, as a result of thrombosed vessels; however, calcification does not always need to be present, and vascular damage may be triggering a premature haemostatic cascade [49].

Perforating disorders. A perforating disorder variously described as perforating collagenosis, Kyrle's disease or perforating folliculitis occurs in renal failure; often there is diabetes, diabetic nephropathy and/or retinopathy. Pruritus is nearly always present, and up to 10% of dialysis patients may be affected. The condition seems to have a higher incidence in Afro-Caribbeans. The cutaneous lesions consist of hyperpigmented papules up to 1 cm in diameter with a central keratinous plug. The extensor surfaces of the limbs are more commonly affected but the trunk and face may be involved. The pathogenesis is uncertain, but there is some histological evidence that it is a perforating collagenosis [50].

Other cutaneous features. Uraemic neuropathy affects some 60% of patients with renal failure or on long-term haemodialysis. This appears to be a predominantly sensorimotor neuropathy [51].

Up to 40% of patients with renal failure may develop gynaecomastia while receiving dialysis [52]. It may be reversed by a low phosphorus diet and aluminium hydroxide gel [53].

Features related to treatment. Premature ageing of the skin and actinic keratoses have been described [54], a reason for avoiding excessive ultraviolet therapy for pruritus. This should be distinguished from the numerous viral, dysplastic and frankly malignant skin lesions which may develop in immunosuppressed, renal allograft recipients. In such circumstances there is also a raised incidence of Kaposi's sarcoma [55]. These aspects are dealt with under cutaneous manifestations of immunosuppressive therapy (Chapter 14).

Cutaneous complications affecting the limb of patients in which their haemodialysis arteriovenous shunt is situated include infection, phlebitis and haematoma. However, both irritant and allergic contact eczema may also develop [56]. Vascular complications of arteriovenous fistula construction are relatively uncommon, but include digital ischaemia and aneurysm formation. The venous hypertension syndrome with or without ulceration, together with pseudo-Kaposi's sarcoma, are rare developments [57].

The diagnosis of the porphyria cutanea tarda-like bullous eruption that may develop in dialysis patients appears to be dependent on the sophistication of biochemical analysis for porphyrins; the importance of accurate assays is emphasized [58–60].

A recently described condition termed nephrogenic fibrosing dermopathy or scleromyxoedema-like illness of renal disease was initially linked with haemodialysis but occurs in other patients with renal failure [61–63]. Clinical features include indurated plaques, sometimes with finger-like projections, that may be erythematous, yellowish or skin coloured. Nodules and contractures occur in more advanced disease. Scleral plaques may also occur, although the face is usually spared (by contrast with scleromyxoedema). There is no associated plasma cell dyscrasia as seen in most patients with scleromyxoedema. Histology shows increased spindle cells and compact collagen bundles, with increased mucin deposition.

Cardiac disease

There are several diseases in which both cardiac and skin involvement may be found (Table 59.7). Most of these are part of a syndrome or are systemic disorders affecting other organs as well [1,2]; most are discussed in other chapters, but some are briefly described below. Disorders of blood vessels are not included here. The effects of skin disease on the heart (e.g. cardiac failure due to erythroderma) and indirect effects, such as anaemia due to immunosuppressive agents used to treat the skin, are not discussed. Numerous infections may occasionally cause myocardial disease and may have an exanthem, but these are not discussed individually. Drug reactions due to cardiac medications are described in Chapter 73.

Consequences of cardiac disease

Dermatological consequences of cardiac disease include skin colour changes such as cyanosis, erythema due to secondary polycythaemia, and a combination of the two that may occur in congenital heart disease (and which has been termed erythremia). Finger clubbing is a consequence of congenital cyanotic heart disease, but occurs in other

Table 59.7 Conditions that affect the heart and skin.

Disease	Main cardiac feature, or comment
Congenital / inherited	
Ehlers–Danlos syndrome	Dilated main vessels, mitral or tricuspid insufficiency
Cutis laxa	Early CAD, aortic aneurysm, mitral valve prolapse
Marfan syndrome	Aortic aneurysm, aortic regurgitation, mitral valve prolapse or regurgitation
Pseudoxanthoma elasticum	Arterial calcification, CAD, mitral valve prolapse
Werner's disease	Early CAD
Progeria	Early CAD
Cockayne's syndrome	Early CAD
Cornelia de Lange's syndrome	Septal defects, persistent ductus arteriosus, pulmonary stenosis
Fabry's disease	Conduction defects, arrhythmias, hypertension, left ventricular hypertrophy, mitral valve prolapse
Noonan's syndrome	Pulmonary stenosis, septal defects, hypertrophic cardiomyopathy, aortic abnormalities, others
Rubinstein–Taybi syndrome	Aortic coarctation, persistent ductus arteriosus, pulmonary stenosis, septal defects
LEOPARD syndrome	E, ECG abnormalities (various forms of heart block); P, pulmonary stenosis. Also subaortic stenosis and hypertrophic cardiomyopathy
Tuberous sclerosis	Cardiac rhabdomyomas
Neurofibromatosis	Hypertension (renovascular or phaeochromocytoma)
Incontinentia pigmenti	Patent ductus arteriosus, tricuspid insufficiency
Alagille's syndrome	Pulmonary artery hypoplasia/stenosis
Di George's syndrome	Tetralogy of Fallot, aortic arch defects
Lymphoedema–distichiasis syndrome	Tetralogy of Fallot, patent ductus arteriosus
Naxos disease	Arrhythmogenic right ventricular cardiomyopathy
Chromosomal syndromes	Various—includes Down's syndrome, Turner's syndrome, trisomy 13, trisomy 18
Inflammatory diseases, connective tissue disease, vasculitis	
Systemic lupus erythematosus	Vegetations (especially mitral, Libman–Sacks endocarditis), pericarditis, myocarditis, aortic/mitral regurgitation
Neonatal lupus erythematosus	Neonatal heart block (various patterns), septal defects, persistent ductus arteriosus, tricuspid/mitral insufficiency
Systemic sclerosis	Pericarditis and effusion, conduction defects, myocardial fibrosis, cardiomyopathy, cor pulmonale
Polyarteritis nodosa	Coronary artery vasculitis, ECG abnormalities, hypertension
Behçet's disease	Pericarditis, pulmonary and coronary artery aneurysm
Antiphospholipid syndrome	Vegetations, coronary artery thrombosis, pericardial effusion
Degos's disease	Pericarditis, pericardial effusion
Churg–Strauss disease	Pericarditis, cardiac fibrosis, pericardial effusion
Wegener's granulomatosis	Cardiomyopathy
Cholesterol emboli	Coronary artery occlusion
Other vasculitides	Coronary artery vasculitis
Dermatomyositis	Conduction defects, arrhythmias, cardiomyopathy, CCF
Relapsing polychondritis	Mitral or aortic insufficiency, dissecting aortic aneurysm, pericarditis, myocardial ischaemia, heart block
Rheumatic fever	Mitral and aortic valve disease
Kawasaki disease	Conduction defects, coronary artery aneurysms, pericardial effusion, cardiomegaly
Multicentric reticulohistiocytosis	Pericarditis, cardiomegaly, CAD, CCF
Hypereosinophilic syndrome	Eosinophilic endomyocarditis, valvular scarring, CCF, restrictive cardiomyopathy
Sarcoidosis	Conduction defects, arrhythmias, CCF
Reiter's disease	Conduction defects, aortic regurgitation
Deposition, metabolic and endocrine disorders	
Amyloidosis	Conduction defects, cardiomegaly, CCF
Haemochromatosis	Arrhythmias, cardiomyopathy, CCF
Wilson's disease	Arrhythmias, cardiomyopathy
Mucinoses: scleromyxoedema	Cardiomyopathy, CCF
Atrial myxoma syndromes	See text
Hyperlipidaemias	CAD
Diabetes mellitus	CAD, cardiomyopathy
Hyperthyroidism	Tachycardia, atrial fibrillation, mitral regurgitation
Hypothyroidism	Bradycardia, CAD, pericardial effusion
Acromegaly	Left ventricular hypertrophy, CCF
Carcinoid syndrome	Tricuspid or pulmonary stenosis, right heart failure
Phaeochromocytoma	Variable heart rate, hypertension/hypotension
Mastocytosis	Tachycardia, hypotension, arrhythmia, angina
Homocystinuria	Atherosclerosis

(*cont'd*)

Table 59.7 (*cont'd*)

Disease	Main cardiac feature, or comment
Embolic diseases	
Subacute bacterial endocarditis	Vegetations, valvular incompetence
Cholesterol emboli	Usually from proximal arteries rather than cardiac
Atrial myxomas	See text
Infections	
Lyme disease	Myocarditis, heart block
Syphilis	Aortitis, aortic aneurysm, aortic and mitral regurgitation, obstructed coronary arteries
Varicella	Myocarditis
Septicaemia	Pustules, infarcts, disseminated intravascular coagulopathy
Congenital rubella	Pulmonary artery and valve stenosis, patent ductus arteriosus
Whipple's disease	Pericarditis, myocarditis, valve deformity (especially mitral valve endocarditis)
Drugs	
Used in cardiology, causing rash	e.g. amiodarone (photosensitivity, pigmentation)
Cardiotoxic and cause skin eruptions	e.g. doxorubicin (cardiotoxic, anagen effluvium, pigmentation)
Used for skin disease, cardiovascular side effects	e.g. ciclosporin (hypertension)
Teratogenic, causing both skin and cardiac defects	e.g. alcohol, phenytoin, retinoids
Miscellaneous	
Earlobe crease	CAD
POEMS syndrome	Cardiac failure
Mycosis fungoides, Sézary syndrome	Heart is infiltrated in advanced disease
Kaposi's sarcoma	Heart is commonly involved
Diffuse neonatal haemangiomatosis	High output cardiac failure
Erythroderma, any cause	High output cardiac failure
Pacemaker reactions	Infection, contact dermatitis, mechanical issues
Clubbing of nails	Cyanotic congenital heart defects
Red lunulae	Occur in CCF

CAD, coronary artery disease; CCF, congestive cardiac failure; ECG, electrocardiogram; LEOPARD, lentigines, ECG abnormalities, ocular hypertelorism, pulmonary stenosis, abnormalities of genitalia, retardation of growth, and deafness (syndrome); POEMS, polyneuropathy, organomegaly, endocrinopathy, M protein, skin changes (syndrome).

situations as well. Applying pressure on the tip of the nail in subjects with aortic regurgitation reveals visible flushing of the nail bed in time with the pulse, due to the wide pulse pressure in this disorder (Quincke pulsation) [2].

Congenital and inherited disorders

Cardiac involvement occurs in several congenital and inherited conditions, such as the LEOPARD syndrome, Anderson–Fabry disease, Alagille's syndrome and the cardiofaciocutaneous and Noonan's syndromes [1–8], as well as in chromosomal abnormalities such as Turner's syndrome and trisomy 13 or 18 [1]. The lymphoedema–distichiasis syndrome, due to mutations in *FOXC2* (*MFH-1*) on chromosome 16q24.3, has been linked to cardiac anomalies such as tetralogy of Fallot and patent ductus arteriosus [9,10]; spinal arachnoid cysts also occur. Cardiac rhabdomyomas occur in about 50% of patients with tuberous sclerosis (see Chapter 12).

In the LEOPARD syndrome (multiple lentigines syndrome; MIM *151100) [3] there are widespread *l*entigines, *e*lectrocardiographic abnormalities, *o*cular hypertelorism, *p*ulmonary stenosis, *a*bnormal genitals, *r*etardation of growth and *d*eafness. The cardiac involvement includes left-axis deviation on the electrocardiogram (ECG), ventricular hypertrophy and arrhythmia.

In angiokeratoma corporis diffusum (Anderson–Fabry disease; MIM *301500) [4], cardiac involvement may be manifest as arrhythmias, an abnormal P–R interval on ECG and left-ventricular hypertrophy. ECG abnormalities may also be found in heterozygotes. Manufactured α-galactosidase is now available to treat this condition [4] and appears to be more beneficial for the renal and cardiac lesions than for the cutaneous angiokeratomas, although accumulated globotriaosylceramide in the skin decreases during treatment.

Coronary artery disease

Coronary artery disease and ischaemic heart disease may occur in premature ageing syndromes such as progeria and Werner's syndrome, and premature myocardial ischaemia has also been reported in pseudoxanthoma elasticum, although it seems to be less common than the presence of a calcifying vascular pathology might suggest [2,11]. Coronary artery disease may be associated with

xanthelasma or xanthomas due to hyperlipidaemia [2]. Both all-cause and cardiac-specific morbidity and mortality have been linked with the presence of a unilateral or bilateral diagonal earlobe skin crease [12,13], although others suggest that the association is with older age rather than with coronary artery disease *per se*. Both antinuclear [14] and high-titre anticardiolipin antibodies [15] have been demonstrated in a high proportion of patients with coronary artery disease; the significance of these is uncertain.

Connective tissue and systemic diseases

Cardiac involvement is common in systemic disorders such as sarcoidosis [16], connective tissue diseases [17–19], vasculitides [20,21] (Chapter 49), dermatomyositis (Chapter 56), relapsing polychondritis (Chapter 65) [22] and the hypereosinophilic syndrome [23,24], although it may be underestimated if symptoms are absent. Sudden death due to conduction defects and ventricular arrhythmias is the most important complication, and is particularly well recognized in sarcoidosis [16]. The major vasculitides that affect the heart are Wegener's granulomatosis, polyarteritis nodosa, Churg–Strauss syndrome, temporal arteritis and Takayasu arteritis. Cardiac involvement is commoner in Churg–Strauss syndrome than in Wegener's granulomatosis, but has low discriminatory value—this is discussed in more detail in Chapter 49 and in the section on respiratory disease and the skin, below.

A number of cardiac complications occur in systemic lupus erythematosus (LE), especially pericarditis, which may be present in 60–80% of patients at autopsy (Chapter 56) [2,25]. Neonatal LE is a particularly important entity, as about two-thirds of affected children have congenital heart block, although the frequency of this manifestation varies between countries [18,19]. Mothers of affected children generally express the 52-kDa and 60-kDa anti-SS-A (Ro) antibodies, even if they have no other features of LE. This antibody group is particularly associated with subacute cutaneous LE, but also with systemic LE. Mothers of children with neonatal LE with heart block tend to have higher titres of anti-SS-A but lower titres of anti-SS-B (La) antibody than mothers of children with neonatal LE rash alone [19].

Cardiac involvement occurs in 80% of patients with systemic sclerosis, but is not always clinically apparent; pericarditis, pericardial effusion, myocardial fibrosis, endothelial damage to coronary arteries and heart failure due to pulmonary arterial hypertension all occur [2,26,27]. Symptoms include heart failure, palpitations and myocardial infarction. Vasospasm may occur due to Raynaud's phenomenon.

In the antiphospholipid syndrome [28], about 50% of patients have valvular heart disease, either vegetations or thickening. The mitral valve is most frequently affected. About 5% require cardiac valve surgery, but many have no symptoms. There is also an increased incidence of coronary artery disease. Intracardiac thrombus is a rare complication.

Cardiac involvement is frequent in primary and in familial amyloidosis [29], causing features of cardiomyopathy such as congestive heart failure, low voltage on the ECG and conduction disturbances. Cardiomegaly is present in about one-third of the patients. Cutaneous signs, macroglossia and demonstration of amyloid deposition on skin histology support the diagnosis.

Kawasaki disease (mucocutaneous lymph-node syndrome) is an acute febrile disease of unknown aetiology, with accepted diagnostic criteria [30]. Coronary artery aneurysms may develop in up to 25% of patients, more commonly in children; conduction defects, pericardial effusion and cardiomegaly also occur. Symptoms and signs may include murmurs, gallop rhythm, angina and myocardial infarction [25,30]. Echocardiography and ECG are indicated. Treatment consists of acetylsalicylates and high doses of intravenous gammaglobulin.

Infections

Subacute bacterial endocarditis (SBE) [31–33] typically occurs in patients with a past history of heart disease (rheumatic fever, congenital heart disease, heart valve operation) or of parenteral drug addiction. About 75–80% of cases are caused by *Staphylococcus aureus* or streptococcal species, predominantly *Streptococcus viridans*. Cutaneous lesions may represent either septic emboli or immune complex disease due to the bacterial focus [31]; organisms can occasionally be cultured from skin lesions [32]. The skin lesions may be purpuric, pustular or erythematous, and various patterns are described. A non-specific small-vessel vasculitis with splinter haemorrhages of the nail fold or nail bed occurs in about half of affected individuals. Similar small haemorrhages occur on the conjunctivae and retina (Roth spots). Osler's nodes are small, tender red papules situated mainly on the distal finger and toe pads; Janeway lesions are faint red macular lesions on the thenar and hypothenar eminences. Both rheumatoid factor and cANCA can be demonstrated in some patients with SBE; these are of uncertain significance, but may erroneously suggest that the diagnosis is of systemic ANCA-associated vasculitis rather than of infective aetiology [33].

Rheumatic fever is a complication of streptococcal infection [34]. It causes arthritis, carditis, neuromuscular disease (Sydenham's chorea, dysphagia, dysarthria, distal weakness) and cutaneous lesions. The latter include erythema marginatum and papular lesions on the extensor surface of the extremities, particularly near the joints—both of these manifestations are usually transient, typically

resolving after a few weeks. Erythema marginatum is a transitory gyrate erythema situated mainly on the trunk and proximal parts of the extremities. Urticaria, erythema nodosum and purpura are described in about 2% of patients. Cardiac features include valvular disease, pericarditis, myocarditis and congestive cardiac failure.

Cardiac myxoma syndromes

Carney complex (type I, MIM #160980; type II, MIM *605244). A number of atrial myxoma syndromes have been described, with various eponyms and acronyms and overlapping features [35–39]. These include LAMB syndrome, NAME syndrome, Danoff syndrome and the Carney complex. LAMB is an acronym for *l*entigines, *a*trial myxoma, *m*ucocutaneous myxoma and *b*lue naevi. The NAME syndrome indicates blue *n*aevi, *a*trial myxoma, *m*yxoid neurofibromas and *e*phelides. The inheritance is autosomal-dominant. In the Danoff syndrome there are, apart from atrial myxomas, adrenocortical dysplasia, lentigines and spindle cell tumours.

About 50% of cases of bilateral, pigmented, micronodular adrenal hyperplasia—a rare cause of ACTH-independent Cushing's syndrome—are associated with the Carney complex; anti-ACTH receptor antibodies are present and stimulate adrenal growth and secretion. Other features include cardiac myxomas (in one-third of patients), skin myxomas (two-thirds), skin pigmentation (96%), myxoid fibroadenomas of the breast (in one-third of women, uncommon in men), GH-secreting pituitary tumours (acromegaly occurs in 8% of patients), Sertoli cell (in 10%) and Leydig cell testicular tumours (which cause male precocious puberty), thyroid cysts, hyperplasia and tumours (10%), and ovarian cysts and tumours (which are felt to be underestimated in frequency) [37–39]. Psammomatous melanotic schwannoma is rare, but is usually part of this syndrome when it occurs [40].

The genetic background of these disorders has been extensively investigated. Carney complex type 1 (CNC1) is linked to a susceptibility gene for the protein kinase A type 1α regulatory subunit gene (*PRKAR1A*) and has loci on chromosomes 2p16 and 17q23–24, whilst CNC2 links to a currently unknown gene on chromosome 2p. Genetic evaluation has demonstrated that this disorder is related to PJS. Any patient with multiple melanocytic and myxomatous tumours of the skin and mucosa (including vulval melanotic macules) should have a cardiac evaluation.

From a dermatological aspect, atrial myxomas may present due to embolic infarction of the skin. They may mechanically interfere with cardiac function and can also lead to pericarditis. Systemic malaise, pleurisy, Raynaud's phenomenon and the occasional occurrence of ANCA [41] may suggest other forms of vasculitis as the cause of skin lesions.

Miscellaneous

Cardiac pacemaker and implantable defibrillator dermatoses. Cutaneous reactions over the site of implanted cardiac pacemakers have been reported [42–45]. Most of these are either infections or mechanical issues (erosions, extrusions, capsular contracture, exposed generator or electrodes, bronchopleural cutaneous fistulae) and may respond to antibiotics or altered positioning of the pacemaker [42,43]. However, contact dermatitis to epoxy resins, nickel or chromium may occur, in which event removal of the implanted material and use of titanium pacemaker casings may be appropriate [44,45]. A reticular telangiectatic pattern of erythema overlying pacemaker or defibrillator sites may occur [46,47]. Cardiac pacemakers also have dermatological surgical relevance, as they may malfunction during the use of electrosurgery [48].

Respiratory system

Pulmonary disease rarely occurs as a direct consequence of a primary skin disease, except for instances such as metastasis from a primary skin tumour (e.g. melanoma).

Similarly, there are relatively few instances in which skin abnormalities occur as a direct consequence of respiratory pathology. Examples include cyanosis due to severe pulmonary disease or intrapulmonary right-to-left shunts, and finger clubbing due to chronic cyanotic lung disease or neoplasm. Dermatomyositis may occur as a paraneoplastic phenomenon due to lung cancer (but, as discussed below, lung disease also occurs as a consequence of dermatomyositis). Amyloidosis may occur secondary to chronic respiratory diseases such as bronchiectasis or cystic fibrosis, but cutaneous signs in secondary amyloidosis are generally few, even though aspiration of subcutaneous fat for histological examination can be diagnostic. Tumours may cause direct nerve damage and abnormalities of sweating [1,2].

However, in most instances in which the skin and respiratory tract exhibit the same disease process, this is as part of a multisystem disorder. This section concentrates on this diverse group of disorders (Table 59.8).

Congenital and inherited disorders

Examples are listed in Table 59.8. NF1 (Chapter 12) is not uncommonly associated with the development of restrictive lung disease if there is severe scoliosis. Intrathoracic, intra-abdominal or retroperitoneal diffuse plexiform neurofibromas can also compromise pulmonary function [3]. Fibrosis is found in around 10% of patients with NF1, mainly in the lower lobes, and bullous changes may occur in the upper lobes [4]. Pleural effusions have been reported in tuberous sclerosis [5] (Chapter 12). Pulmonary involvement is uncommon but, especially in adult female patients, there may be numerous small cysts which represent lymphangioleiomyomatosis [6]. These may be mistaken for tuberculosis or sarcoidosis radiologically. Diffuse lower lobe fibrosis and laryngeal involvement has been reported in Darier's disease [7] (Chapter 34). α_1-Antitrypsin deficiency, particularly the ZZ genotype, links cutaneous panniculitis with emphysema and hepatic cirrhosis [8]. In familial dysautonomia (Riley–Day syndrome), there are acute episodes of bronchopneumonia, with profuse mucous secretion causing dyspnoea. Skin changes include multiple excoriations, and erythematous mottling associated with fever and sweating [9]. Radiological features of lung disease [10] may be accompanied by abdominal distension as the 'chest–abdomen' sign [11]. Ataxia–telangiectasia (Louis-Bar syndrome) may be associated with pulmonary problems, including recurrent pneumonia, bronchiectasis and pulmonary fibrosis [12].

Table 59.8 Conditions that affect the skin and respiratory system.

Disease	Respiratory tract features or comment
Congenital / inherited	
Atopic disease	Asthma, hay fever
Cutis laxa	Emphysema, cor pulmonale
Tuberous sclerosis	Rhabdomyomas
Neurofibromatosis	Kyphoscoliosis, intrathoracic neuromas, lung fibrosis, bullae
Ataxia–telangiectasia	Pneumonia, bronchiectasis, pulmonary fibrosis
Hereditary haemorrhagic telangiectasia	Haemoptysis, dyspnoea, cyanosis due to arteriovenous shunting
α_1-antitrypsin deficiency	Emphysema
Darier's disease	Lower lobe fibrosis, laryngeal involvement
Lipoid proteinosis	Laryngeal involvement
Riley–Day syndrome	Lung infiltrate
Birt–Hogg–Dubé syndrome	Lung cysts, pneumothorax
Infections and infestations	
Tuberculosis	Specific skin lesions, erythema nodosum
Mycobacterium avium–intracellulare infection	May disseminate to skin (usually in HIV infection)
Leprosy	Laryngeal involvement
Mycoplasma infection	Causes erythema multiforme (often mucosal)
Dissemination of pulmonary fungal infections	Blastomycosis, coccidioidomycosis, cryptococcosis, aspergillosis, histoplasmosis, melioidosis
Scrub typhus	Pneumonia (common)
Varicella	Pneumonia
Measles	Pneumonia
Larva migrans	Asthma/bronchitis with eosinophilia
Chronic mucocutaneous candidiasis	Bronchiectasis
Whipple's disease	Cough, pleural effusion, pulmonary infiltrate, hilar lymphadenopathy
Infiltrations and metabolic	
Histiocytoses (Langerhans' cell histiocytosis, Rosai–Dorfman disease, haematophagocytic syndrome, necrobiotic xanthogranuloma, sea-blue histiocytosis, others)	Pulmonary nodules and fibrosis, upper respiratory tract infiltration disease, xanthoma disseminatum
Amyloidosis	Cutaneous amyloid deposition secondary to chronic lung disease, lung infiltration in primary amyloidosis
POEMS	Pleural effusion, bronchospasm
Carcinoid syndrome	Bronchospasm
Hypothyroidism	Laryngeal involvement
Myxoma	Pleurisy
Inflammatory	
Sarcoidosis	Pulmonary fibrosis, hilar lymphadenopathy, laryngeal involvement
Pulmonary vasculitides	See text (this section)
Systemic sclerosis	Interstitial fibrosis, pneumothorax, pulmonary hypertension
Sjögren's syndrome	Decreased secretions, sinusitis, bronchoalveolitis, interstitial lung disease
Lupus erythematosus	Pleurisy
Mixed connective tissue disease	Fibrosing alveolitis (especially U_1 ribonucleoprotein antibody-positive)
Antiphospholipid syndrome	Pulmonary embolism, infarction, thrombosis, haemorrhage
Dermatomyositis	Muscular weakness, pharyngeal dysfunction (aspiration pneumonia), interstitial lung disease, bronchiolitis obliterans
Relapsing polychondritis	Tracheal collapse
Multicentric reticulohistiocytosis	May be associated with bronchial neoplasia, also lung infiltration, pleural effusion
Bullous diseases (epidermolysis bullosa, pemphigus, erythema multiforme/Stevens–Johnson syndrome/ toxic epidermal necrolysis)	Upper respiratory tract involvement; paraneoplastic pemphigus is associated with intrathoracic disease, especially Castleman's disease, thymoma
Graft-versus-host disease	Restrictive defect, fibrosis
Pyoderma gangrenosum	Neutrophilic nodules in lung, tracheal pyoderma
Familial Mediterranean fever	Pleuritis
Drugs	
Used in respiratory disease, causing rash	e.g. co-trimoxazole (drug rash)
May cause skin eruptions and respiratory tract disease	e.g. antibiotic-induced toxic epidermal necrolysis, cisplatin (bronchospasm, pigmentation)
Used for skin disease, respiratory side effects	e.g. isotretinoin (bronchospasm)
Miscellaneous	
Angio-oedema	Upper airway obstruction
Anaphylaxis	Bronchospasm
Pancreatitis	May cause basal pleural reaction, and cutaneous fat necrosis
Yellow nail syndrome	Pleural effusion, bronchiectasis
Mastocytosis	Rhinorrhoea, laryngeal oedema, bronchospasm
Tumours	Metastatic disease, Kaposi's sarcoma, lymphomatoid granulomatosis, extensive mycosis fungoides/Sézary syndrome, others

HIV, human immunodeficiency virus; POEMS, polyneuropathy, organomegaly, endocrinopathy, M protein, skin changes (syndrome).

Infections

Numerous infections may be associated with both respiratory and skin disease, and only a selection of these have been listed. Many viral infections, for example, may cause upper and sometimes lower respiratory tract symptoms in association with either a non-specific exanthem or with erythema multiforme. *Mycoplasma infection* is particularly associated with erythema multiforme with mucosal involvement (Stevens–Johnson syndrome). *Psittacosis (ornithosis)* may be accompanied by erythema nodosum and erythema multiforme (Bateman's syndrome).

Associations between *tuberculosis* and the skin include non-specific reactions such as erythema nodosum or erythema multiforme, as well as several patterns of specific skin lesion such as lichen scrofulosorum, Bazin's disease or papulonecrotic tuberculide (Chapter 28). Several *systemic mycoses* are caused by inhalation but may subsequently cause skin lesions (Table 59.8)—either non-specific reactions such as erythema multiforme or erythema nodosum, or specific lesions caused by haematogenous dissemination. Other mycoses may have primary cutaneous lesions with occasional spread to internal organs, including the lung (e.g. sporotrichosis). *Pulmonary melioidosis* may run a subacute course and last for one to several weeks. It may be contracted by inhalation, causing early pneumonic symptoms, or via skin defects, in which case abscess formation precedes the septic stage. Urticaria may occur in chronic melioidosis [13].

Connective tissue diseases

This group of disorders have a variety of respiratory features.

Respiratory disease is frequent in the various forms of *scleroderma* [14,15]. Systemic sclerosis is associated with fibrosing alveolitis and interstitial fibrosis, causing a restrictive defect. This occurs in at least 50% of patients. Symptoms (exertional dyspnoea and cough) may be relatively late in presenting—pulmonary function tests including transfer factor should be measured. Pneumothorax, pleural effusion, respiratory muscle involvement and 'splinting' of the chest by sclerotic skin may all occur. Pulmonary vascular disease leading to pulmonary hypertension is a particular concern in CREST syndrome.

Over 50% of anti-U1RNP-positive patients with *systemic lupus erythematosus* (SLE) and about a quarter of those with *mixed connective tissue disease* may have pleurisy [16]. These conditions are discussed in more detail in Chapter 56. Pulmonary embolism, haemorrhage, infarction and hypertension may occur in patients with the *antiphospholipid syndrome* [17].

Relapsing polychondritis [18] is due to autoantibodies against type II collagen, and is a potentially fatal disease. Dyspnoea and inspiratory stridor occur due to swelling of the respiratory tract, and collapse of cartilages of the larynx and trachea, in over 50%. Costal cartilage is involved in one-third of cases. Inflamed nasal and auricular cartilages are present in most patients, with nasal obstruction, arthropathy and high erythrocyte sedimentation rate (ESR). The disorder may therefore mimic one of the vasculitides, such as Wegener's granulomatosis. The non-cartilaginous lobe of the ear is classically spared in relapsing polychondritis.

In *dermatomyositis*, there are three main mechanisms that provide a link with respiratory disease [19–21]. Firstly, dermatomyositis may occur as a consequence of bronchial carcinoma, the commonest malignancy associated with dermatomyositis in males [19]. Muscular weakness due to myositis may affect the intercostal and thoracic musculature, or may affect the larynx and pharynx—the latter may lead to aspiration pneumonia as a complication. Finally, interstitial lung disease or bronchiolitis obliterans may occur due to dermatomyositis. The lung disease is typically associated with the presence of antiaminoacyl-tRNA synthetase antibodies, notably anti-Jo-1, and with anti-tRNA antibodies such as anti-$tRNA^{his}$. Patients with these antibodies only comprise 15–20% of individuals with dermatomyositis, but most patients with lung disease have one of these antibodies. The antisynthetase syndrome consists of dermatomyositis (or polymyositis) with interstitial lung disease, arthritis and Raynaud's phenomenon [21]. Presence of antisynthetase antibodies is also associated with the clinical entity of 'mechanic's hands' in dermatomyositis, but they are not usually a feature of paraneoplastic dermatomyositis. Dermatomyositis may also indirectly be associated with lung disease as a consequence of treatment—either infection due to immunosuppression, or rarely drug-induced pneumonitis (methotrexate).

In *Sjögren's syndrome*, alveolitis can be demonstrated in about 50% of patients, but is often asymptomatic. Inspissated secretions may predispose to pneumonia; obstructive and interstitial lung disease may occur [22].

Vasculitis and neutrophilic dermatoses

(see also Chapter 49)

Vasculitis of many types may affect the lung. The major pulmonary vasculitides are Wegener's granulomatosis, Churg–Strauss disease, polyarteritis nodosa and Behçet's disease [23].

Behçet's disease. The frequency of lung involvement in Behçet's disease may be as high as 19%, although 5–10% is a more frequent estimate. Pleurisy or perihilar radiological opacities may be found [23], and pulmonary arterial aneurysm is an important feature, which can be fatal [24]. About 90% of patients with Behçet's disease complicated by pulmonary artery aneurysm also have thrombophlebitis.

Small-vessel vasculitis. Any form of small-vessel vasculitis can also affect the lung, even urticarial vasculitis. In one large series, over 20% of patients with urticarial vasculitis had pulmonary disease, either chronic obstructive pulmonary disease or asthma. Although it is not clear that these were always causally related to the vasculitis, obstructive pulmonary disease was more frequent in the group of patients with hypocomplementaemia [25], and lung vasculitis or serological evidence of LE was demonstrated in over 50% of patients with lung disease.

Wegener's granulomatosis [26,27]. This is a rare disease. The 'classic' syndrome is characterized by necrotizing granulomatous vasculitis of the upper and lower respiratory tracts, necrotizing glomerulonephritis and disseminated vasculitis of various organs. Skin lesions are frequent, including vasculitis with purpura, subcutaneous nodules and ulcers (see also Chapter 49). Upper airway disease causes nasal discharge, ulceration and bleeding, and oral ulceration. Pulmonary changes are typical with bilateral infiltrate, nodules or cavities. Subglottic or tracheobronchostenosis may also occur. There is no hilar or mediastinal lymphadenopathy. Prognosis is poor in patients with lung or renal disease; chronic nasal staphylococcal carriage is also associated with a poorer prognosis. Treatment consists of immunosuppressive agents (cyclophosphamide, azathioprine, chlorambucil and methotrexate). Trimethoprim-sulfamethoxazole (co-trimoxazole) also appears to be of benefit in induction of remission [28]. Diffuse alveolar haemorrhage, due to extensive pulmonary capillaritis, is a life-threatening complication of Wegener's granulomatosis—it also occurs in microscopic polyangiitis, and more rarely in SLE, antiphospholipid syndrome, Behçet's disease and secondary to drugs such as D-penicillamine [29].

Churg–Strauss syndrome (allergic granulomatous angiitis) [26,27]. This rare condition comprises rhinitis, asthma, pneumonitis, fever, malaise, eosinophilia (usually over 10%) and widespread vasculitis, which may cause skin lesions, neuropathy and cardiac or less commonly renal disease. Cutaneous lesions include palpable purpura and nodular lesions. Distinction from Wegener's granulomatosis or microscopic polyangiitis may be difficult in the early stages—peripheral eosinophilia is the most useful discriminatory feature [30], but eosinophils in inflammatory infiltrates may occur in all three disorders (also in SLE and Sjögren's syndrome), as may mononeuritis multiplex. Cardiac disease is more frequent in Churg–Strauss syndrome than in Wegener's granulomatosis, but is not specific; a history of asthma and other allergies with the other features suggest Churg–Strauss syndrome [23,26]. There is some concern that leukotriene receptor antagonists may provoke Churg–Strauss syndrome in patients with asthma, although an alternative explanation is simply that disease progression or altered corticosteroid therapy allowed additional clinical features to become apparent [31,32]. Therapy consists of high-dose corticosteroids, if necessary with other immunosuppressive agents such as cyclophosphamide, azathioprine or chlorambucil.

PAN and microscopic polyangiitis (microscopic polyarteritis) [26]. These conditions are distinguished by the size of vessels affected and by the usual absence of antineutrophil cytoplasm antibodies against myeloperoxidase (MPO-ANCA) in 'classic' PAN. The term 'polyangiitis' is preferred to polyarteritis for the microscopic disease, as arterioles, venules and capillaries may all be affected. Lung disease is not a particular feature of classic PAN, although bronchial arteries can be affected. By contrast, microscopic polyangiitis has many similarities to Wegener's granulomatosis, including nasopharyngeal involvement, renal vasculitis and tendency to cause alveolar haemorrhage [26,29]. However, the presence of granulomas and proteinase 3-ANCA (which suggest the diagnosis of Wegener's granulomatosis) help to distinguish these disorders.

Neutrophilic dermatoses. Pulmonary and major airway involvement have been described with pyoderma gangrenosum and neutrophilic dermatoses [33–37], usually comprising focal, dense neutrophilic infiltrates with scattered radiological opacities. Tracheal lesions may occur. Endobronchial involvement may also occur in eosinophilic states such as the hypereosinophilic syndrome, although cardiac disease is more important in this condition.

Other systemic diseases

Sarcoidosis [38] is discussed in Chapter 58. Hilar lymphadenopathy occurs with erythema nodosum in acute sarcoidosis. Pulmonary involvement is the major feature in chronic sarcoidosis, about 30% of such patients also having skin lesions.

Multicentric reticulohistiocytosis is associated with pleural effusion and hilar lymphadenopathy [39]; it may also occur as a paraneoplastic phenomenon.

Scleromyxoedema has been associated with lung disease, causing dyspnoea, in a sixth of reported cases [40]. Pulmonary hypertension has been reported.

Amyloidosis (Chapter 57). Involvement of the respiratory tract is common in primary amyloidosis; it may cause dyspnoea, but is often asymptomatic.

Lymphomatoid granulomatosis [41,42] is a rare disease which primarily affects the lung; radiology shows multiple,

small nodules that predominantly affect the periphery of the lower lung fields. Cutaneous lesions are present in about 50% of cases, typically on the face, and consist of infiltrated flat or nodular lesions that may become necrotic and ulcerated. Histologically, there are necrotizing angiocentric lesions of various organs, with an infiltrate of atypical lymphocytes. Epstein–Barr virus infection has been demonstrated [43]. The condition behaves as a lymphoma with poor prognosis; corticosteroids and cyclophosphamide may help in some cases.

Miscellaneous

Yellow nail syndrome (MIM #153300). Associated respiratory features include recurrent pleural effusion, bronchiectasis and chronic infections such as empyema [44,45].

Hoarseness as a sign of systemic disease [46]. Hoarseness from laryngeal or tracheal involvement is an important audible sign of certain systemic diseases with skin involvement. Examples are pachyonychia congenita, de Lange's syndrome, Farber's disease, erythema multiforme, sarcoidosis, secondary syphilis, epidemic typhus, LE and dermatomyositis. Voice changes are of major diagnostic value for the recognition of lipoid proteinosis, pemphigus vulgaris, relapsing polychondritis and hypothyroidism. Carcinoma of the larynx may complicate some of these chronic conditions.

Haematology [1]

Anaemia. The mucocutaneous signs of iron-deficient or hypochromic anaemia—pallor, koilonychia (Fig. 59.12), brittle and ridged nails, angular cheilitis and atrophic glossitis—are recognized, but unreliable indicators of anaemia, especially compared with the ease of a blood-haemoglobin estimation. Pallor is usually only discernible if the haemoglobin level is below 9.0 g/dL, and this in turn is often dependent on temperature and skin blood flow. When anaemia is acute and extreme, retinal haemorrhages may be present [1].

Syndromes associated with gastrointestinal haemorrhage may point to iron deficiency and anaemia; perhaps hereditary haemorrhagic telangiectasia (Osler–Rendu–Weber disease, Chapter 50) and blue rubber-bleb naevus syndrome (Chapter 15) are the most noteworthy. Occasionally, iron deficiency is linked with generalized pruritus [2], but this association remains controversial.

There are no specific cutaneous markers of megaloblastic anaemias, but in pernicious anaemia (PA) the deep-red cobblestone appearance of the tongue is an archetypal, but late manifestation. A lemon tinge of jaundice due to excess production of unconjugated bilirubin subsequent to defective erythropoiesis is characteristic. Premature greying of the hair (canities) is a recognized occurrence, as is melanin pigmentation of the skin. Other autoimmune associations such as vitiligo, thyroid disorders and Addison's disease may occur, the latter sometimes producing its own pigmentary changes, especially in the skin creases and mucosal surfaces. Late onset of vitiligo may be of particular significance as an indicator of PA.

Fig. 59.12 Koilonychia. (Courtesy of Dr P. Dufton, Clatterbridge Hospital, Wirral, UK.)

Sickle cell anaemia may be suggested by the occurrence of leg ulcers, particularly when occurring at an early age. Unequal growth of the digits as a result of dactylitis in childhood may result in hand–foot syndrome [1]. Haemosiderosis and melanosis of the legs may also occur [3]. In dermatitis herpetiformis, anaemia is often due to dapsone-induced haemolysis [4], but malabsorption from gluten enteropathy may result in folate deficiency. This reduction in folate may also occur in extensive skin disease and occasionally causes a macrocytic anaemia. Anaemia not uncommonly occurs in patients with erythroderma [5], but this in part may be explained by a haemodilution effect. In dermatoses in which there is an increased turnover of skin, such as psoriasis, iron may be lost; this may be aggravated by a relative malabsorption of iron from a dermatogenic enteropathy [6]. However, defective handling rather than real deficiency may more often explain the hypoferraemia.

Leukocytosis is common with infection, but may frequently occur in erythroderma, without coexistent sepsis [5]. Leukocytosis also occurs in pustular psoriasis, pustular miliaria, erythema multiforme and as a result of corticosteroid therapy.

A neutrophil leukocytosis usually occurs in acute febrile neutrophilic dermatosis (Sweet's syndrome) (Chapter 49). Approximately 10–15% of published cases of Sweet's syndrome are associated with malignancy, the commonest being acute myeloid leukaemia; but correlation with other myelo- and lymphoproliferative disorders is well documented [7,8], including a small number of cases of non-Hodgkin lymphoma [9]. Both typical Sweet's syndrome and a variant termed disseminated pustular dermatosis have been described in polycythaemia rubra vera [10,11].

Several cases have been reported in which a polycyclic dermatosis, possibly representing an allergic reaction to exogenous factors, has been associated with a blood eosinophilia [12]. Sézary cell counts may be raised in an erythrodermic variant of mycosis fungoides (Sézary syndrome) or a pre-Sézary syndrome state, but may also occur in exfoliative erythroderma with a non-specific dermatitis as its aetiology [13].

Down's syndrome in infants is associated with increased risk of haematological abnormalities, including a vesiculopustular eruption with a myeloproliferative disorder that may be self-limiting. It is important to differentiate this and other benign or transient conditions from potentially life-threatening infections or conditions that may progress to leukaemia [14].

Platelets. Purpura may arise from intravascular, vascular or extravascular mechanisms (Chapter 48). Whilst decreased platelet formation as in Wiskott–Aldrich syndrome or

increased platelet consumption as in Kasabach–Merritt syndrome are obvious, intravascular causes of purpura, excessive platelet production or thrombocythaemia, as found in some myeloproliferative disorders, can also give rise to it [15]. Thrombocythaemia may also give rise to cutaneous manifestations, which are often present at the time of primary diagnosis in essential thrombocythaemia; these can include haematoma, bruising, purpura, erythromelalgia, livedo reticularis, recurrent superficial thrombophlebitis, ischaemic limbs and leg ulcers [16].

Disseminated intravascular coagulation (DIC) resulting from severe sepsis and giving rise to purpura fulminans is a more dramatic and fulminant presentation of thrombocytopenia than idiopathic thrombocytopenic purpura. Purpura fulminans can also represent a marker of protein C deficiency [17]. A diffuse angioma-like change has been rarely associated with chronic DIC, possibly as a result of vasculitis [18].

Vascular purpura (Chapters 48 and 49), with or without evidence of vasculitis, is probably the largest group causing purpura. This includes hypersensitivity vasculitis, of which Henoch–Schönlein purpura is the best recognized cause of palpable purpura. Cases of mixed cryoglobulinaemia often develop palpable purpura on the lower limbs and can also exhibit livedo reticularis, cold-induced urticaria and frank ulceration or gangrene. Purpuric vasculitis can also be found in most of the connective tissue diseases, urticarial vasculitis and occasionally with malignancy. More rarely, purpura can occur with larger vessel necrotizing vasculitis, including PAN, giant cell arteritis and granulomatous vasculitis. Urticaria, livedo and necrotic ulceration are also cutaneous manifestations of these large-vessel vasculitides.

Between the inflammatory and non-inflammatory purpuras are the pigmented purpuric eruptions, in which the inflammatory changes are much less severe. The non-inflammatory causes include plasma cell dyscrasias, amyloidosis and embolic phenomenon with cholesterol or fat [15].

Livedo and erythromelalgia may be causally linked with thrombocythaemia and PRV. Classically, the latter may present with pruritus, especially on cooling of the skin, often after bathing, although iron deficiency may be a co-factor [19].

Antiphospholipid syndrome. Cutaneous manifestations may occur with antiphospholipid syndrome, including livedo reticularis with or without cerebrovascular disease, leg ulcers, necrotizing purpura, distal cutaneous ischaemia, peripheral gangrene, thrombophlebitis and haemorrhage [20]. An examination for antiphospholipid antibodies may be worthwhile in all patients with thrombotic cutaneous signs [20].

Haemorrhagic cellulitis, a syndrome presenting with painful erythema, followed by dermal haemorrhage, sloughing of overlying epidermis, associated with a non-cutaneous Gram-positive or -negative infection and underlying systemic disease, has been linked with the presence of tumour necrosis factor-α [21].

ESR is non-specifically raised in many inflammatory dermatoses, particularly erythroderma, when it is often associated with a raised gammaglobulin [5].

Lymphoma. After the gastrointestinal tract, the skin is the extralymphatic organ most frequently affected by malignant lymphomas. Most are cutaneous T-cell lymphomas, which are dealt with elsewhere (Chapter 54), but cutaneous involvement with B-cell tumours is not that uncommon and may represent up to one-third of such primary neoplasms [22]. Specific skin involvement in Hodgkin's disease is rare, but does occur in around 0.5% of cases [23]. Approximately 50% of patients with lymphomatoid granulomatosis have cutaneous involvement, mostly scattered nodules, but other changes include eroded and crusted lesions, facial oedema, papules and a folliculitis-like eruption [24].

Leukaemia. Specific cutaneous leukaemic infiltrates can occur in all types of leukaemia, but are more common in monocytic forms [25,26]. Very rarely, a long latent period can occur from cutaneous presentation to clinical illness [27]. Urticaria is documented as being an uncommon manifestation of acute basophilic leukaemia [28]. A pemphigus foliaceus-like dermatosis has been described in chronic lymphocytic leukaemia [29]. Paraneoplastic pemphigus in association with chronic B-cell lymphocytic leukaemia has been reported, and its more aggressive clinical behaviour was noted by comparison with the less aggressive course associated with neoplasms such as thymomas and Castleman's disease [30]. The leukaemias are discussed in more detail elsewhere (Chapter 54).

Pyoderma gangrenosum (PG) (Chapter 49) is perhaps a better-known cutaneous presentation of myeloproliferative diseases, including leukaemias [31]. PG and subcorneal pustular dermatosis may be associated with paraproteinaemia with or without multiple myeloma [32]. PG can occur in allogeneic bone marrow transplant recipients [33], but is more commonly a manifestation of inflammatory bowel disease and rheumatoid arthritis.

Disseminated cutaneous granulomatous eruptions have been reported with myelodysplastic syndrome and acute myeloid leukaemia [34].

Miscellaneous. Blood dyscrasias are common in dyskeratosis congenita (DC) (Chapter 12) and in Fanconi's anaemia

(FA). In the latter, olive-brown skin pigmentation is a common finding. Both DC and FA represent familial forms of aplastic anaemia [35]. DC is a rare multisystem disease with a whorled hyperpigmentation of the skin, in which there is an 80% incidence of bone marrow failure; pulmonary manifestations have infrequently been reported, and immune dysfunction and consequent infection contribute to the morbidity and mortality of the disorder. The X-linked form of DC has been identified on Xq28 and designated as *DKC1* [36]. RTS (Chapter 12), a rare autosomal-recessive condition caused by a DNA repair defect, has been associated with myelodysplasia. Early onset of skin changes of poikiloderma, photosensitivity, scaling, hyperkeratosis and disordered hair growth are characteristic together with ocular and skeletal abnormalities [37].

Raynaud's phenomenon, scleroderma and oedema are features of the plasma cell dyscrasia found in the POEMS syndrome [38,39]. This multisystem disease is characterized by the presence of polyneuropathy, organomegaly, various endocrine disorders and the aforementioned skin changes; these features are thought to be secondary to the plasma cell dyscrasia and in most cases the production of IgM [40]. Thrombocytosis has been noted in many cases, less commonly polycythaemia [40]. The differentiation of POEMS from osteosclerotic myeloma with peripheral neuropathy does not appear to serve any clinical function [41]. Skin angiomas have been reported in many of the cases and a patient with angio-endotheliomatosis associated with Castleman's lymphoma and POEMS syndrome has been reported [39].

Bullous pemphigoid has also been reported, as well as the more commonly associated paraneoplastic pemphigus in Castleman disease [42].

Erythematous papules, nodules and urticarial weals may develop in the hypereosinophilic syndrome [43]; pruritus is a frequent finding [44]. Eosinophilic pustular folliculitis, apart from an association with human immunodeficiency syndrome, has haematological associations with myelodysplastic syndrome, bone marrow transplantation, leukaemia and lymphoma [45].

A papulonodular, pruritic, therapeutically resistant eruption occurring in patients with blood dyscrasias has been termed the eosinophilic dermatosis of myeloproliferative disease [46].

Concurrent polycythaemia and mastocytosis have been reported [47]. Cold agglutinins may manifest with Raynaud's syndrome, acrocyanosis or gangrene. Cold haemolysins may give rise to cold urticaria or Raynaud's syndrome.

Rarely, cutaneous extramedullary haemopoiesis may develop in myelofibrosis [48]; multicentric reticulohistiocytosis may also occur with this disorder [49]. PG in PRV may herald deterioration to myelofibrosis or myeloid leukaemia [50].

The histiocytic syndromes represent a rare group of disorders resulting from proliferation of the monocyte–macrophage cell line (Chapter 52). They can be divided into self-healing (non-X) or progressive (X) types. The histiocytosis X group includes Letterer–Siwe disease, in which cutaneous changes can take on a seborrhoeic dermatitis-like or purpuric appearance, although semi-translucent red-yellow papules are more typical skin changes. Hepatosplenomegaly is common, but lymphadenopathy is a rarer manifestation. Eosinophilic granuloma rarely shows cutaneous manifestations, and only about one-third of cases of Hand–Schüller–Christian disease do. Non-histiocytoses include self-healing reticulohistiocytosis, benign cephalic histiocytosis, sinus histiocytosis with massive lymphadenopathy and multicentric reticulohistiocytosis, amongst others [51].

Scleromyxoedema is associated with a paraproteinaemia, almost always IgG [52].

Scleroedema of Buschke may be associated with multiple myeloma as well as benign monoclonal gammopathies [53].

Necrobiotic xanthogranuloma is usually associated with paraproteinaemia [54], but not invariably [55].

Occasionally, von Willebrand's disease may show albinism; in the Hermansky–Pudlak syndrome, oculocutaneous albinism is associated with platelet dysfunction, as it is a similar disorder with the additional feature of pulmonary fibrosis [56,57].

Bone and joint diseases

There are several diseases in which bone or joint abnormalities occur together with skin changes (Tables 59.9 and 59.10) [1,2]. In some instances, as occurs in several inflammatory diseases, these may be symptomatic; in other conditions they may be asymptomatic but demonstrated radiologically. For example, more than half of adults with *mastocytosis* may have diffuse bone disease detected radiologically [3], and the osteopoikilosis of *Buschke–Ollendorf syndrome* (Fig. 59.13) is asymptomatic and usually only demonstrated as an incidental finding or if the patient presents due to cutaneous elastomas. Bony changes may be an important factor in diagnosis in several *genodermatoses* [4,5] and *congenital lesions* (especially midline lesions, such as faun tail and facial or scalp nodules and pits) [6,7]. The genetic and metabolic basis for some of these are now well understood—for example, the role of G proteins in *McCune–Albright syndrome* [5].

Soft-tissue calcification, and less commonly ossification, occurs in numerous disorders [8]. It is particularly prominent in *childhood dermatomyositis* and is discussed in more detail in Chapter 56. *Progressive systemic sclerosis* and *CREST* (Chapter 56) are characterized by atrophy and dystrophic calcifications in the soft tissues, ultimately leading to joint deformities and resorption of the terminal tufts of the phalanges. Resorption of bone occurs at other sites as well, and marginal erosions may develop in the metacarpophalangeal and interphalangeal joints of the hands [9].

Table 59.9 Skin disorders that are commonly associated with bony abnormalities.

Disorder	Skin lesions	Bony change
Congenital/inherited		
Ectodermal dysplasias and keratodermas	Various	Chapter 34
Conradi–Hunermann syndrome	Chapter 34	Chondrodysplasia punctata
Neurofibromatosis	Neurofibromas, café-au-lait patches	Kyphoscoliosis, vertebral erosions, partial absence of sphenoid bone, cystic lesions, pseudarthroses
Tuberous sclerosis	Angiofibromas, ash leaf macules, collagenomas	Intracerebral calcification, bony sclerosis (especially skull), cortical thickening, bone cysts (especially phalanges)
Klippel–Trenaunay syndrome	Port-wine stains, other vascular lesions, lymphangioma	Bony hypertrophy, macrocephaly, polydactyly/syndactyly
Proteus syndrome	Soft-tissue overgrowth, epidermal naevi	Partial gigantism (usually hand/foot), scoliosis and vertebral abnormalities, exostoses, osteochondromas
Maffucci's syndrome	Haemangiomas, lymphangiomas	Enchondromas (especially hands), chondrosarcoma
Sturge–Weber syndrome	Port-wine stain	Calcification of meningeal vessels, hemiatrophy
Gorham's syndrome (osteovascular dysplasia)	Vascular malformations	Lytic lesions, 'disappearing bones'—usually unilateral
Gardner's syndrome	Cysts, lipomas, fibromas	Osteomas, exostoses
Ehlers–Danlos syndrome	Skin laxity, atrophic scars, molluscoid pseudotumours	Kyphoscoliosis (especially type IV), abnormalities of long bones, short clavicles, occipital exostoses (all in type IX)
Osteogenesis imperfecta	Atrophic skin	Brittle bones, otosclerosis
Marfan syndrome	Arachnodactyly	Increased limb length, arachnodactyly, chest deformities, joint laxity
Focal dermal hypoplasia (Goltz's syndrome)	Dermal atrophy, telangiectasia, fatty herniation	Syndactyly, scoliosis, skeletal asymmetry, osteopathia striata, bony tumours, dental abnormalities
Rothmund–Thomson syndrome	Poikiloderma	Hypoplasia of thumbs or forearm bones, dental abnormalities, osteosarcoma
Linear naevus sebaceus syndrome	Sebaceous naevi (often facial or widespread)	Asymmetry (especially skull), spinal abnormalities, hypophosphataemic rickets
Linear epidermal naevus syndrome	Epidermal naevi	Asymmetry, kyphoscoliosis, bone cysts, equinovarus deformity
Incontinentia pigmenti	Atrophic streaks, fatty herniations	Dental abnormalities (conical teeth), spina bifida occulta, skeletal asymmetry, vertebral/rib abnormalities, phalangeal lytic lesions
Hypomelanosis of Ito	Pale, whorled streaks	Kyphoscoliosis, spina bifida occulta, skeletal asymmetry, various digital anomalies
Buschke–Ollendorf syndrome	Elastomas	Osteopoikilosis
McCune–Albright syndrome	Pigmented macules	Fibrous dysplasia, asymmetry, scoliosis, sclerosis of base of skull, fractures, rickets, osteomas
Lipoid proteinosis	Confluent waxy papules, alopecia	Intracranial calcification
Disseminated lipogranulomatosis	Nodules on digits	Destructive arthropathy
Pseudoxanthoma elasticum	'Plucked chicken' appearance of neck, flexures	Calcification of soft tissues, falx cerebri, dura, choroid plexus
Nail–patella syndrome	Hypoplastic nails	Absent or small patellae, iliac horns, scoliosis, hypoplasia of first rib, absent fibulae
Fabry's disease	Angiokeratomas	Necrosis of femoral head, arthritis of distal interphalangeal joints
Werner's syndrome	Premature ageing	Osteoporosis, sclerodactyly, joint contractures, sarcomas
Progeria	Aged appearance	Skeletal dysplasia, osteolysis, osteoporosis, dislocation or avascular necrosis of hip, non-union of fractures
Gaucher disease	Pigmentation	Bone pain, fractures, cortical destruction
Naevus of Ota	Facial naevus	Posterior cranial fossa defects
Midline lesions	Various, includes scalp nodules/cysts, nasal gliomas, pits and sinuses, faun tail	Various; connections between skin and CNS may be associated with bony defects, e.g. spina bifida

(*continued*)

Table 59.9 (*cont'd*)

Disorder	Skin lesions	Bony change
Infection		
Local		
Dental sinus	Localized nodule, may discharge	Usually periapical abscess, may be retained root, cyst
Chronic ulcer	Skin ulcer	Underlying osteomyelitis
Systemic		
Syphilis	Various; see Chapter 30	Periostitis, osteitis, focal osteolysis or sclerosis
Cryptococcosis	Skin nodules	Osteolytic lesions
Blastomycosis	Skin nodules	Osteomyelitis
Inflammatory and systemic diseases		
Psoriasis and Reiter's syndrome	See Chapter 35	Erosive arthritis, sacroiliitis
Palmoplantar pustulosis	Palm and sole pustules	See text (this section)
Sarcoidosis	See Chapter 58	Honeycomb change and bone cysts (especially hands), acrosclerosis
Scleroderma	See Chapter 56	Resorption of terminal phalanges (acronecrosis), soft-tissue calcification, erosive arthritis Linear scleroderma may show underlying linear hyperostosis Acro-osteolysis is typical of vinyl chloride disease
Scleromyxoedema	Mucinosis	Arthralgia, carpal tunnel syndrome, acro-osteolysis
Acne fulminans/conglobata	See Chapter 43	Lytic lesions, especially clavicles; clavicular hyperostosis
Neutrophilic dermatoses	See Chapter 49	Periosteal reaction adjacent to pyoderma gangrenosum, osteomyelitis-like lesions (chronic recurrent multifocal osteomyelitis)
Gout	Tophi	Erosive arthritis
Multicentric reticulohistiocytosis	Skin and subcutaneous nodules	Destructive polyarthritis, especially terminal interphalangeal joints (similar to rheumatoid disease), atlantoaxial disease
POEMS syndrome	Pigmentation, sclerosis, hypertrichosis	Sclerotic lesions, may have central lucency
Neoplastic		
Naevoid basal cell carcinoma syndrome (Gorlin's syndrome)	Basal cell carcinomas	Cysts of jaw and other bones, frontal bossing, calcification of falx cerebri, bifid ribs, spina bifida and other spinal abnormalities, polydactyly/syndactyly, shortened metacarpals
Histiocytoses (Langerhans' cell histiocytosis, Rosai-Dorfman disease, Erdheim–Chester disease, juvenile xanthogranuloma, others)	See Chapter 52	Lytic lesions, defects of skull and mandible, vertebral lesions
Mastocytosis	See Chapter 47	Diffuse or focal osteoporosis or sclerosis
Fibromatoses	See Chapter 53	Various; most characteristic are cystic lesions of skull and long bones in infantile myofibromatosis
Other		
Subungual exostosis	Hard subungual nodule	Underlying exostosis
Osteoma cutis	Hard plaque(s)	Focal bone formation, possibly primary or within a preceding lesion
Becker's naevus	Pigmented hairy lesion	Scoliosis, spina bifida
Thyroid acropachy	Finger clubbing	Expanded distal phalangeal tuft
Acromegaly	See p. 59.2	Increased periosteal bone growth
Fat embolism	Petechial rash on anterior trunk	Causative fracture(s)

POEMS, polyneuropathy, organomegaly, endocrinopathy, M protein, skin changes (syndrome).

Table 59.10 Some inflammatory and metabolic disorders that affect skin and joints.

Psoriasis, Reiter's syndrome, palmoplantar pustulosis
Connective tissue diseases
Lupus erythematosus (especially systemic and subacute cutaneous)
Mixed connective tissue disease
Sclerodermas
Still's disease
Rheumatic fever
Rheumatoid disease
Gout
Behçet's disease and related disorders
Sarcoidosis
Interstitial granulomatous dermatitis with plaques and cords
Vasculitis (any; see Chapter 49)
Neutrophilic dermatoses
Bowel-associated dermatosis–arthritis syndrome
Acne fulminans and conglobata
Relapsing polychondritis
Periodic fevers, e.g. familial Mediterranean fever
Whipple's disease
Pancreatic panniculitis
Amyloidosis
Multicentric reticulohistiocytosis
Scleromyxoedema, cardiac myxoma
Ochronosis
Acromegaly
Fabry's disease

Fig. 59.13 Osteopoikilosis in Buschke–Ollendorf syndrome (Courtesy of Dr C. Blasdale, Newcastle upon Tyne, UK.)

Skin lesions may also occur as a consequence of bone injury. *Fat embolism*, particularly with fractures of the long bones, may present cutaneously with petechiae, usually 2 or 3 days after trauma; other symptoms may include respiratory distress and cerebral impairment. The intensity of the petechiae may indicate the severity of other organ involvement. Fat globules may be observed histologically in affected tissue, including the skin, when suitably processed. The distribution of skin petechiae is principally on the anterior trunk; they are seldom found on the back or face [10].

Inflammatory conditions

Arthralgia and/or arthritis is frequent in a number of inflammatory and metabolic conditions which also affect the skin, such as psoriasis and sarcoidosis (Table 59.10). Most of these are discussed in more detail elsewhere, but some of the multisystem disorders are briefly described here.

Vasculitides and connective tissue disease. These are discussed in Chapters 49 and 56. Arthralgia or arthritis is a common feature of many disorders in this spectrum, occurring for example in about 90% of patients with systemic lupus erythematosus, two-thirds of those with Henoch–Schönlein purpura and about 40% of those with Behçet's disease.

Relapsing polychondritis (Chapter 65). Migratory arthritis of small and large joints, usually sparing the hands, is a frequent feature [11]. It probably occurs in about two-thirds of patients. Chondritis affecting spinal vertebra may cause chronic back pain.

Multicentric reticulohistiocytosis (Chapter 52). Polyarthritis, especially affecting the interphalangeal joints of the hands, occurs as the first manifestation of the disorder in half to two-thirds of patients. It is typically rapidly progressive, and all of the synovium-lined joints may become affected, with arthritis mutilans the end result in one-third to half of cases. The erosions are strikingly symmetrical and well circumscribed, and accompanying osteoporosis is disproportionately mild. The arthritis may burn out, but residual hypertrophic osteoarthropathy may persist [9,12]. A disorder reported as familial histiocytic dermatoarthritis [13] has been described in which there is early onset of a papulonodular eruption, a symmetrical destructive arthritis and ocular lesions such as cataract and glaucoma. Subsequent cases and electron microscopy studies [14] suggest that this may be part of the spectrum of multicentric reticulohistiocytosis, but this remains uncertain.

Palmoplantar pustulosis (Chapter 35). A group of overlapping joint diseases occur in conjunction with palmoplantar pustulosis, and less frequently with psoriasis, acne and non-dermatological conditions such as inflammatory bowel disease. The various patterns have been brought together under the acronym SAPHO (*s*ynovitis, *a*cne, *p*ustulosis, *h*yperostosis and *o*steitis). Individual components include predominant sternoclavicular disease (variously termed intersternocostoclavicular osteitis, sternoclavicular pustulotic osteitis, sternocostoclavicular hyperostosis, pustulotic arthro-osteitis or anterior chest wall syndrome, Fig. 59.14) and a more widespread non-purulent chronic recurrent multifocal osteomyelitis [15–17]. Diagnostically, scintigraphy is more sensitive than radiographic

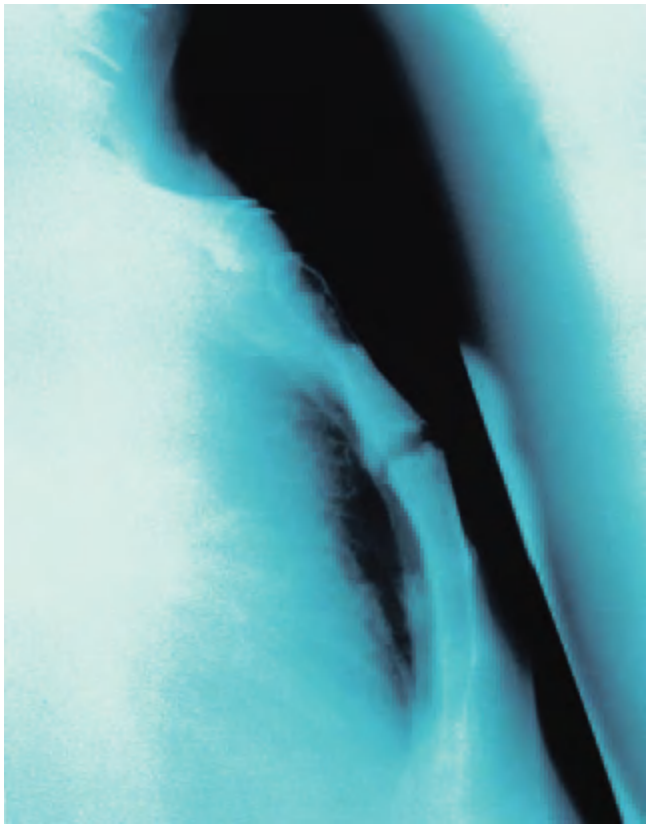

Fig. 59.14 Tomogram showing inflammatory changes of the sternal synchondrosis with widening and 'woolly' appearance in a patient with palmoplantar pustulosis.

examination. Therapeutic options include non-steroidal anti-inflammatory drugs, doxycycline, methotrexate and intra-articular corticosteroid injections.

Acne. In addition to the SAPHO pattern described above, arthritis of larger joints occurs in about a third of patients with acne fulminans—most have arthralgia. This is associated with fever, systemic malaise and weight loss, and can usually be controlled with short-term oral corticosteroids. Other skeletal manifestations linked to acne are those secondary to therapeutic agents (skeletal hyperostosis due to isotretinoin, usually only if given long term, and arthralgia in the lupus-like syndrome caused by minocycline); infectious arthritis due to *Propionibacterium acnes* may also occur [18].

Periodic fevers. The most important are familial Mediterranean fever (FMF; MIM *249100), FMF with amyloidosis (MIM *134610), Hibernian fever—now redesignated as *t*umour necrosis factor (TNF) *r*eceptor–*a*ssociated *p*eriodic *s*yndrome, TRAPS, MIM #142680—and the hyperimmunoglobulin D and periodic fever syndrome (HIDS; MIM #260920). All are characterized by recurrent fever with serositis (peritonitis-like abdominal pain, pleurisy, pericarditis), headache and arthralgia or arthritis [19–23]. In FMF, there may be urticarial lesions, subcutaneous nodules, purpura, leukocytoclastic vasculitis (described, probably incorrectly, as Henoch–Schönlein purpura), or transient cellulitis-like erythematous plaques [19–22]. Like the articular symptoms [22], the erysipelas-like lesions are predominantly on the lower leg [20]. Erythematous macules and nodules, but not the erysipelas-like lesions, may occur in HIDS [19]. In TRAPS, the cutaneous features include migratory patches, oedematous plaques and periorbital oedema [23]. FMF is due to a variety of mutations in the *MEFV* gene [24]; classic-type HIDS is due to mutations in the *MVK* gene leading to deficient activity of mevalonate kinase [25,26]; and TRAPS is due to mutations in *TNFRSF1A,* which codes for the 55-kDa TNF receptor [23].

Neutrophilic dermatoses. This group of disorders is discussed in relation to gastrointestinal and haematological disease in this chapter, and in more detail in Chapter 49. Sweet's syndrome may be associated with arthralgia, with a frequency of around one-third to over 60% in some series [27,28]. Multifocal osteomyelitis (usually in children), which may be chronic or recurrent, or localized osteitis may occur in association with PG [29,30].

Interstitial granulomatous dermatitis. This histological pattern may occur in many situations including infections (such as borreliosis or hepatitis C infection), lymphoreticular malignancies, drug eruptions and autoimmune disease. Various skin lesions have been described in *palisading neutrophilic and granulomatous dermatitis (PNGD) of immune complex disease,* including papulonodules, urticaria, vasculitis and granuloma annulare-like lesions. Arthralgia may occur due to systemic vasculitis, and PNGD may occur in rheumatoid arthritis [31]. There are also several reports of a related disorder in which arthritis occurs together with cutaneous lesions that may be plaques or subcutaneous cords, which are linear or arciform and typically on the trunk or proximal limbs; this disorder is usually termed *interstitial granulomatous dermatitis with plaques* [32,33].

Metabolic conditions

Gout may present to dermatologists due to tophi, but is generally diagnosed due to acute arthropathy or chronic erosive joint disease. Recent developments from the rheumatological perspective are use of CT or MRI to detect tophi within the carpal tunnel, and a suggestion that ciclosporin in patients with renal transplant may predispose to gout. Intermittent excessive alcohol consumption remains the major aetiological factor [34].

Haemochromatosis. Arthropathy is a frequent complication, probably due to abnormal accumulation of metal ions [35,36]; other aspects are discussed elsewhere in this chapter.

Ochronosis is discussed in Chapter 65. Calcium crystal deposition accompanies the cartilage degradation characteristic of this disease [36].

Amyloidosis (Chapter 57) is closely linked to joint disease, as rheumatoid arthritis is the commonest cause of secondary amyloidosis [37]. Amyloid A has cytokine-like properties and may be actively involved in inflammatory processes.

Scleromyxoedema causes arthralgia or arthritis in 10% of patients, and is also associated with rheumatoid arthritis and sicca syndrome. Carpal tunnel syndrome and acroosteolysis may also occur [38].

Other metabolic disorders that may have skin and bony or joint symptoms include Fabry's disease, Gaucher's disease and Farber's disease [36]. Bone symptoms are an important part of *Gaucher's disease* [36,39]. Bone crises may be related in part to haemorrhage; they may be treated with prednisolone, bisphosphonates or with prophylactic enzyme replacement therapy. Avascular necrosis, pathological fractures and cortical destruction of bones with extraosseous extension also occur.

Infections

Numerous infective conditions may affect both the skin and joints. Arthralgia is associated with the exanthem of viral infections such as parvovirus, hepatitis B or rubella. *Reiter's syndrome* may be provoked by genital infections such as *Chlamydia*, or by various enteritic organisms such as *Yersinia*, *Shigella* or *Campylobacter*. Arthralgia is frequent, with constitutional symptoms and a non-specific exanthem, in brucellosis. Other bacterial causes of arthritis with pustular or vasculitis skin lesions include disseminated *gonococcal infection* and *chronic meningococcal septicaemia*. Arthralgia may be prominent in spirochaetal diseases such as *Lyme disease* or *secondary syphilis*. In the latter, the flat bones of the skull are frequently involved, causing headache. Osteomyelitis is a feature of tertiary syphilis. Arthralgia is the presenting feature in two-thirds of patients in the early stage of *Whipple's disease* [40,41].

Annular and figurate reactive erythemas

Numerous dermatoses produce annular lesions, many of which occur in conjunction with other lesional morphology (for example, in psoriasis) or lead to a specific diagnosis (for example, tinea corporis or granuloma annulare). However, there are a group of often chronic, annular and figurate eruptions that do not easily lead to a specific diagnosis. This group, and some of the important differential diagnoses, may have systemic causes and may pose diagnostic and therapeutic problems. The nomenclature of this group of disorders has been discussed in detail elsewhere [1] but most of the descriptive and eponymous terms that are applied do not help greatly in management of the patient. Equally, although the pathological features can be divided into those cases with superficial or deep perivascular lymphohistiocytic infiltrate ('superficial or deep gyrate erythema' [2], clinically corresponding to annular erythema with scaling or with smooth surface respectively), the clinical relevance of this is not clear.

For the purposes of this section, the following will be discussed:

1 erythema (chronicum) migrans
2 erythema marginatum (rheumaticum)
3 erythema gyratum repens
4 erythema annulare centrifugum
5 annular erythema of infancy
6 annular erythema associated with extractable nuclear antigens.

Erythema migrans (Chapter 27)

SYN. ERYTHEMA CHRONICUM MIGRANS

Erythema migrans is the term applied to skin lesions of Lyme borreliosis. It is caused by infection with *Borrelia burgdorferi sensu lato*, *B. afzelli* or *B. garinii*, which are spirochaetes transmitted by bites from *Ixodes* ticks [1]. The primary lesion of erythema migrans at the site of a tick bite is usually solitary and usually macular but may be urticated or haemorrhagic (lesions of *B. burgdorferi* are usually more inflammatory and more rapid in evolution than those caused by the other species). Malaise, flu-like symptoms and lymphadenopathy are common at this stage. The lesion expands slowly over a period of weeks to a median size of about 15 cm with central clearing (the early-localized stage) [2–6]. The term 'chronicum' is something of a misnomer. In the early disseminated stage, which occurs within a few weeks, multiple similar annular plaques may develop in up to half of patients and may be multiple. These may have a polycyclic pattern that resembles erythema annulare centrifugum or an annular erythema multiforme-like appearance.

Histology shows a deep and superficial perivascular lymphocytic infiltrate, which may contain plasma cells.

Treatment is usually with tetracyclines (generally doxycycline 100 mg b.d. for 2–3 weeks) or ampicillin; third-generation cephalosporins are the alternative. Vaccination is also now available.

Other skin lesions that may occur include nodular lymphocytomas (early disseminated stage) and acrodermatitis chronica atrophicans (late stage). Associated systemic manifestations include arthralgia and arthritis, myalgia, cardiac involvement (especially atrioventricular block or pericarditis) and a variety of neurological manifestations (cranial nerve palsies, peripheral neuropathy, meningitis, encephalitis).

Erythema marginatum (rheumaticum)

SYN. ERYTHEMA ANNULARE RHEUMATICUM

Rashes of various morphologies can occur in rheumatic fever and Still's disease, erythema marginatum being the most classical and distinctive, but now rare, pattern. Along with carditis, migratory polyarthritis, chorea and

subcutaneous nodules, it is one of the Duckett Jones major criteria for the diagnosis of rheumatic fever, and is probably specific for this diagnosis (two major, or one major and two minor, criteria are strictly required for the diagnosis but newer echocardiography techniques and Doppler colour flow mapping may extend the diagnostic criteria). However, erythema marginatum may be subtle, and only occurs in about 10% of patients (especially in children) with active rheumatic fever [1–3]; one study of 126 children (80 first attacks and 46 recurrences) did not identify any with erythema marginatum [4].

The eruption consists of rings or segments of rings, pale or dull red in colour, flat or palpably thickened. The rings may be discrete, or may enlarge and merge to produce a polycyclic or reticular pattern.

Characteristically, the lesions fade in a few hours or at most in 2–3 days, and tend to be more prominent in the afternoon. Recurrent crops, often in different sites, may appear at intervals for many weeks. The lesions occur most frequently on the trunk, especially on the abdomen, but are occasionally seen on the limbs. They are asymptomatic.

Histologically, an infiltrate of polymorphs can help to distinguish this disease from other annular erythemas [5], but is not always found.

A similar eruption has been reported with psittacosis [6], and erythema marginatum has been reported preceding attacks of hereditary angioneurotic oedema [7,8].

Erythema gyratum repens

The first description of this condition in 1953 is attributed to Gammel, who reported a case associated with breast carcinoma [1]. It is exceptionally rare but clinically distinctive (Fig. 59.7) [2–5].

Clinical features [2,4,6,7]. Regular waves of erythema spread over the body to produce a series of concentric figurate bands in a pattern resembling the grain of wood. The characteristic feature is the way rings, swirls or waves appear within existing lesions to form a concentric pattern of sequential eruptions, with day-to-day migration of the leading edge by about 1 cm. Scaling, usually at the trailing edge, and itch are usually prominent. This is by contrast to the more common 'annular erythemas' of erythema annulare centrifugum pattern, in which each lesion is usually a distinct ring or arc with variable but usually not prominent scale, and no concentric arrangement. Hyperkeratosis of palms occurs in about 10% and has been reported in both paraneoplastic and idiopathic cases.

Aetiology. This eruption has been briefly discussed earlier (p. 59.20) as a paraneoplastic eruption; about 80% of reported cases are associated with an internal tumour [4,6–8], most commonly of the lung. Other tumour sites include bowel, urogenital tract, pancreas and haematological neoplasia.

However, not all cases are paraneoplastic. Since the report of a case associated with tuberculosis [9], several cases have been reported in apparently well patients or associated with other disorders such as CREST syndrome (reviewed in [4,6]). Drug hypersensitivity has also been implicated. Some of these non-paraneoplastic cases are questionable in the absence of photographic documentation, but some cases appear very convincing, such as a patient with recurrent pregnancy-associated episodes [10]. An infant was reported in whom lesions were controlled by long-term systemic ketoconazole [11].

Pathology [12]. There is a superficial, and occasionally deep, perivascular lymphocytic infiltrate associated with acanthosis, spongiosis and parakeratosis. Deposition of C3 or IgG in the sub-lamina densa region supports the concept that the eruption is immunologically mediated, possibly by immune complex deposition [5,13].

Investigation. Biopsy should be performed to exclude other causes such as unusual morphologies of vasculitis. Fungal infection should be excluded, especially tinea imbricata in relevant populations. The paramount issue is a detailed search for underlying malignancy. Skin biopsy is important as a similar gyrate eruption may be a prodromal manifestation of pemphigoid [14], and similar but rather localized lesions have been reported due to vasculitis in lupus erythematosus [15]; a morphologically similar disorder termed lupus erythematosus gyratus repens has been reported [16]. Necrolytic migratory erythema (p. 59.45) and erythrokeratoderma variabilis (Chapter 34) may produce very similar lesions, as may the subacute annular (Lapière) variant of psoriasis, although none of these typically have multiple concentric lesions. Cases of apparent idiopathic erythema gyratum repens have also been suggested to represent a stage in the evolution of pityriasis rubra pilaris [17,18].

Erythema annulare centrifugum (EAC)

This term was originally used by Darier [1], who delineated EAC from a more scaly and itchy eruption described earlier by Colcott Fox as erythema gyratum perstans. The term EAC is conveniently applied to the annular erythemas that do not obviously fall into one of the more specific categories discussed previously, although EAC probably constitutes a mixed group of disorders with similar histological features. Annular erythema of infancy is discussed separately, as it can be defined by the age group, and annular erythemas associated with anti-SSA (anti-Ro) and anti-SSB (anti-La) antibodies can now be separated and discussed as a group.

Clinical features. EAC has been reviewed by several authors [2–6]. It is commonest in young and middle-aged adults, although onset may occur in infancy (discussed separately below). Some authors suggest a female preponderance [5]. A small, pink, infiltrated papule slowly enlarges and forms a ring, as the central area flattens and fades (Fig. 59.15). The rate of extension is variable; although a diameter of 6–8 cm may be achieved in less than 2 weeks, extension is usually much slower (typically 2–3 mm/day), especially in the cases with epidermal involvement. Extension may be irregular, to leave arciform segments. Lesions may be solitary or, more often, multiple. The edge may be quite flat or easily palpable with a superficial cord-like quality, and lesions may be smooth or show slight scaling behind the advancing edge. Rarely, vesiculation occurs. Itching is variable, but seldom intense. The commonest sites are the buttocks, thighs and upper arms, but any areas may be involved. Sometimes lesions are mainly on the extremities, but the face is seldom affected.

Fig. 59.15 Erythema annulare centrifugum; an expanding lesion with central clearing and scaling at the 'trailing edge'. This case was seasonally recurrent.

Individual lesions last for a few days, more often a few weeks, or slowly extend for a few months. Further lesions usually occur, and the disease is usually chronic with periodic fluctuations over many years. Purpura and pigmentation may rarely occur within the lesions [7].

Pathology. The characteristic feature in EAC is a perivascular 'sleeve-like' lymphohistiocytic infiltrate, referred to as a 'gyrate erythema', which may be mainly superficial, mainly deep, or mixed. The pathological changes may be entirely within the dermis, whereas in other cases there is much more obvious epidermal change (spongiosis and parakeratosis) [8,9]. There is dispute about whether these represent two separate diseases or a continuous range. Eosinophils may occasionally be seen around superficial vessels. Significant peripheral eosinophilia raises the possibility of parasitic infection as the underlying cause.

A very rare eruption that has clinical features of EAC but with a frankly eosinophilic infiltrate has been described under the name 'eosinophilic annular erythema' [10,11].

Aetiology. A broad range of associations have been described as causes of EAC (Table 59.11) [12–26]; some 'associations' that have been described may be coincid-

Table 59.11 Possible causes and associations of erythema annulare centrifugum.

Category	Examples
Idiopathic	Including annually recurrent forms [12]
Familial	Dominant inheritance [13], twins [14]
Infantile onset	(see p. 59.74)
Fungi	Cutaneous tinea [5], intestinal *Candida* [15,16], ingested fungi (cheese) [15]
Other infections [2–6]	Molluscum contagiosum , Epstein–Barr virus, genital herpes, Q fever, recurrent appendicitis, *E. coli* urinary tract infection, tuberculosis, *Ascaris* infection, trypanosomiasis
Drugs [2–6]	Aldactone, amitryptiline, ampicillin, cimetidine, etizolam, granulocyte colony-stimulating factor, gold, hydrochlorthiazide, hydroxychloroquine, penicillin, piroxicam, salicylates, thiacetazone, vitamin K
Endocrine	Hyperthyroidism [17], Hashimoto's thyroiditis, autoimmune progesterone dermatitis, polyglandular autoimmune syndrome type I (the latter possibly mediated by *Candida* infection)
Haematological disorders	Lymphomas (various) [4,5,18,19], leukaemias [20], thrombocythaemia [21], polycythaemia rubra vera, myelodysplastic syndrome, hypereosinophilic syndrome [22], myeloma, dysproteinaemia, cryoglobulinaemia
Other neoplastic conditions [4,5,23]	Carcinomas of bronchus, prostate, nasopharynx, ovary, rectum and liver; carcinoid tumour
Immunological	Relapsing polychondritis [24,25], sarcoidosis [26]
Miscellaneous	Liver disease, following biliary surgery, localized at pacemaker site

ental, and some may be more properly categorized as unusual presentations mimicking EAC. In the large majority of cases the aetiology remains obscure, even after prolonged observation and investigation.

One study of 66 cases identified cutaneous fungal infection as the most important aetiological factor (in 72%), other causes being internal neoplasm in 13%, other skin diseases in 18% and other internal diseases in 21% [5]. However, a causal association could not always be proven, and the high frequency of fungal infection may have been influenced by the geographical location of the study in Korea.

Investigations. These are aimed at excluding alternative diagnoses, and search for an underlying cause (see section on Aetiology, above).

Fungal infections should be excluded by microscopy and culture of skin scrapings in all cases where scaling occurs. Granuloma annulare can usually be distinguished on clinical and/or histological features, and has slower evolution of individual lesions, but can cause diagnostic difficulty in some cases. Lymphomas, especially mycosis fungoides, may produce annular lesions very similar to those of annular erythemas; these usually have a broader edge, but a very EAC-like appearance over 10 years prior to diagnosis has been reported [19]. Pseudolymphomas also pose a diagnostic dilemma, as they may be both clinically and histologically similar to EAC—especially a disorder termed palpable migratory arciform erythema of Clark, which may be a variant of Jessner's lymphocytic infiltrate [27]. Genodermatoses such as erythrokeratoderma variabilis and erythrokeratoderma en cocardes should be considered in children, and similar lesions may be seen in carriers of chronic granulomatous disease. Several immunobullous diseases have been reported to have EAC-like lesions, especially in the prodromal phase, including bullous pemphigoid, pemphigus, dermatitis herpetiformis and linear IgA disease. Sarcoidosis, Still's disease, necrolytic migratory erythema, subacute annular psoriasis, pityriasiform seborrhoeic dermatitis, neutrophilic dermatoses, vasculitides, acute haemorrhagic oedema of childhood, leprosy, leishmaniasis and trypanosomiasis may all cause clinical confusion at times, but should be identifiable by histology and evolution of the eruption. Cases of pityriasis rosea in which there are few and large lesions may cause confusion but are self-limiting. Lupus erythematosus and Sjögren's syndrome need to be excluded, particularly cases with a dermatosis mediated by extractable nuclear antigens (see below).

Otherwise, it is seldom possible to establish an underlying cause. A search for a neoplasm should be made, especially in those with older age of onset, but exhaustive investigations are not recommended in the absence of other clues. Tinea pedis, *Candida* infection of the gut and other underlying infections are always worth excluding.

Treatment. Discovery and elimination of the cause are seldom possible. Numerous other treatments have been used including antihistamines, oral or topical corticosteroids, various types of allergen avoidance, and systemic immunosuppressive therapies. In cases where there is a marked epidermal component, topical steroids or calcipotriol [28] may be helpful, but most treatments appear to be relatively unsuccessful. The eosinophilic variant of annular erythema has been reported to respond to chloroquine [11].

Annular erythema of infancy

This term was first applied by Peterson and Jarratt [1] although infantile onset of a similar eruption had been reported previously [2]; numerous cases have been reported subsequently [3–8]. Although the age group does not define a category that can be distinguished from other cases of EAC, and probably also represents a range of disorders, the implications for investigation are somewhat different. For example, cutaneous fungal infection and malignant diseases are unlikely causes, whereas other infections and lupus erythematosus-related antibodies (see below) are important to exclude. However, the fact that some cases started in teenage years and others in infancy in a family with autosomal dominantly inherited annular erythema [9] argues against there being a specific infantile variant.

Clinical features. The clinical morphology of lesions is generally as described for EAC.

Pathology. Histological appearances are typically the same as in cases of EAC. However, some authors have reported eosinophils to be prominent [7,8] and they may be the predominant cell type and associated with peripheral eosinophilia [10]. A neutrophilic variant has also been reported [11].

Aetiology. As in EAC, no cause can be identified in many patients, often despite extensive investigation. Some childhood cases may be discovered to have lupus erythematosus or have had transplacental transfer of maternal antibodies against extractable nuclear antigens, as discussed below; a clinical pattern described as erythema gyratum atrophicans transiens neonatale is now felt to be a variant of neonatal lupus erythematosus [12]. Heavy intestinal colonization with *Candida albicans* has been documented as a cause [13], and concurrent Epstein–Barr virus infection has been reported in an infant [14]. *Pityrosporum* infection in an infant has been reported as a mimic of EAC [15]; other differential diagnoses that may apply in children are listed previously.

Treatment. Any associated infection should be treated as discussed in the section on aetiology. Responses to sodium cromoglycate and to IFN-α have been reported, but in many cases new lesions continue to erupt over many years.

Annular erythema associated with extractable nuclear antigens

It has been recognized for many years that annular lesions in neonatal lupus erythematosus are related to maternal antibodies against SSA(Ro) [1]. Neonatal lupus erythematosus with annular lesions but without anti-SSA antibodies may be explained by the demonstration that some patients have anti-U1RNP antibodies instead [2].

More recently, it has been recognized that annular lesions may occur in anti-SSA(Ro)-positive patients with Sjögren's syndrome, lupus erythematosus (or both together), and less commonly in otherwise well patients who do not fit criteria for either of these diagnoses [3–6]. A role for anti-SSB(La) antibodies has also been proposed in patients with a rather more tumid-appearing pattern of annular erythema [7]. Further investigation has shown that patients with Sjögren's syndrome and/or lupus erythematosus who have anti-tRNA antibodies as well as anti-SSA or anti-SSB antibodies are more likely to have recurrent papulosquamous annular erythema than are those with anti-SSA or anti-SSB alone [8]. Conversely, anti-alpha-fodrin antibodies (which are most common in primary Sjögren's syndrome) do not appear to be linked with annular erythema [9].

Affected patients are usually young adults, although childhood onset occurs [10], and they are usually female; individuals of Japanese origin seem to be particularly likely to develop annular lesions. Although the edge of the lesions is often broader than in many cases of EAC, and the distribution is often photosensitive and limited to the face, it is likely that some cases previously classified as EAC may be explained by this mechanism.

Chapter 60

The Skin and the Nervous System

C.B. Archer & D.J. Eedy

Introduction

The relationship between the nervous system and the skin is complex, and the aim of this chapter is to outline the physiology and pathophysiology of the interactions. Nervous system disorders may be divided broadly into those associated with sensory abnormalities and those associated with autonomic abnormalities, although there is overlap between these two groups. Skin manifestations may occur when the pathology is predominantly located either in the central nervous system (CNS), such as the spinal cord, or in the peripheral nervous system.

The sensory innervation of the skin allows the detection of a number of stimuli from the surrounding environment and the transmission of this information to the CNS (Chapter 4).

Groups of disorders affecting the skin and nervous system simultaneously might include genetic conditions (e.g. neurofibromatosis and tuberous sclerosis, Chapter 12), metabolic abnormalities (e.g. the mucopolysaccharidoses and Tangier disease, Chapter 57), Refsum's disease (Chapter 34), vitamin deficiency states (e.g. pellagra, Chapter 57) and exposure to toxins (e.g. arsenic poisoning) or infective agents (e.g. *Meningococcus*).

Skin innervation

The skin is innervated by a dense three-dimensional network of highly specialized afferent sensory and efferent autonomic nerve branches. The sensory system contains receptors for touch, temperature, pain, itch and various other physical and chemical stimuli [1,2]. The autonomic system comprises post-ganglionic cholinergic parasympathetic nerves and adrenergic and cholinergic sympathetic nerves. It plays a crucial role in maintaining cutaneous homeostasis by regulating vasomotor function, pilomotor activity and eccrine gland secretion. As many as 1000 such afferent neurones may innervate 1 cm^2 of skin. The afferent sensory neurones are unipolar and branch off with a single axon travelling towards the skin. The autonomic nerves innervate the skin in a different pattern. Post-ganglionic fibres originate in the sympathetic chain and are co-distributed with the sensory neurones until they arborize into plexuses around sweat glands, blood vessels and arrector pili muscles [1,2]. Skin nerves may contain myelinated and/or unmyelinated fibres: subgroups of sensory neurones are myelinated A fibres, whereas unmyelinated C fibres contain sensory and autonomic fibres. The sensory myelinated fibres can be further subdivided, on the basis of diameter, into rapidly conducting Aα and slowly conducting Aδ nerves, which transmit tactile sensitivity or temperature, noxious sensation and itch, respectively [2–4]. In the upper dermis, small myelinated nerves lose their nerve sheaths and, together with the unmyelinated nerves, end in either free nerve endings or in association with receptors, such as Merkel cells or nerve ending organs [2,3].

Sensory innervation

Sensory innervation follows well-defined dermatomes with some overlap between adjacent dermatomes. Sensory nerves not only function as an afferent system to conduct stimuli back from the skin to the CNS, but also act in an efferent neurosecretory fashion, releasing neuropeptides with important visceromotor, inflammatory and trophic effects on skin (see below). Unmyelinated type C fibres terminate as either free nerve receptor endings or in association with receptors such as the pacinian or Meissner's corpuscles. Pacinian corpuscles, innervated by a single myelinated sensory axon, are most densely located on the palms and soles, where they act as mechanoreceptors. Meissner's corpuscles also occur in greatest density on the palms and soles; being innervated by one or more sensory nerve endings, they also act as mechanoreceptors, and in addition transmit touch sensation. Merkel cells, which occur at low density generally, with an increased density around hair follicles and at the palms, nail beds and lips, are innervated by synaptic nerve endings. Merkel cells produce and contain a wide range of neuropeptides, which may be important in the local regulation of inflammation [2].

Afferent sensory nerves, either unmyelinated C fibres or myelinated Aδ fibres, derive from the dorsal root ganglion and are capable of the release of a variety of neuropeptides in response to noxious stimuli [2–4]. Sensory impulses are conducted in the peripheral and central axon of the spinal ganglion cell in the dorsal root ganglion, and pass via the lateral spinothalamic tract and the lemniscus spinalis to the thalamus [4]. From the thalamus the information reaches consciousness via the thalamic radiation to the post-central gyrus of the parietal lobe.

C and Aδ fibres not only conduct nociceptive information to the dorsal root ganglion but also have an important efferent function, in that they stimulate target tissues by releasing a range of neuropeptides in response to noxious stimuli, such as chemical, electrical, thermal and mechanical injury, or UV radiation. Neuropeptides with an important neurotransmitter function contained in primary sensory neurones include the tachykinins, substance P, neurokinin A and calcitonin gene-related peptide (CGRP) [5]. These three neuropeptides most frequently coexist in the same subpopulation of primary sensory neurones, the Aδ and C fibres, and are involved in the nerve transmission of impulses initiated by noxious stimuli. They usually occur in free nerve endings in the upper dermis (Fig. 60.1) and epidermis throughout the body, but are at greatest density on the palms and soles, where some end in a plexus around Meissner's corpuscles (Fig. 60.2) [5].

Release of neuropeptides often leads to neurogenic inflammation. The key components of neurogenic inflammation are precapilliary vasodilation, plasma protein extravasation and leukocyte infiltration, which follow antidromic stimulation of peripheral nerves. Neuropeptides can regulate both acute and chronic inflammation by influencing vascular motility and cellular trafficking. After release, neuropeptides are metabolized by membrane-bound endopeptidases that occur on target structures such as blood vessels and eccrine sweat glands in skin [6].

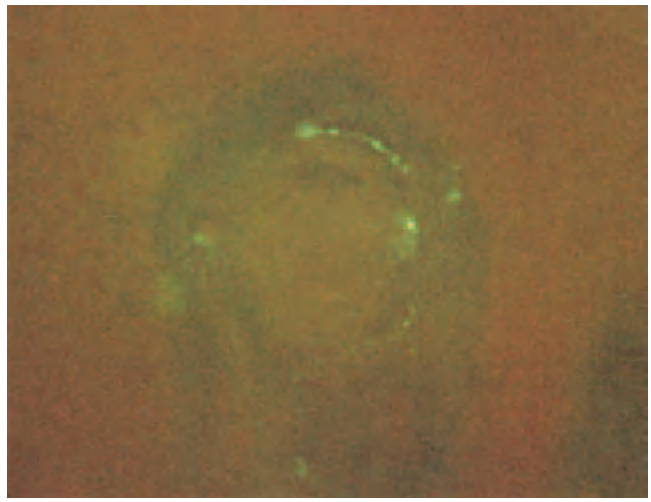

Fig. 60.2 Substance P fibres ending in Meissner's corpuscles of skin.

Autonomic nervous system

The autonomic nervous system innervates the skin through post-ganglionic fibres originating in sympathetic ganglia, and terminating in autonomic plexuses that supply sweat glands, blood vessels and arrector pili muscles [1]. Histochemically there are two main groups of post-

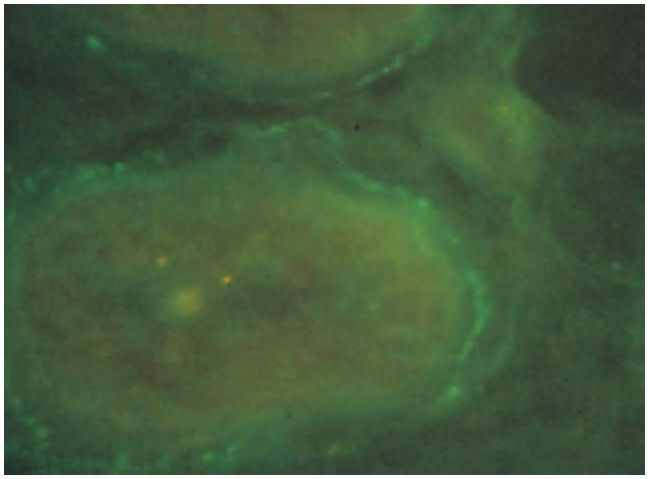

Fig. 60.3 Vasoactive intestinal peptide immunoreactive fibres surround secretory cells of eccrine sweat gland.

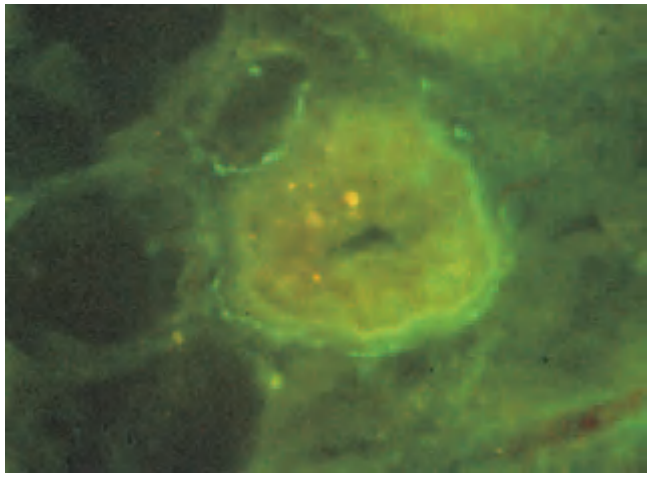

Fig. 60.4 Peptide histidine methionine immunoreactive fibres surround eccrine sweat glands.

ganglionic nerve fibre in the skin. Firstly, adrenergic fibres synthesize and store catecholamines and norepinephrine (noradrenaline). The second major group consists of the cholinergic fibres containing acetylcholine. Co-localizing with acetylcholine are 'secretory' neuropeptides such as vasoactive intestinal peptide (VIP) and peptide histidine methionine (PHM). Nerves containing these should be regarded, at least physiologically, as parasympathetic [5]. The secretory portion of the eccrine sweat glands, myoepithelial cells and nearby blood vessels are innervated by a basket-weave pattern of nerves containing predominantly acetylcholine but also significant numbers of fibres containing 'secretory neuropeptides' including VIP (Fig. 60.3), PHM (Fig. 60.4), neuropeptide Y (NPY), CGRP, galanin, atrial natriuretic peptide (ANP) and norepinephrine. Secretory neuropeptides, mainly VIP and ANP, together with norepinephrine, are not as effective as acetylcholine at sweat production, and probably synergistically amplify acetylcholine-induced adenosine 3',5'-cyclic monophosphate (cAMP) accumulation, which is the most important secondary messenger in sweat production. ANP may be responsible, at least in part, for regulation of sodium and other electrolytes being released in sweat [5]. NPY has been identified in the periarteriolar nerve fibres of the deep and superficial vascular plexus, and in eccrine sweat glands, and is likely to play a role in regulation of skin blood flow and eccrine sweating [5].

Blood vessels in the skin are innervated by adrenergic fibres which are vasoconstrictor, while acetylcholine and neuropeptides, such as VIP and PHM, act as vasodilators and increase vascular permeability [5,7]. Thus, by increasing release of acetylcholine and secretory neuropeptide, the body has a mechanism of increasing blood flow to the skin and increasing sweating, both of which act to reduce body temperature. If body temperature falls, this is detected in the preoptic region of the hypothalamus, which activates the sympathetic nervous system, which in turn reduces skin blood flow and sweating. Conversely, if warmer blood is detected in the hypothalamus, inhibition of sympathetic response allows skin sweating and blood flow to increase, thereby reducing core temperature [8,9].

Adrenergic fibres mediate strong vasoconstriction and arrector pili muscle activity, thus diverting blood from the skin, and pulling hairs into the upright position, in the classical 'fight or flight' reaction [1].

The digital nerves in patients with Raynaud's phenomenon and with systemic sclerosis are deficient in CGRP fibres [10], and intravenous infusions of CGRP increase digital blood flow in such patients. A similar depletion of CGRP fibres has been described in digital nerves of patients with vibration white finger, and this may be responsible for both the vasoconstriction and sensory abnormalities characteristic of this condition [11].

Wound healing and trophic effects

Impaired wound healing is often found in patients suffering from peripheral neuropathies, spinal cord lesions or after peripheral nerve trauma. Depletion of neuropeptides in animal models using capsaicin, and *in vitro* studies demonstrating that certain neuropeptides such as substance P, neurokinin A, CGRP and VIP stimulate DNA synthesis in fibroblasts, keratinocytes, melanocytes and endothelial cells, suggest that they are likely to act as mitogens stimulating proliferation of tissue cells, thereby aiding the healing process [5,11–14]. The sprouting of sensory nerve endings, containing large amounts of substance P, occurs in wounds during the first 3 weeks, and is probably important in wound healing. Substance P has also been shown to up-regulate the synthesis of interleukin-1 (IL-1), IL-6 and transforming growth factor-α (TGF-α) in keratinocytes [14]. Nerve growth factor (NGF)

is a neurotrophic factor released from sensory neurones, as well as fibroblast mast cells, lymphocytes and keratinocytes, which may act as a major controller of cutaneous wound healing and inflammation [14].

CGRP has a trophic effect in the regeneration of UV-damaged skin, and synthesis of CGRP increases after nerve injury, suggesting that this peptide may have a role in nerve regeneration [15].

Neuroimmunology

There is significant evidence of a close interaction between the nervous system and the immune system. Substance P, neurokinin A and CGRP predominantly function as pro-inflammatory mediators, whereas VIP, somatostatin and α-melanocyte-stimulating hormone (α-MSH) largely have anti-inflammatory properties [16].

Substance P *in vivo* and *in vitro* enhances proliferation and function of B and T cells and induces cytokine secretion from monocytes, including IL-1, IL-6, tumour necrosis factor-α (TNF-α) and interferon-γ (IFN-γ) [17]. Substance P influences inflammatory responses by enhancing macrophage and leukocyte activity, and acts to release histamine, prostaglandin and leukotriene from mast cells [18]. Furthermore, it activates human dermal microvascular endothelial cells to express vascular adhesion molecule 1 [19].

While VIP is a potent releaser of histamine for mast cells, a mechanism that is independent of IgE activation, it also has anti-inflammatory effects, suppressing delayed hypersensitivity *in vitro* and inhibiting phospholipase A2 [20]. VIP inhibits natural killer cell activity and may have an inhibitory effect in inflammatory processes, such as contact dermatitis, an effect which may be mediated through an increased production of IFN-γ in peripheral blood monocytes [20].

Neuropeptides can activate a number of target cells including keratinocytes, Langerhans' cells, mast cells, epithelial cells, granulocytes, eosinophils, macrophages and lymphocytes, all of which have been shown to have receptors for neuropeptides. Recent evidence shows that many of these cells may also synthesize these neuropeptides. In addition cytokines, including IL-1, TNF-α and NGF are potent stimulators of neuropeptide production [16]. The release of substance P, CGRP and other neuropeptides may ultimately hold the link between psychological stress and the flaring of inflammatory skin diseases [21,22]. Substance P, neurokinin A and CGRP are all up-regulated by UV light exposure of human skin, and may contribute to the inflammation of acute UV exposure, while in the longer term CGRP inhibits Langerhans' cell activity, thus leading to immunosuppression as a result of UV exposure [23]. Similarly, α-MSH is produced in the skin as a result of UV irradiation, which has been shown to induce the production of IL-10 and inhibit the production of IL-1 and IL-12, thereby inhibiting the chemokine-mediated migration of antigen-presenting cells [24].

In addition to their role as neurotransmitters, neuropeptides can modulate immune responses, leading to the concept of the neuro–immuno–cutaneous system, representing an interrelationship between the nervous system, immunity and skin. This may explain the link between the flare up of inflammatory diseases, such as atopic dermatitis [25] and psoriasis [21,22,26], during periods of emotional stress.

Neurophysiological testing for skin innervation

Sympathetic skin response

Sympathetic skin response (SSR) is a safe, simple and non-invasive electrophysiological test used to evaluate sudomotor function in a variety of clinical settings [27,28]. It can be used to assess autonomic function in patients with suspected sympathetic nerve dysfunction. The SSR is a polysynaptic reflex associated with the activation of sweat glands. It is usually performed by electrical stimulation of the median, ulnar, peroneal or sural nerves and measuring the change in galvanic resistance on glabrous skin brought about by sweating using a conventional electromyograph apparatus. The afferent component may be activated by non-specific sensory stimuli or repeated electrical stimulation; the efferent component depends on the functioning of the sympathetic-cholinergic fibres from the sympathetic chain to the sweat glands. In autonomic failure the SSR cannot be elicited.

Cold-induced vasodilation

Hand cooling is a cold pressor test, in which an extremity is placed in cold water leading to a rapid decrease in skin temperature, accompanied by initial strong vasoconstriction aimed at limiting heat transfer to the environment [29–33]. After a few minutes, skin temperature starts increasing as a consequence of cold-induced vasodilation. The precise mechanism of this reflex is unknown, but it is thought to be mediated through an increase in sympathetic stimulation, although factors independent of the sympathetic nervous system may also play a role. Exposure of the human body to cold stress elicits generalized cutaneous vasoconstriction. This is a response mediated by a sympathetic control process, triggered partly by stimulation of cutaneous cold receptors and partly by cold blood returning to the general circulation and stimulating the temperature-regulating centre in the hypothalamus. The tone of cutaneous vessels is controlled mainly by vasoconstrictor skin sympathetic nerve activity. A reduction in this response has been reported in diabetic and

neuropathic patients, and in the immature and elderly, probably resulting from reduced skin sympathetic nerve vasoconstriction [32,33].

Triple response of Lewis

Lewis described the capacity of the cutaneous microcirculation to vasodilate in response to direct stimulation with a firm mechanical stroke or with a dermographometer (the axon reflex) [33–35]. The amount of vasodilatation can be measured by Doppler flow meter. The axon reflex, known as 'antidromic vasodilation', does not occur in chronically denervated skin or skin in which neuropeptides have been depleted by capsaicin. The antidromic vasodilatation and plasma extravasation, which occurs in the skin following stimulation of the dorsal nerve roots or peripheral sensory nerves, can be mimicked by intra-arterial infusion of substance P.

Histamine is known to be a principal mediator of the triple response of Lewis, and to act via H_1 and H_2 receptors to produce vasodilatation and increased vascular permeability. However, it is known that substance P, neurokinin A and CGRP from primary sensory fibres are also mediators in the skin flares of the triple response of Lewis [36,37].

Post-herpetic neuralgia

Herpes zoster (Chapter 25) is itself painful, and is sometimes followed by neuralgia. The risk of developing post-herpetic neuralgia rises with age, which influences both the duration and the severity of the neuralgia once it appears [1]. Post-herpetic neuralgia, defined as pain persisting beyond 4 weeks, occurred in 16% of patients

younger than 60 years but in 47% of those older than 60 years [2]. Only about one-quarter of those with pain 4 weeks after the vesicles have healed still have pain a year later, but this pain, which is chronic and debilitating, especially in the elderly, can be so severe that it interferes with sleep, and causes depression or even suicidal tendencies.

Patients may report a variety of painful sensations with different components, including spontaneous and continuous deep aching and throbbing pain, burning, lancinating pain, or paroxysms of burning pain, sometimes provoked by non-noxious stimuli, such as contact with clothing or changes in temperature [3]. The pain is accompanied by autonomic instability and its intensity is exacerbated by physical and emotional stress and alleviated by relaxation. Some patients with post-herpetic neuralgia have profound sensory loss in the area of maximum pain (anaesthesia dolorosa), while others have pronounced allodynia with minimal sensory loss. Another group of patients have areas of sensory loss surrounded by a 'transition zone', within which a noxious stimulus can elicit a particularly unpleasant pain that radiates widely [3]. The patient may go to extraordinary lengths to protect the area from innocuous stimuli, while firm compression of the skin may actually produce pain relief.

Why some patients develop post-herpetic neuralgia is incompletely understood. There is, for example, no consistent relationship between this type of pain and a loss of large fibres in the damaged nerves, but *in vitro* studies [4] suggest that the virus itself may cause normally silent neurones to produce spontaneous action potentials.

Pathophysiology of pain

Post-herpetic neuralgia may be caused by neurological lesions at all levels of the nervous system including peripheral, central and autonomic components.

In pain associated with peripheral damage in the dorsal root ganglion, spinal cord and afferent neurones, ectopic impulse generation may occur at the site of damage, and these impulses can be evoked by mechanical or thermal stimuli in the local environment (tactile allodynia) [3]. For this type of disorder, membrane-stabilizing drugs are likely to work best. There is also some evidence that nociceptors in painful skin of post-herpetic neuralgia patients have enhanced adrenergic sensitivity [3].

When sensory deficits are present, suggesting destruction of dorsal root ganglion cells, the pain is primarily sustained by processes in the CNS, resulting in what is known as 'deafferentation pain' [3].

With the realization that several pain mechanisms may be operating in any one individual, it is unrealistic to expect any one drug to completely alleviate the pain in all neuropathic pain disorders, or to significantly reduce the pain in all patients suffering from the same neuropathic condition.

Prevention of post-herpetic neuralgia
